The measurement of squeezing at a fixed frequency $\Omega = 2$ MHz is shown in Fig. 4, where trace (i) is the squeezing as a function of the local oscillator phase, trace (ii) is the shot noise, and trace (iii) is the squeezing when the phase of the local oscillator is fixed manually at the minimum noise level. By averaging the noise of trace (iii), we determine the squeezing level to be 5.5 ± 0.2 dB below the vacuum noise level. For the measurement shown, the pump power was approximately 3/4 the threshold power. Further increasing the pump power led to a higher gain, but additional noise degraded the squeezing. We believe that this effect is due to pump fluctuations, inasmuch as the pump was not shot-noise limited at 2 MHz. From measurements at lower pump powers we find the total efficiency of detection $\xi = 92\%$, which agrees within 2% with the following measured individual efficiencies: 98.5% homodyne, 98% propagation after the OPO, and 97% detector quantum efficiency. Once we corrected for these values, the inferred squeezing amounted to 7.9 dB outside the resonator.

B. Squeezing Ellipse and Wigner Function

The usual way to represent a squeezed state of the electromagnetic field in the phase space defined by its quadrature components x and p is a depiction of an uncertainty region with the shape of an ellipse. The principal axes of this ellipse correspond to the standard deviation of the fluctuations in the (possibly rotated) squeezed and the antisqueezed quadrature components. The ellipse represents a contour of the Wigner function $W(x, p)$ of that state.

The Wigner function is a quasi-probability distribution in phase space, differing from a classical distribution mainly by the fact that it may be negative and by the fact that it cannot be measured directly, inasmuch as it is a joint distribution of the eigenvalues of two noncommuting observables.[23] What is measurable, though, for any pair of rotated quadrature components $\hat{x}_\theta = \hat{x}\cos(\theta) + \hat{p}\sin(\theta)$, $\hat{p}_\theta = -\hat{x}\sin(\theta) + \hat{p}\cos(\theta)$, are the marginal distributions $P_\theta(x_\theta) = \int_{-\infty}^{\infty} W[x_\theta \cos(\theta) -$

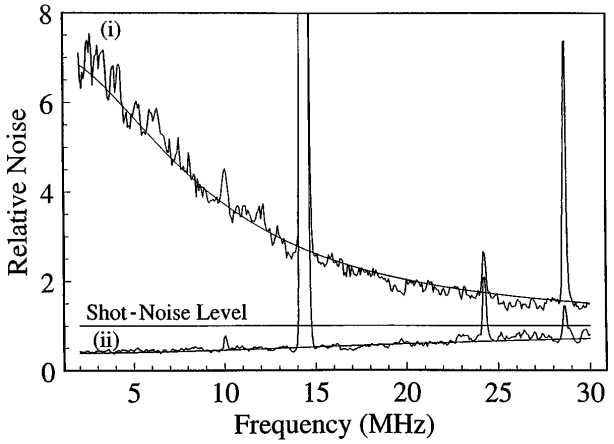

Fig. 3. Spectral density Ψ_- as a function of the analysis frequency Ω, with trace (i) being the antisqueezing spectrum and trace (ii) the squeezing spectrum. The theoretical expectations are denoted by the solid curves superimposed upon traces (i) and (ii). The peak at 14.5 MHz and its harmonic at 29 MHz come from the modulation of the doubling cavity used for locking. The resolution bandwidth was 100 kHz; the video bandwidth, 100 Hz.

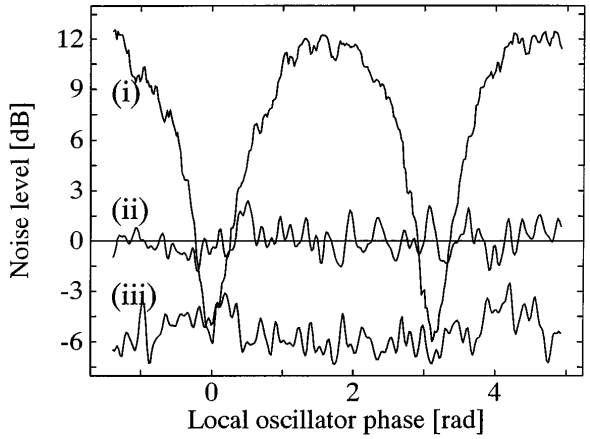

Fig. 4. Squeezed vacuum from the monolithic OPO. In trace (i) the phase of the local oscillator is being scanned; in trace (iii) the phase is fixed manually for minimum noise. One obtains the shot-noise level by averaging trace (ii). The resolution bandwidth was 100 kHz; the video bandwidth, 1 kHz.

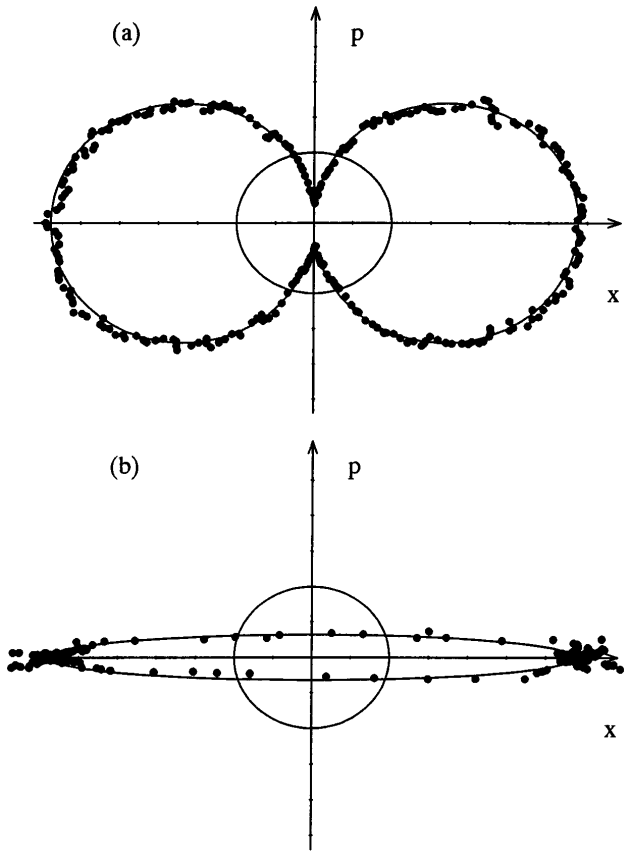

Fig. 5. (a) Standard deviations of the electric-field amplitudes of a squeezed-vacuum state in phase space. The circle represents the unsqueezed vacuum state. (b) The same data transformed into a squeezing ellipse. The points correspond to measured values corrected for total efficiency, and the curves represent the theoretical expectations.

$p_\theta \sin(\theta),\ x_\theta \sin(\theta) + p_\theta \cos(\theta)]\mathrm{d}p_\theta$.[17] These marginal distributions are classical probability distributions. For the case of a squeezed state, they are Gaussian. The recently established technique of optical homodyne tomography permits the reconstruction of the Wigner function from these marginal distributions by use of the inverse Radon transform.[17,18] Because the Wigner function is related to the density matrix through a Fourier transform, it is possible to determine completely the quantum-mechanical state of a system.

In the following discussion, we first show how to visualize the uncertainty region of the quantum-mechanical state of the light field in our experiment based on a measurement of the variances, and then we describe the reconstruction of its entire Wigner function.

The square roots of the experimental values of the variances (measured as in Fig. 4) correspond, when corrected for escape and detection efficiency and the electronic noise floor, to the standard deviation of the electric-field operator $\hat{E}$ in phase space as a function of the phase angle θ. Its equation is given by $\Delta\hat{E}(\theta) = [(\Delta\hat{x})^2 \cos^2(\theta) + (\Delta\hat{p})^2 \sin^2(\theta)]^{1/2}$, which is the equation of a lemniscate. The phase-space representation of our experimental data is shown in Fig. 5(a). The circle represents the unsqueezed vacuum state. The principal axes of the lemniscate, $a = \Delta\hat{x}$ and $b = \Delta\hat{p}$, correspond to maximum noise suppression or enhancement in the respective quadrature component.

The variances of the E field can be thought of as being projections of the uncertainty region in phase space onto the direction of observation determined by the phase angle θ. Geometrically, this means that the E-field variances form the pedal curve of the uncertainty region.[24] Therefore the uncertainty region and thus the contour of the Wigner function are calculated with the transformation

$$[r(\theta)\cos(\theta),\ r(\theta)\sin(\theta)] \Rightarrow \left[\frac{a^2}{r(\theta)}\cos(\theta),\ \frac{b^2}{r(\theta)}\sin(\theta)\right]. \tag{3}$$

The result for a 4-dB squeezed-vacuum state is shown in Fig. 5(b). The area of the ellipse and the circle are approximately equal, as is expected for a minimum uncertainty state.

Although this transformation of the values of the variances to the contour of the Wigner function is correct for a minimum uncertainty state, it is not correct for arbitrary states of the light field. The information contained in the variances is in general not sufficient to infer the geometrical shape of the uncertainty region.

We gain more information about the state of the light field by recording not just the variance but rather the whole distribution $P_\theta(x_\theta)$ of the electric-field fluctuations.

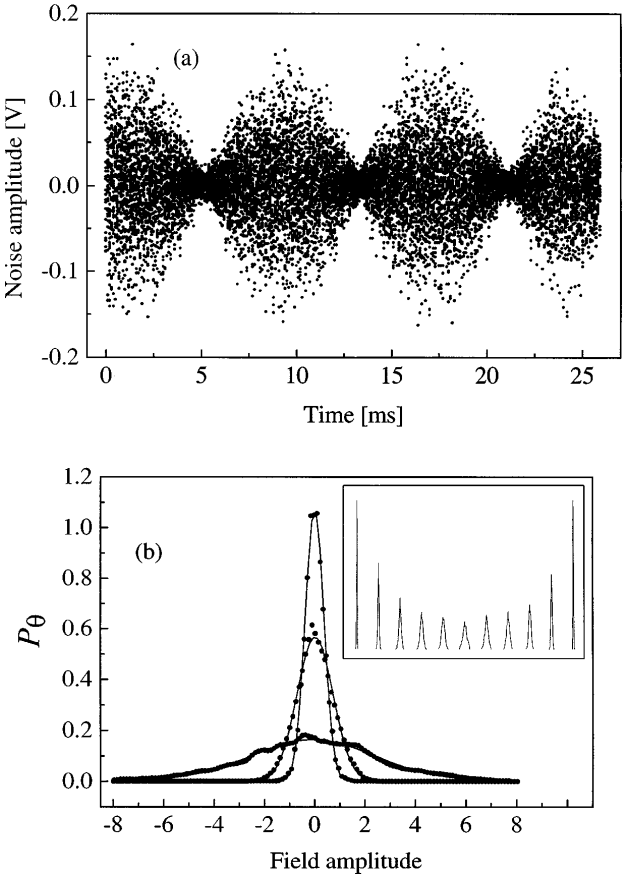

Fig. 6. (a) Noise of the photocurrent i_- of the squeezed vacuum from the OPO at 2 MHz as a function of the local oscillator phase. The detection bandwidth is 100 kHz. (b) Distributions of the photocurrent fluctuations for maximum squeezing, shot noise, and maximum antisqueezing. The curves are fits of Gaussian distributions. The inset shows the distributions for eleven different phase angles from 0 to π.

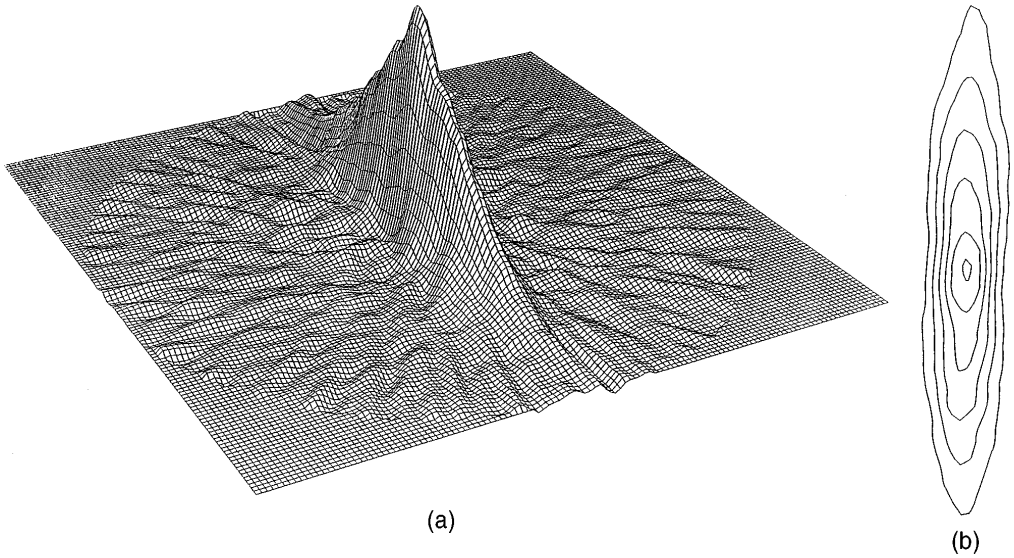

Fig. 7. (a) Reconstruction of the Wigner function for the squeezed vacuum. (b) Contour plot of the Wigner function. The ellipticity of the contours is slightly smaller than in Fig. 5 because no corrections for the detection efficiency were made.

As mentioned above, this procedure allows us to employ the method of optical homodyne tomography to determine the Wigner function completely. The inverse Radon transform corresponds in two dimensions to the step of backprojecting the variances, carried out above.

For a squeezed-vacuum mode of frequency Ω relative to the carrier optical frequency, the Wigner function is given by

$$W_{\mathrm{sq}}(x,\,p) = (1/2\pi)\exp\left(-\frac{1}{2}\{[1+\rho S_{-}(\Omega)]x^2 + [1+\rho S_{+}(\Omega)]p^2\}\right), \tag{4}$$

where S_{+} and S_{-} are defined by Eq. (1). Thus there is a spectrum of Wigner functions that differ in the ratio of their half-widths. For our reconstruction we chose the field mode at $\Omega = 2$ MHz.

Following the procedure described in Ref. 18, we first obtained the distributions of the electric-field amplitude at several different phase angles in phase space. The intermediate-frequency output of the spectrum analyzer at 2 MHz with a resolution bandwidth of 100 kHz, was recorded by a Nicolet 400 digitizing oscilloscope, as the local oscillator phase was slowly scanned. In this way it is possible to observe the variance of the electric field directly on the spectrum analyzer while accumulating the amplitude data. A typical trace of the resulting photocurrent fluctuations is shown in Fig. 6(a). We divided this time trace of 161,000 points into 79 sections corresponding to 79 different phase angles. For each phase angle interval the time-dependent amplitude noise was sorted into 128 bins. Thus histograms of 128 bins at 79 different phase angles θ were created, each having the shape of a Gaussian [Fig. 6(b)]. These histograms correspond, when normalized, to the Gaussian distributions of the amplitude noise at different phase angles.

Finally, the collection of histograms was transformed with the inverse Radon transform. The main part of the inversion algorithm consists of a convolution of the measured histogram values with a given filter function (filtered backprojection). A quadratic regularization was used to approximate this filter function. The Wigner function and its contour lines are shown in Fig. 7. Note that no corrections for detection and escape efficiency were made. For the chosen parameters, the numerical error of this reconstruction process is estimated to be less than 2%, which is consistent with a comparison of the ratio of the two half-widths of the Wigner-function sections at $x = 0$ and $p = 0$ and the directly observed squeezing and antisqueezing of 5.5 and 11 dB for this measurement.

4. CONCLUSIONS

In conclusion, we have used a monolithic continuous-wave OPO pumped below threshold to generate squeezed vacuum at 1064 nm. With this device 5.5 dB of squeezing was observed at a frequency of 2 MHz, and the whole squeezing spectrum from 2 to 30 MHz was recorded. Furthermore, the Wigner function of the squeezed-vacuum state was reconstructed. With the same device we have generated a beam of bright squeezed light by the process of parametric deamplification. 4-dB noise reduction in the amplitude noise of a 0.25-mW beam was achieved.[25] The level of detected squeezing was limited mainly by the finite detection efficiency and the noise of the pump laser. We plan a further investigation of the effect of the latter in the future.

The reconstruction of the Wigner function of a squeezed state represents a first step in a complete experimental characterization of a squeezed state. Because of the high degree of squeezing and its good stability, the experimental determination of the photon statistics and density-matrix elements in Fock-state representation appears to be possible.[26]

We believe that, beyond the demonstration of the performance of monolithic resonators as very stable, compact squeezing sources with a high degree of squeezing, they can be useful in several applications of squeezed light. The broad bandwidth makes it suitable for spectroscopic investigations, and its simplicity should make

proposed experiments that require more than one source of squeezed light more accessible.

ACKNOWLEDGMENTS

We are indebted to R. Paschotta for essential help at the beginning of the experiment, especially for the design of the frequency doubler. We thank M. G. Raymer, A. Faridani, and D. MacAlister for providing us with the original source code for the inverse Radon transform, and U. Janicke and U. Leonhardt for several improvements regarding the numerical inversion. Furthermore, we gratefully acknowledge several enthusiastic discussions with A. G. White and S. Kohler. S. F. Pereira was supported by the Humboldt Foundation. J.-Ph. Poizat was supported by the European Community (EC) network "Non-classical Light" and thanks the Konstanz group for its hospitality during his stay. Financial support for this research was provided by the Deutsche Forschungsgemeinschaft, by the EC network Nonclassical Light, and by EC Basic Research Project 6934-QUINTEC.

Journal of Space Exploration, Mehta Press

Foreword to the sixth (special) issue, September 2014

Guest editor: Prof. Jochem Hauser,
Hpcc-Space GmbH, Hamburg, Germany

Festschrift in Honor of the 80th Birthday of

Dr. Williamson Berry

ret., Head of Propulsion and Aerothermodynamics Division, European Space research and Technology Centre European Space Agency Noordwijk, The Netherlands

This special Issue of the *Journal of Space Exploration* is dedicated to my friend, colleague, and (former) boss at ESA, the eminent

Dr. Williamson (William, Bill) Berry

on the occasion of his 80th birthday (recent picture). As head of the Propulsion and Aerothermodynamics Division at ESTEC for more than twenty-six years, Bill, as one of the leading chemical propulsion experts in Europe, exerted a major influence on European aerospace industry to further his goal in making European rocketry competitive with U.S. and Russian industry. When Bill left ESA in July 1999, he could look back on the Ariane success story, to which ESA in general, and he

personally had contributed a major part. Space activities in Europe had changed from humble beginnings into commercial business. In particular, Bill played an active role in the creation of an autonomous, world-class capability in spacecraft propulsion and aerothermodynamics for Europe. However, Bill exerted also a major influence on my career, when he hired me (a physicist) as the head of the aerothermodynamics section in 1988 in his division. Among many other things, we worked together in the early 1990s on the Hermes space-plane, the European version of the U.S. space shuttle. Though Bill was responsible for the European propulsion activities, which means that his view had to be on technically realizable propulsion systems, he was well aware of the severe limits of current propulsion and had a keen vision on the physics of advanced propulsion. I still remember our discussions on *field propulsion*, a term already coined by W. Corliss in 1960, i.e., propulsion without propellant based on hitherto unknown long-range physical fields, which became again a major topic in NASA's *Breakthrough Propulsion Physics* program from 1996-2001.

Because of his outstanding personality and open-mindedness William Berry assembled a long list of friends among his engineering colleagues during his long career in ESA, but I am proud (as a non-engineer) to consider myself friend of Bill who also was a wonderful boss during my time at ESA. In addition to his skillful work in the world of European propulsion, William Berry always saw himself as a contributing citizen both to the larger field of science and humanity, which included, of course, animal world.

When I was asked by the editor in chief of JSE, Prof. T. Musha, to choose a topic of my own for the sixth issue of JSE, I suggested the theme

Spaceflight Perspectives from Novel Concepts of
Spacetime, Gravitation and Symmetries.

Numerous colleagues, both in the academic departments and in the engineering community whom I contacted, approved this title. I am convinced that William Berry would have done the same, but, for obvious reasons, I could not contact him. A dominant theme in Bill's work was the quest to find the ultimate space propulsion technology. Of course, he was well aware that such a technology has to come from novel physics, and not from the refinement of engineering.

It therefore feels very appropriate to me to dedicate this special issue of JSE as Festschrift to William Berry.

At the European Space Agency (ESA) we experienced first-hand the immense technical difficulties and extreme cost to place relatively small payloads into low earth orbit. Space propulsion is still dealing with the technologies developed in the 50s and 60s of the last century, and the vision portrayed by Werner von Braun in his famous article in Collier's magazine in 1952, entitled *Man on the Moon*, did not become a reality. The shuttle era came to an end in 2012, and NASA will not fly a next generation space vehicle any time soon. The problem of propulsion is not the engineering, but it is linked to the underlying physics that remains unchanged since the days of ancient Chinese rockets. It is the physical principle of classical momentum conservation, which stands in the way of producing an efficient, and effective propulsion system. It is the basic physics itself that prevents progress.

Consequently, all contributions to this Festschrift belong to the (speculative) physics of advanced propulsion, energy generation, and gravitation, and report on the progress made since 2001, when the NASA Breakthrough Propulsion Physics program ended. When I contacted the potential contributors, I offered them free choice of topic, but mentioned that all papers will be reviewed, and none of the editors would interfere with the verdict of the reviewers. I feel that the final collection of papers displays an exciting variety, just as William Berry does wish to see!

Recently, the scientific community has been shaken by numerous scandals, where authors published exciting results that eventually had to be retracted, because data had been deliberately manipulated (remember, for instance, the infamous hockey stick curve in climate science, or the large number of articles with falsified measurements in the field of bioscience from authors already considered for a noble prize). Moreover, journals were found to publish articles of questionable quality, i.e., using an insufficient review process. As a consequence, all papers presented in this special issue were thoroughly reviewed. Finally, seven out of eight papers were accepted, three papers were completely rewritten and four papers saw minor modifications. The review process for the paper of my long-time co-author Walter Dröscher and for my own paper was handled by the editor in chief of JSE. I am indebted to these referees, both in Europe and the U.S., who do their work in anonymity, for their patient, but relentless efforts to improve style, readability, clarity, and content of the papers.

All of the authors have been in the field long enough to be widely known from their publications, but of course, there is no guarantee that the novel ideas discussed in these papers actually reflect physical reality. If they do, a revolution will occur both in science and technology, but it may well be that our ideas turn out to be wrong. If, in hindsight, some or all of the ideas presented here, appear incorrect, the reader should be assured that, at least, we were acting as honest fools, which is scientifically legitimate as was stated by the well known physicist Richard P. Feynman.

The last paper, accessible for the intelligent layman, by C. Daigle, summarizes from a design perspective the ensuing revolutionary technological aspects that could follow from this novel physics.

In this special issue we are presenting to the scientific community the state of theoretical and experimental research concerning the latest results in the emerging field of physics for novel gravity-like fields that might represent a new paradigm shift regarding the very nature of gravitation, including the evaluation of recent experiments that might have measured extreme gravitomagnetic fields outside general relativity.

Therefore, the motivation to further exploring the mysterious nature of gravitation is understandable, aiming beyond Newtonian (Einsteinian) gravity. Gravitation has maintained the interest of researchers at every stage in the history of physics, and it became Einstein's quest to unify gravitation with the other forces since 1916. Hence,

it should be no surprise that new theoretical attempts along with experimental work are presented in this special issue to continue where Einstein was forced to leave off.

The quantization of the gravitational field has been unsuccessful, despite great efforts in this direction. The problem may be that the number of fundamental forces is not known, in other words, there is a belief that only four forces exist (strong, weak, electromagnetic, and gravitational force). Perhaps gravity is of a more subtle nature than Newtonian gravity, and an interaction between gravity and electromagnetism might exist?

New gravitational experiments have been published since 2006, and geometrical theories from the 1950s have gained prominence (for instance, by Finzi, Heim, Wheeler). They have been extended and combined with concepts of modern physics, trying to explain novel experimental results for extreme gravitomagnetic and gravity-like fields. For instance, in his monograph on *Quantum Field Theory*, M. Kaku presents a calculation of the Coleman-Weinberg potential that might be employed to calculate the coupling strength for extreme gravitomagnetic fields. More recently, as pointed out by A. Zee in *Quantum Field Theory in a Nutshell*, gravity might be the square of two spin 1 fields (it should be noted that particles of spin 1 can be described by Yang-Mills fields), an idea that also might be applicable in the explanation of the experiments on extreme gravitomagnetic fields. These and other exciting ideas are presented to the reader, shedding new light on the nature of gravity as well as the number and type of fundamental forces that should exist in Nature.

As Einstein felt, the most important objective of any theory is to comprise as few and basic elements as possible without contradicting physical experience in conjunction with practical applications. For example, a relationship between the physical phenomena of electromagnetism and gravitation might exist at cryogenic temperatures. Any novel theory must be verifiable by laboratory experiments or astronomical observations.

Performing gravitational experiments is not an easy endeavor since highly sensitive devices have to be produced and utilized at cryogenic temperatures, often at liquid Helium temperature. Even if experimental findings or theories eventually cannot be verified, one should not denounce the serious experimenter or theorist for failure, since the history of science has shown that every step forward is a complicated venture, needless to say that all programs for novel theoretical models initially contain many unclear points. But this is true even for established theories. Gravitational experiments are notoriously difficult as can be seen from the fact that the physics of gravitational wave astronomy, despite the early efforts of J. Weber starting out in 1969, is still not an established fact.

As was pointed out by theoretical physicist Richard P. Feynman, there occur numerous strange phenomena in the complex situations of solid-state physics. He prophetically foresaw an enormous number of technical applications that could arise from such physics. Might it be possible that a combination of low temperature and

solid state physics could lead to strange phenomena and, this is the most important point, to a large number of technical applications, but this time in the field of gravitational engineering?

Finally, in order for science to progress, both theorists and experimenters have to be willing to leave the save (funding issues) and (sometimes) sacred ground of established physical theory and dare to propose speculative novel ideas. If a blind alley is met, the courage to reverse one's direction of research is required. In particular, the speaking silence of the Large Hadron Collider at Geneva is at odds with all of the so-called advanced physical theories beyond the standard model of particle physics. Instead, if ideas of novel gravitational fields at cryogenic temperatures turn out to be true, the new scientific age of gravitational engineering might have begun.

Whether or not this special issue of JSE, which can be considered a sequel of the recent book on *Gravity-Superconductor Interactions: Theory and Experiment, G. Modanese, G. A. Roberson (eds.), Bentham Publishers 2012,* is revealing novel scientific facts, or even stands for a paradigm shift in science, remains undecided at present. New experiments, hopefully as suggested in this special issue, need to be carried out in order to prove the existence of gravity-like fields outside Newtonian gravity. Nevertheless, I am convinced that the articles presented here contain a large amount of exciting material that will be of substantial benefit to those readers willing to leave the trodden path of science and to accept the challenge.

Subtle is the Lord…Albert Einstein

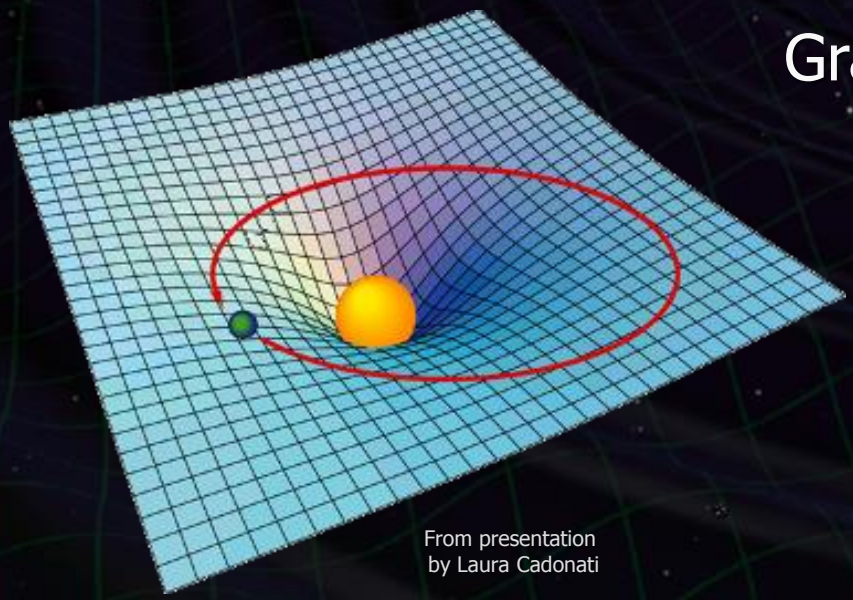
Gravitational Wave Astronomy

Gravitational Wave



From presentation
by Laura Cadonati

General Relativity

Gravity : Curvature of space-time

Acceleration of Mass
→ Fluctuations in space-time
→ Propagates as
'Ripples in space-time'

"Mass tells space-time how to curve,
and space-time tells mass how to move."
John Archibald Wheeler

Gravitational Waves

Gravitational-Wave Astronomy

Reveal the universe by Gravitational Waves.

Nature of GWs
- Radiated by accelerated masses
- Strong transmissivity

New probe to the universe
- Complementary with EMWs.
- Unique sciences
  - Early universe before CMB era
  - High-energy phenomena

Large-scale Cryogenic Gravitational-wave Telescope

2nd generation GW detector in Japan

Large-scale Detector

Baseline length: 3km

High-power Interferometer

Cryogenic interferometer

Mirror temperature: 20K

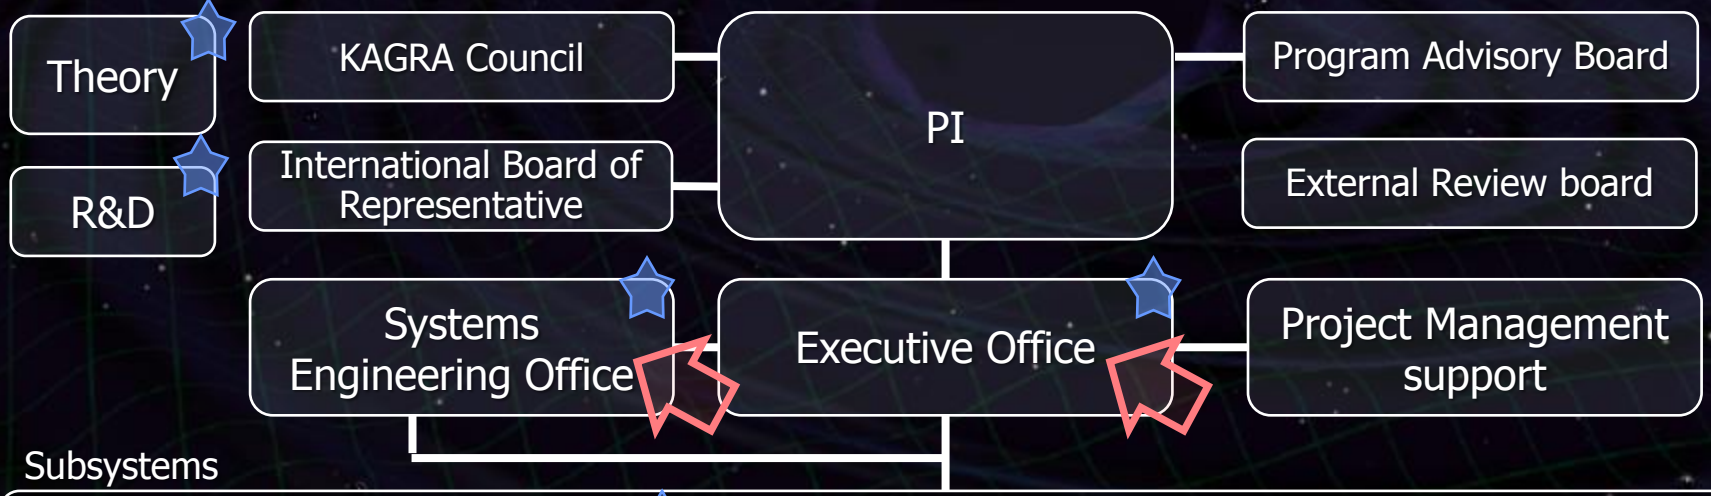
Underground site

Kamioka mine,

1000m underground

Organization of KAGRA

~150 Collaborators (Host : ICRR, Co-hosts: NAOJ, KEK)

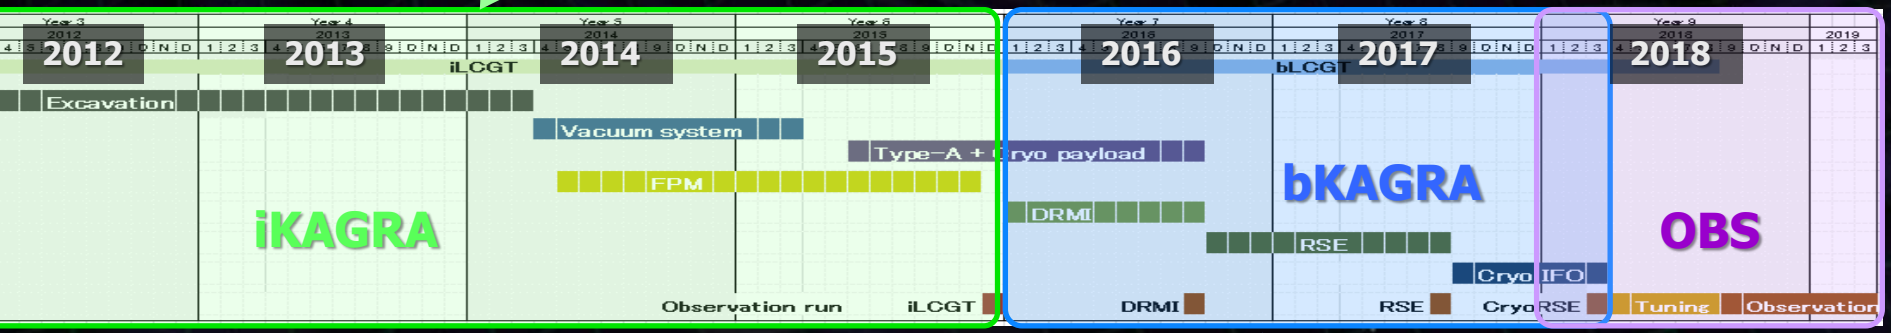


Subsystems

Tunnel (TUN)	Facility (FCL)	Vacuum (VAC)	Cryogenics (CRY)	Vibration Isolation (VIS)
Mirror (MIR)	Laser (LAS)	Main Interferometer (MIF)	Input-output Optics (IOO)	Auxiliary Optics (AOS)
Analog Electronics (AEL)	Digital System (DGS)	Data Management (DMG)	Data Analysis (DAS)	Geophysics Interferometer (GIF)

KAGRA Schedule

- **iKAGRA** (2010.10 – 2015.12)
  3-km FPM interferometer
  - Baseline 3km room temp.
  - Operation of total system with simplified IFO and VIS.



- **bKAGRA** (2016.1 – 2018.3)
  Operation with full config.
  - Final IFO+VIS configuration
  - Cryogenic operation.

Schedule and Budget

	FY2010	FY2011	FY2012	FY2013	FY2014	FY2015	FY2016	FY2017
Budget	'Leading-edge Research Infrastructure' program (~98M$) for iKAGRA			'Specially Promoted Research' program (~5M$) for detector upgrade				
	Budget from MEXT (~33M$) for excavation			Budget from MEXT (~20M$) for detector upgrade				

KAGRA configuration

iKAGRA

- KAGRA facility
- 3km simple room-temp. interferometer

Upgrade

bKAGRA

- Cryogenic mirrors
- Full-power RSE configuration

Purpose

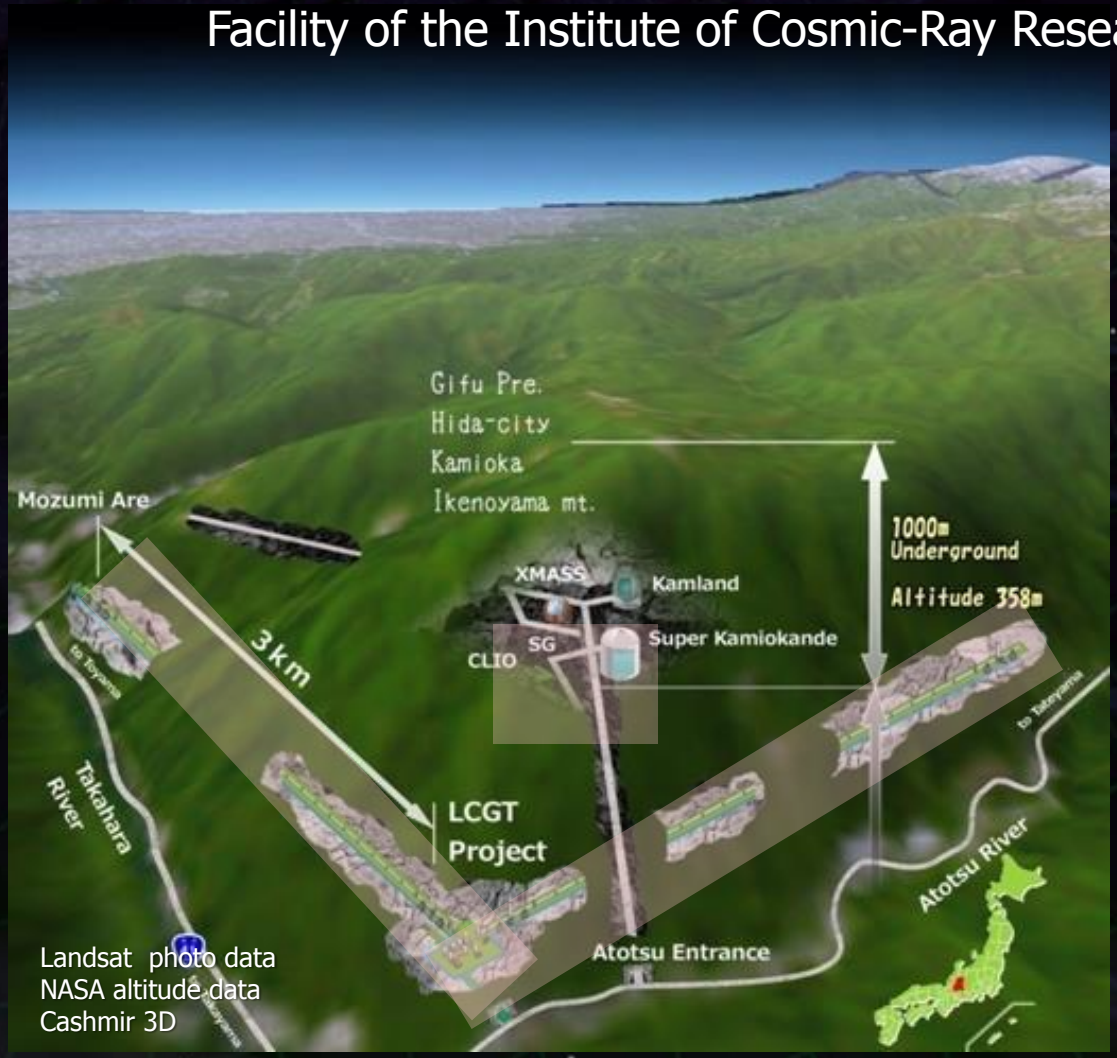
Preparation of infrastructure

GW detection and astronomy

KAGRA Site

Underground site at Kamioka, Gifu prefecture

Facility of the Institute of Cosmic-Ray Research (ICRR), Univ. of Tokyo.



Neutrino
- Super Kamiokande, Kamland

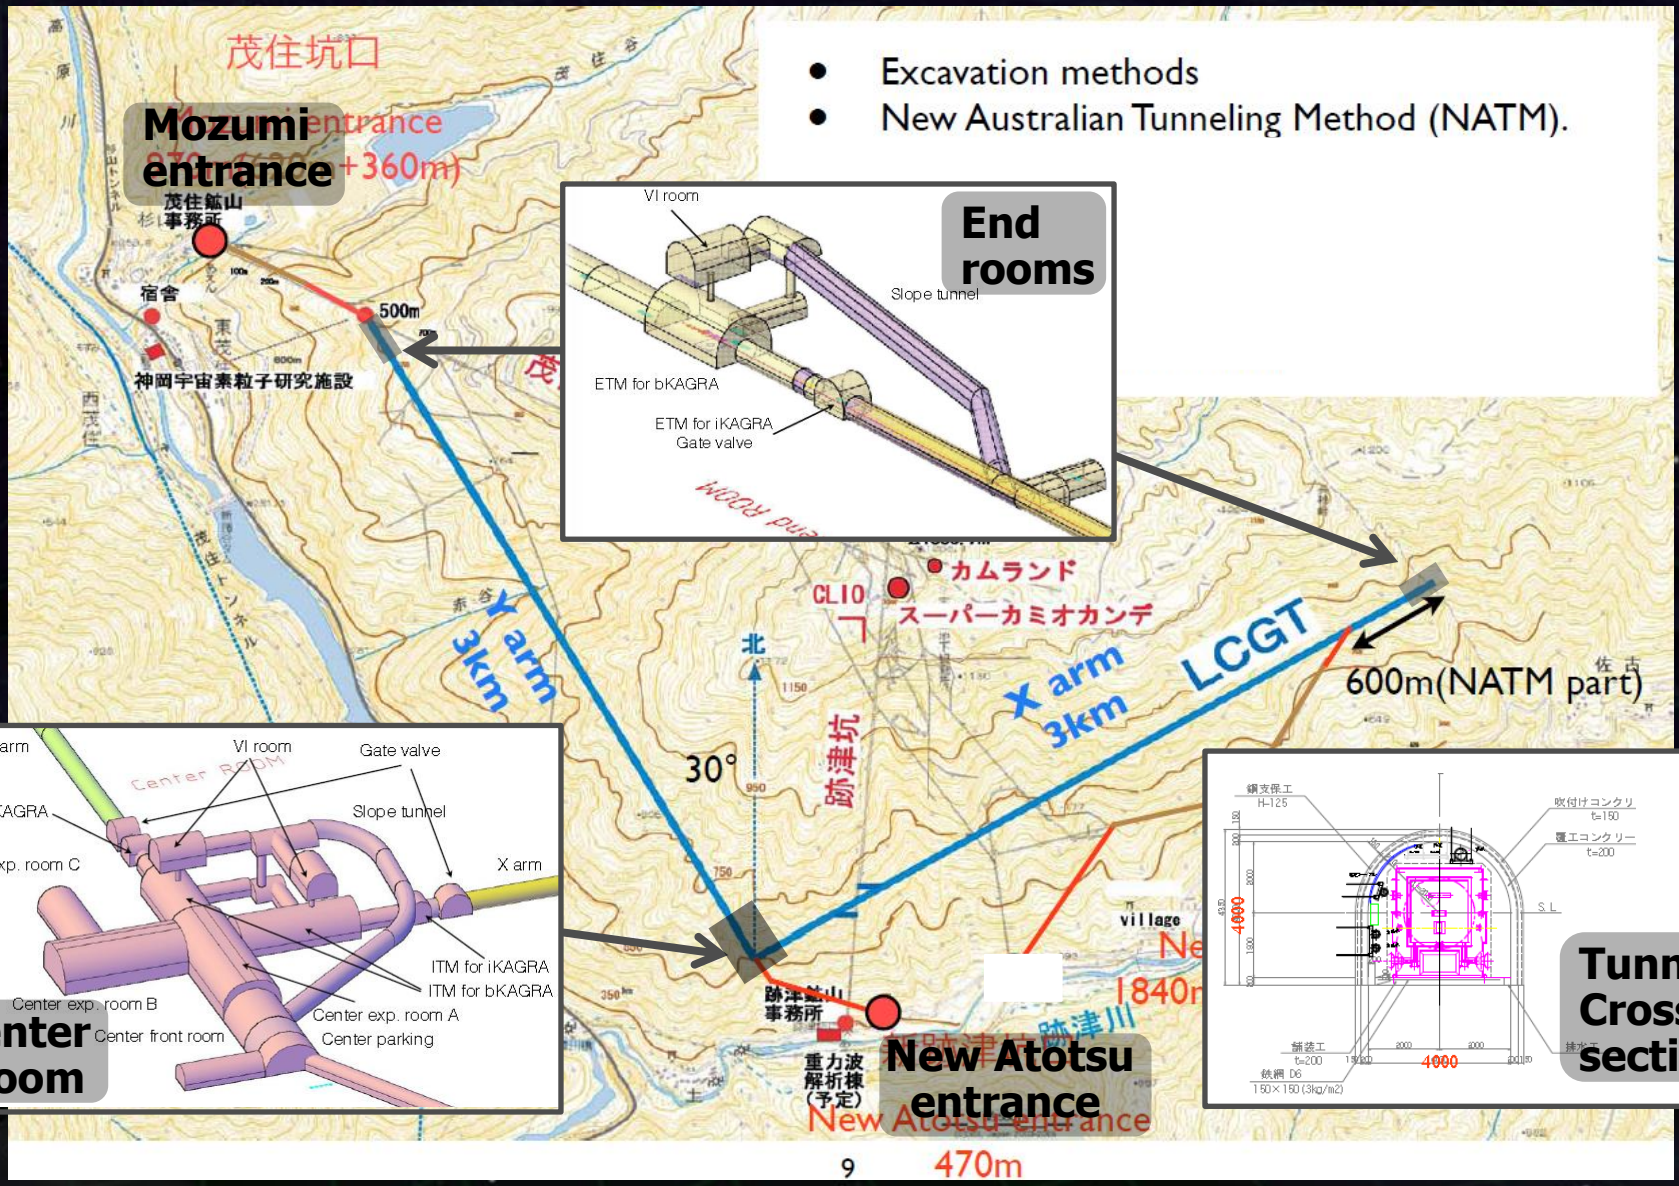
Dark matter
- XMASS

Gravitational wave
- CLIO, KAGRA

Geophysics
- Strain meter

- 220km away from Tokyo
- 1000m underground from the top of the mountain. (Near Super Kamiokande)
- 360m altitude
- Hard rock of Hida gneiss (5 [km/sec] sound speed)

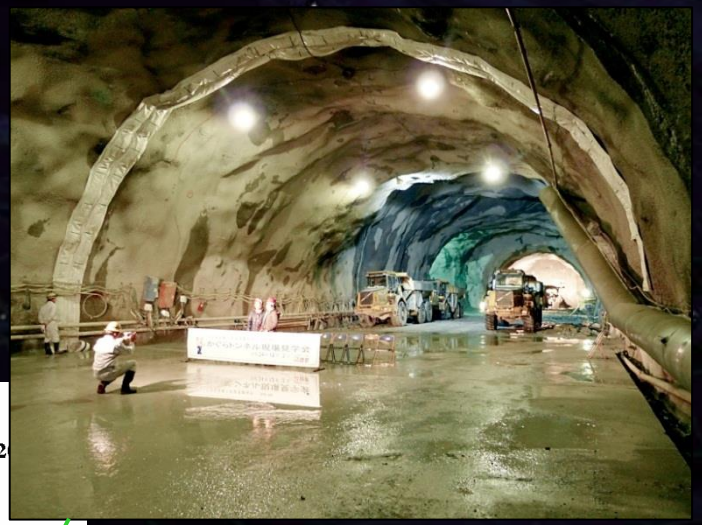
Tunnel Design

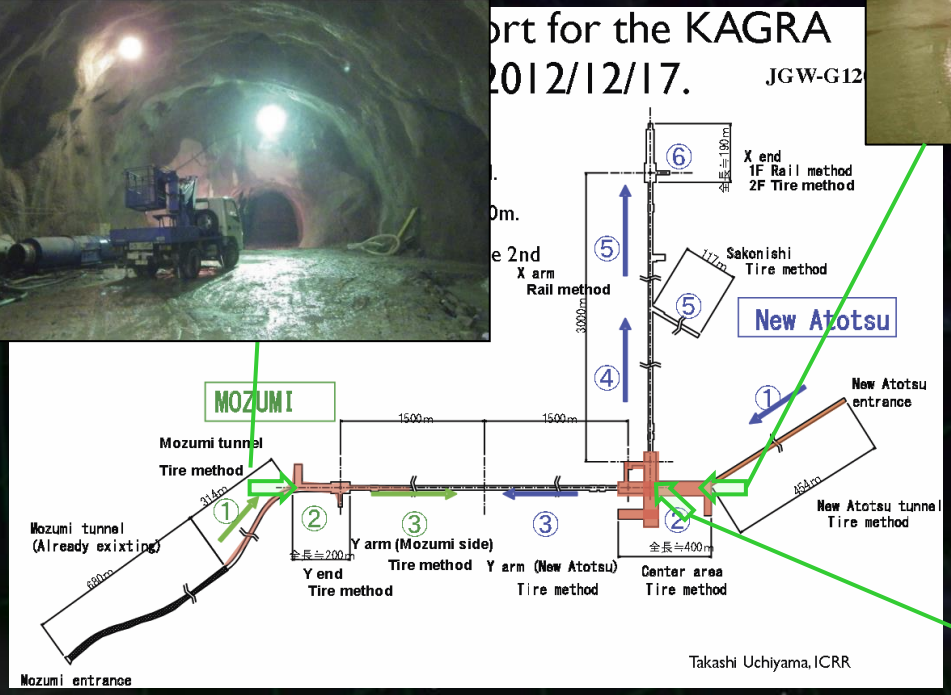


Status of Tunnel Excavation

Mozumi :
Y-arm tunnel
(~1000m)

New Atotsu：Center room





Surface Facility at Kamioka

Rent and remodel a public building (140m^2) for free.

→ On-site office and laboratory for GW group.

Aug. 29, 2012
Announcement for local people
→ Open as office in Nov.

KAGRA Vacuum duct

- 12m, Φ800mm ducts for 3km x 2 arms.
  → ~90% of 478 ducts have been delivered.

Press to form a duct

Bellows for each duct

2 Sapphire substrates were delivered
(Φ220mm, t 150mm, c-axis)

Summary

Summary

KAGRA : Under Construction

- Sufficient sensitivity for direct GW detection
- Form global network as one of the 2nd-gen. detectors

⇨ Aim to detect GW, and to open new astronomy

- KAGRA will demonstrate 3rd generation detector techniques: cryogenics and underground

Status

- Technology based on TAMA and CLIO experiences
- Tunnel and facilities are becoming real.
- Prototype developments : SAS, Cryostat, Control Sys.

Experiences in GCOE

For me…

- Enjoyed life in Kyoto.
- Research experiences in Kyoto was vary fruitful.
  - 'Tentaikaku' astrophysics theory group:
    → Interactions with theorists
  - Quantum Optics group.
    → Precise atomic spectroscopy for fundamental phys.

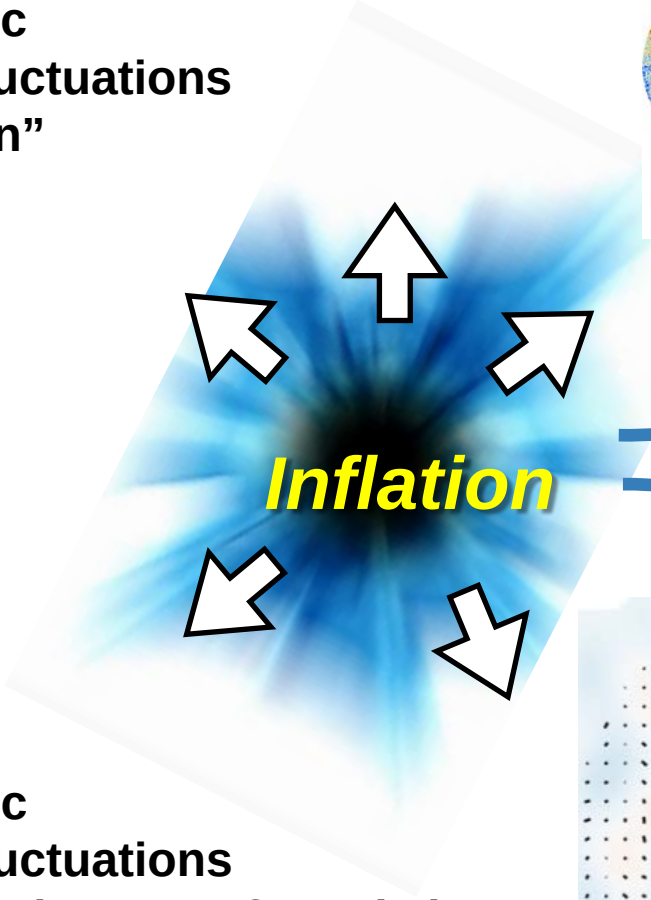
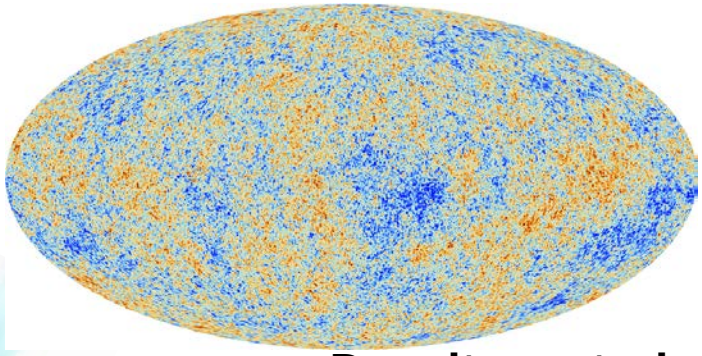
Density perturbations and gravitational waves

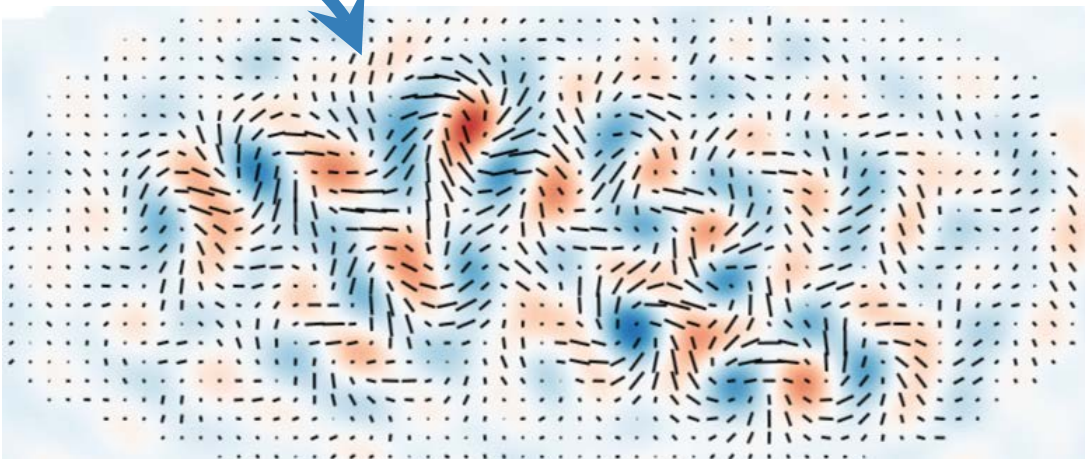
Sub-atomic vacuum fluctuations of "inflaton"





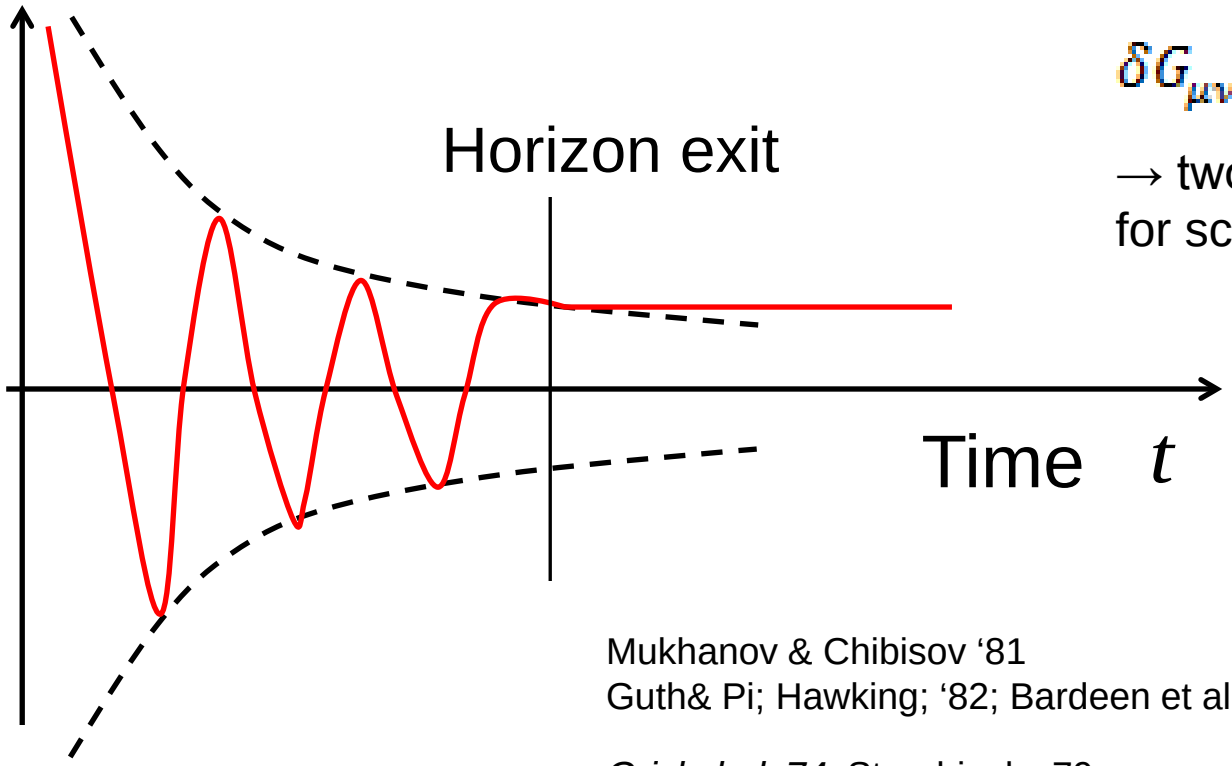
Density perturbations *studied* by Planck, WMAP, SPT, etc.

Gravitational waves



Sub-atomic vacuum fluctuations of *graviton* (quanta of gravity)

Generation of ***scalar/tensor*** perturbations



$$\delta G_{\mu\nu} = 8\pi G \delta T_{\mu\nu}$$

→ two linear wave equations for scalar /tensor

Mukhanov & Chibisov ‘81
Guth& Pi; Hawking; ‘82; Bardeen et al., ’83, Sasaki ‘83

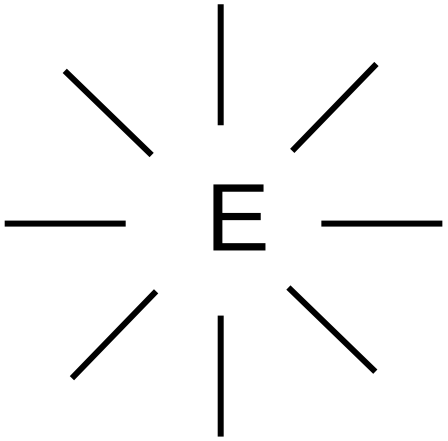
Grishchuk 74; Starobinsky 79
Rubakov et al, 82; Frabri & Pollock , 82

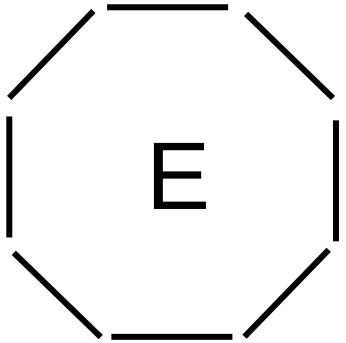
Quantum fluctuations in the vacuum state of the *inflaton*/*graviton* fixes the r.m.s of the linear solutions

Inflationary B-modes, known as the "Holy Grail" of cosmology

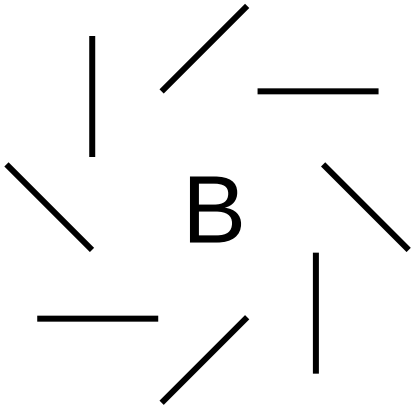
- Started out as *graviton* vacuum fluctuations
- Energy scale of inflation ~ expansion rate ~ GW amplitude
- Alternative models generate no GW
- *Field range and "UV" completeness*

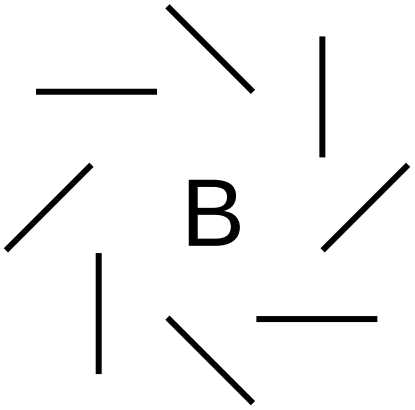
Only gravitational waves can generate B-modes

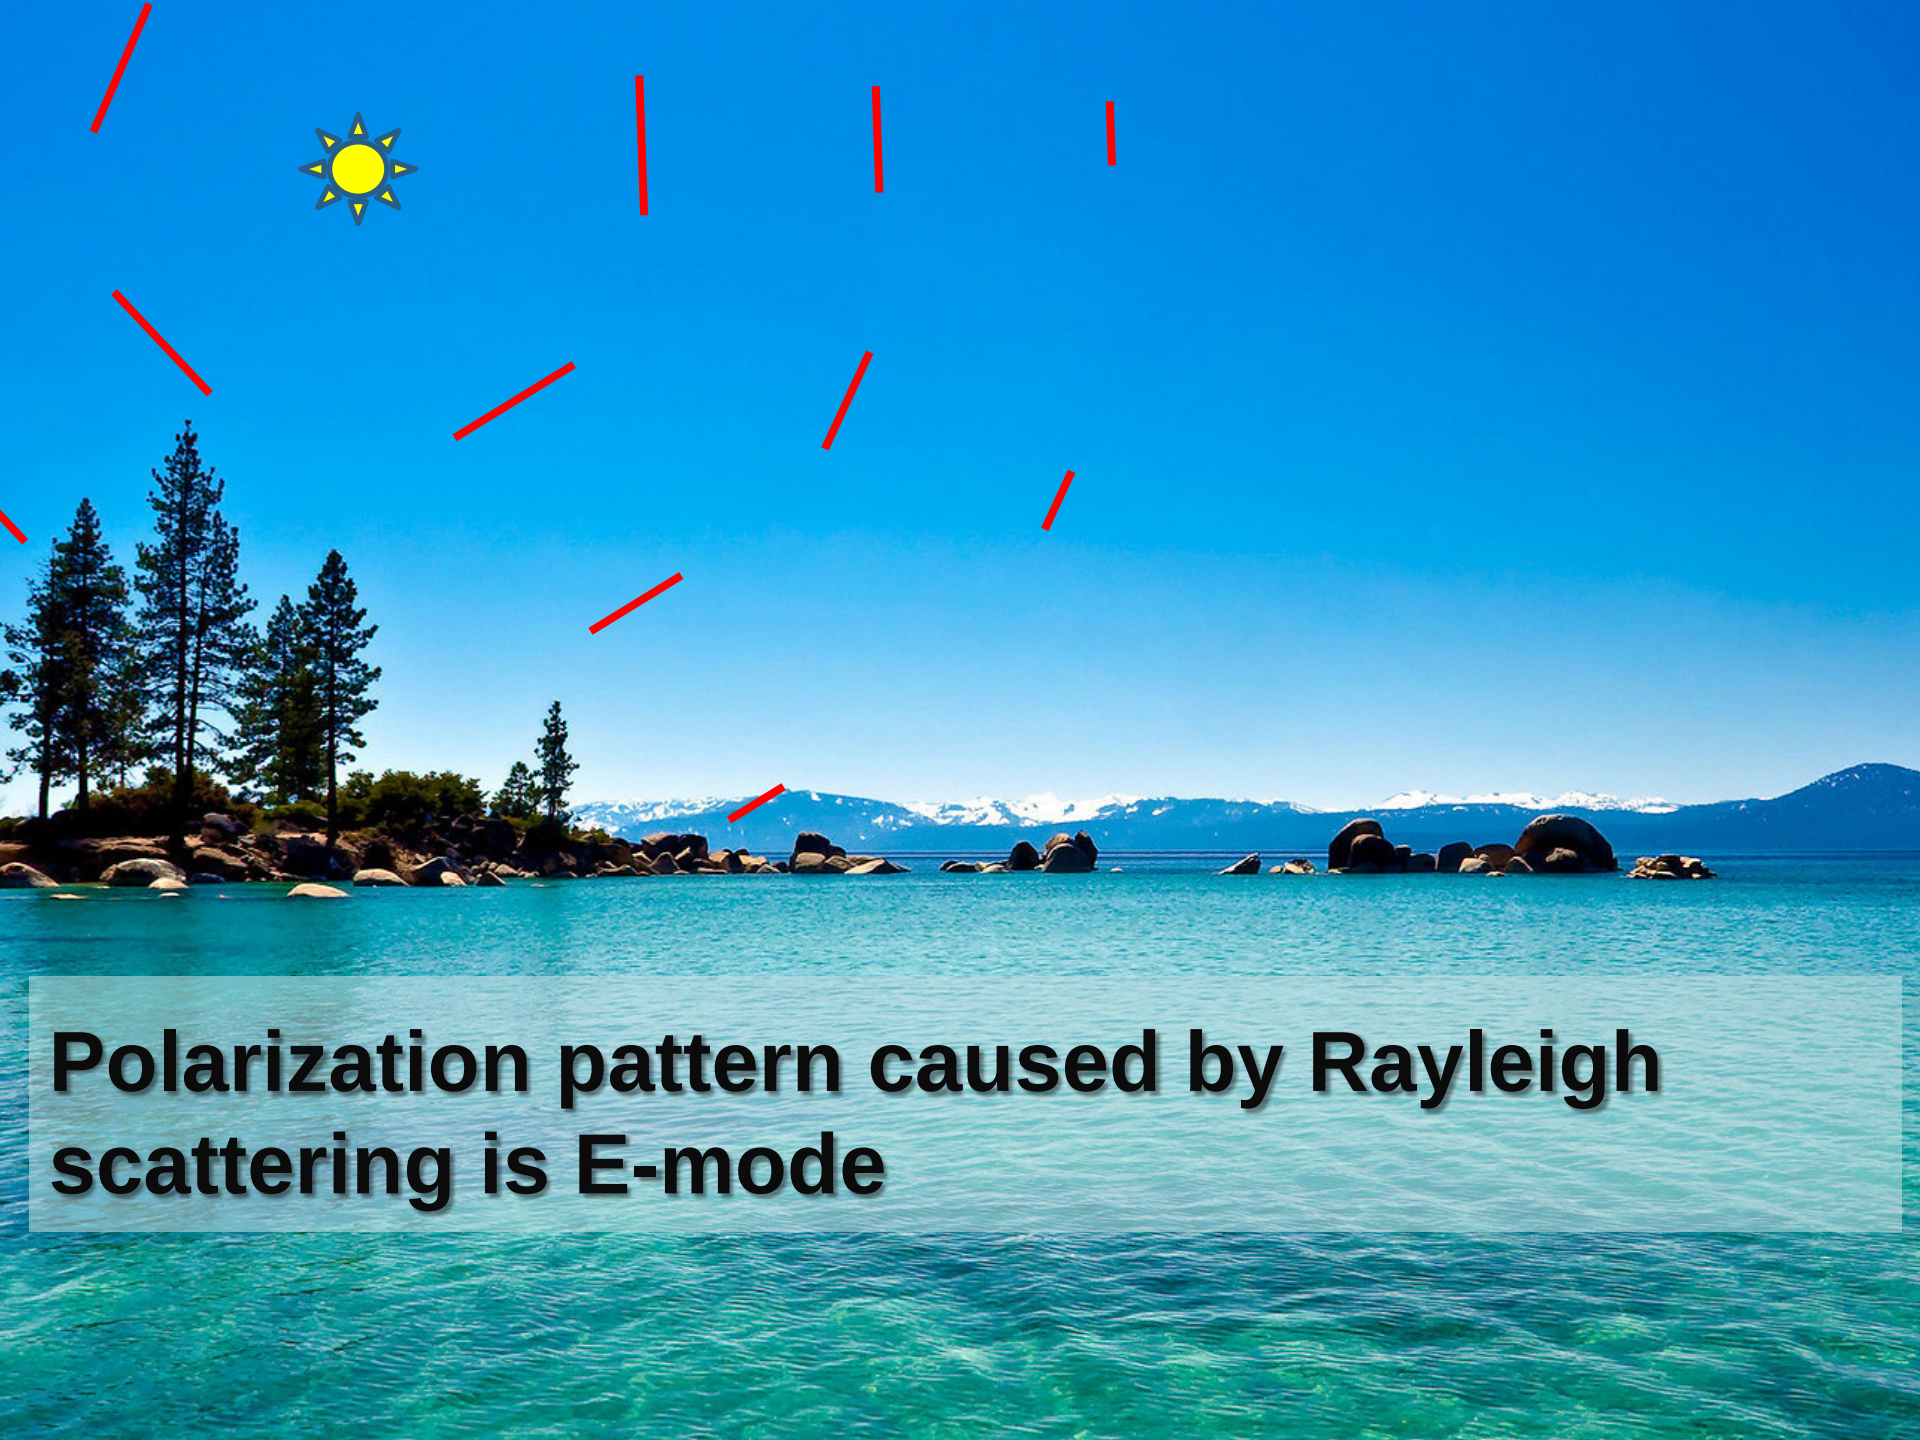




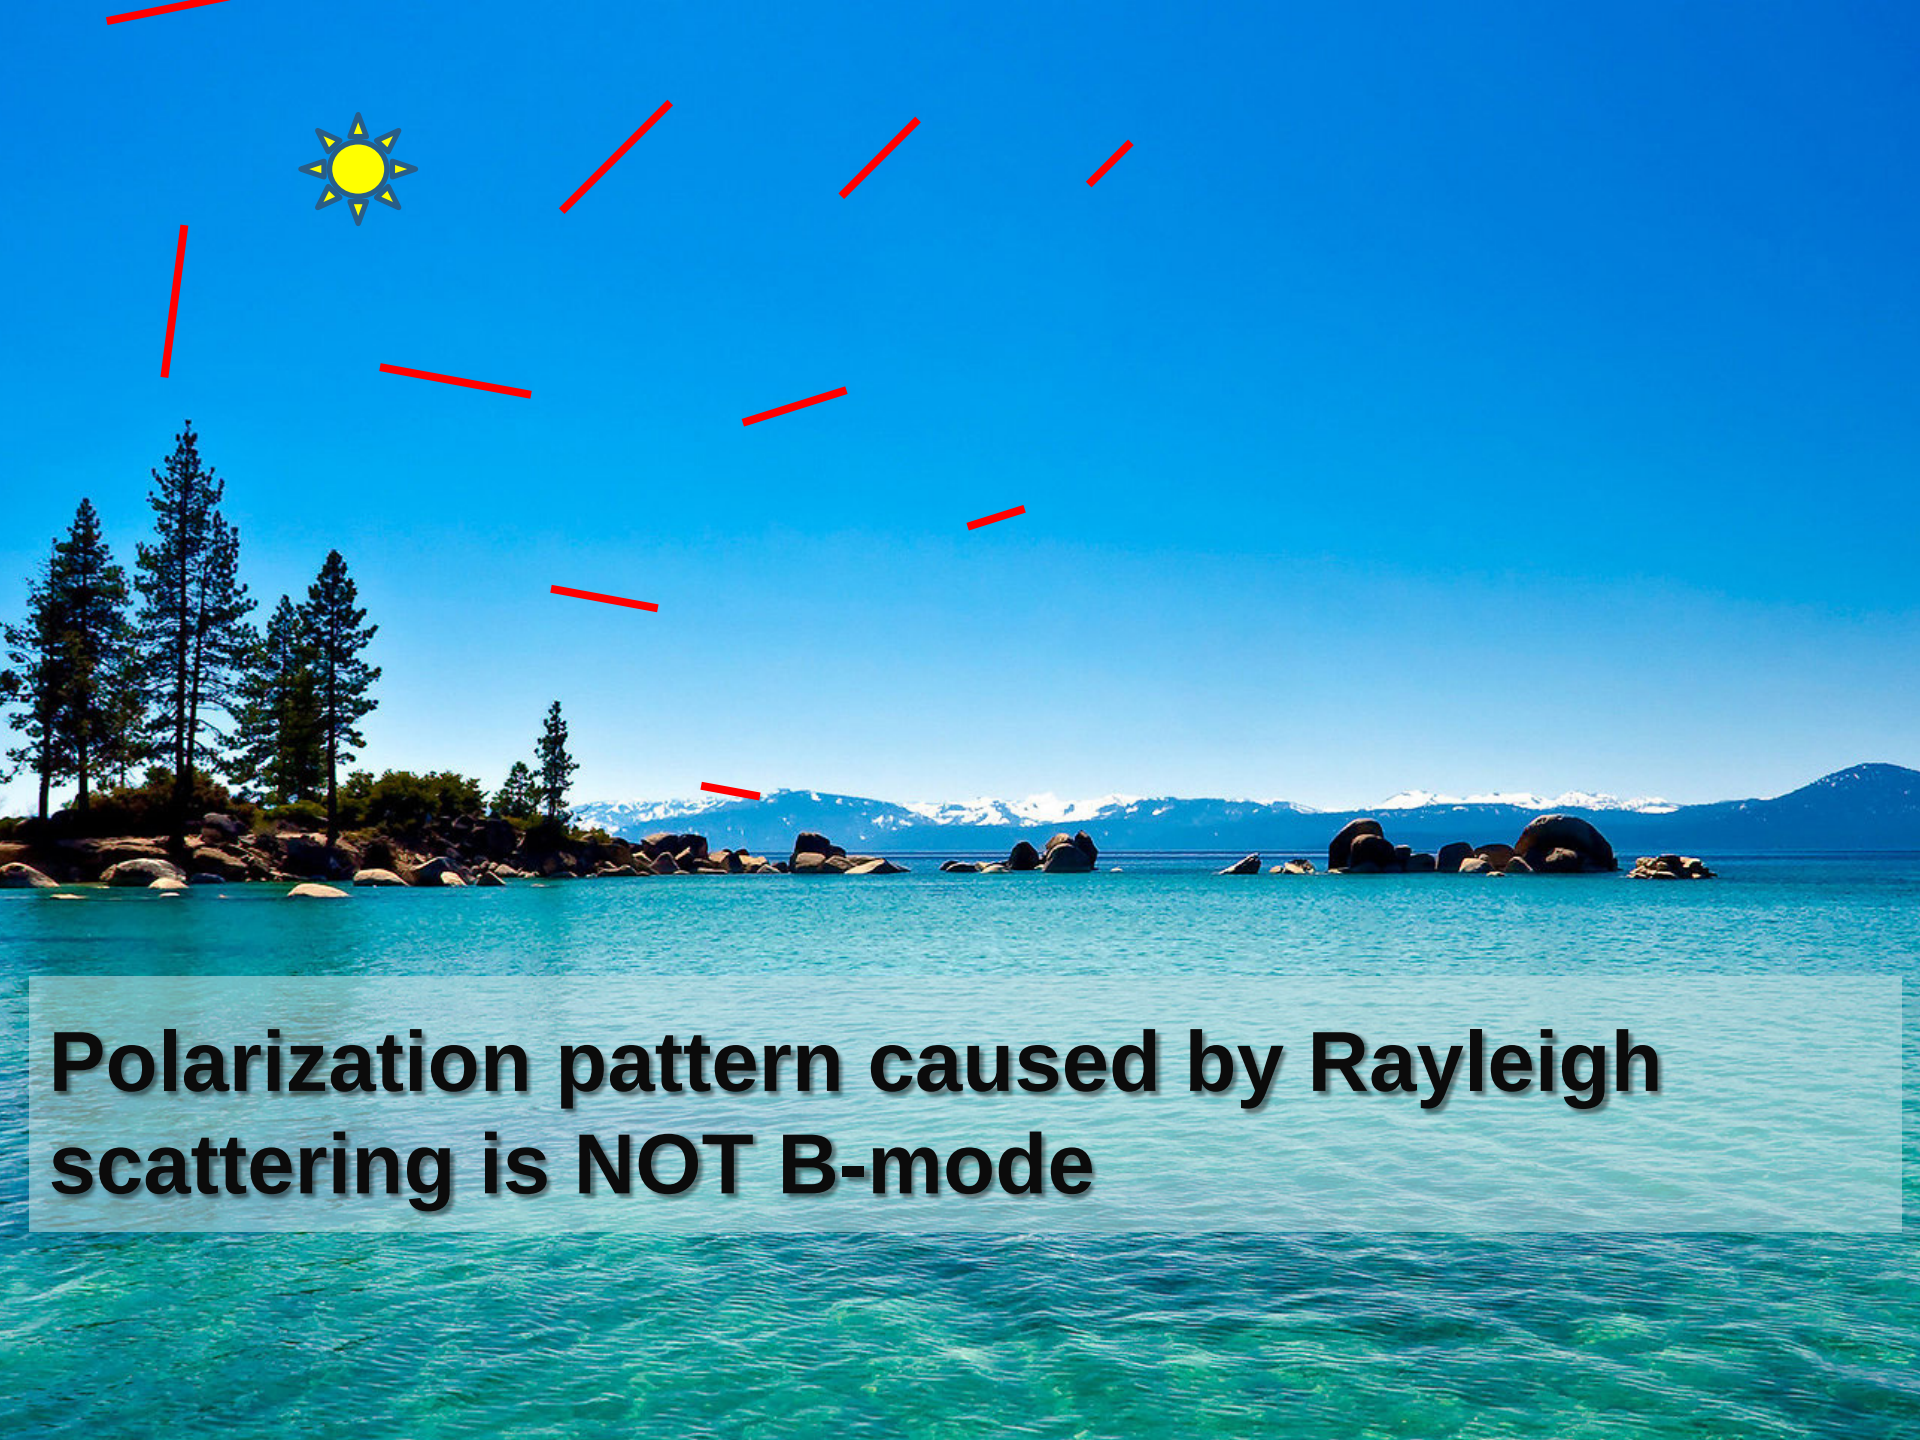
Seljak & Zaldarriaga ‘97
Kamionkowski, Kosowsky, Stebbins ‘97





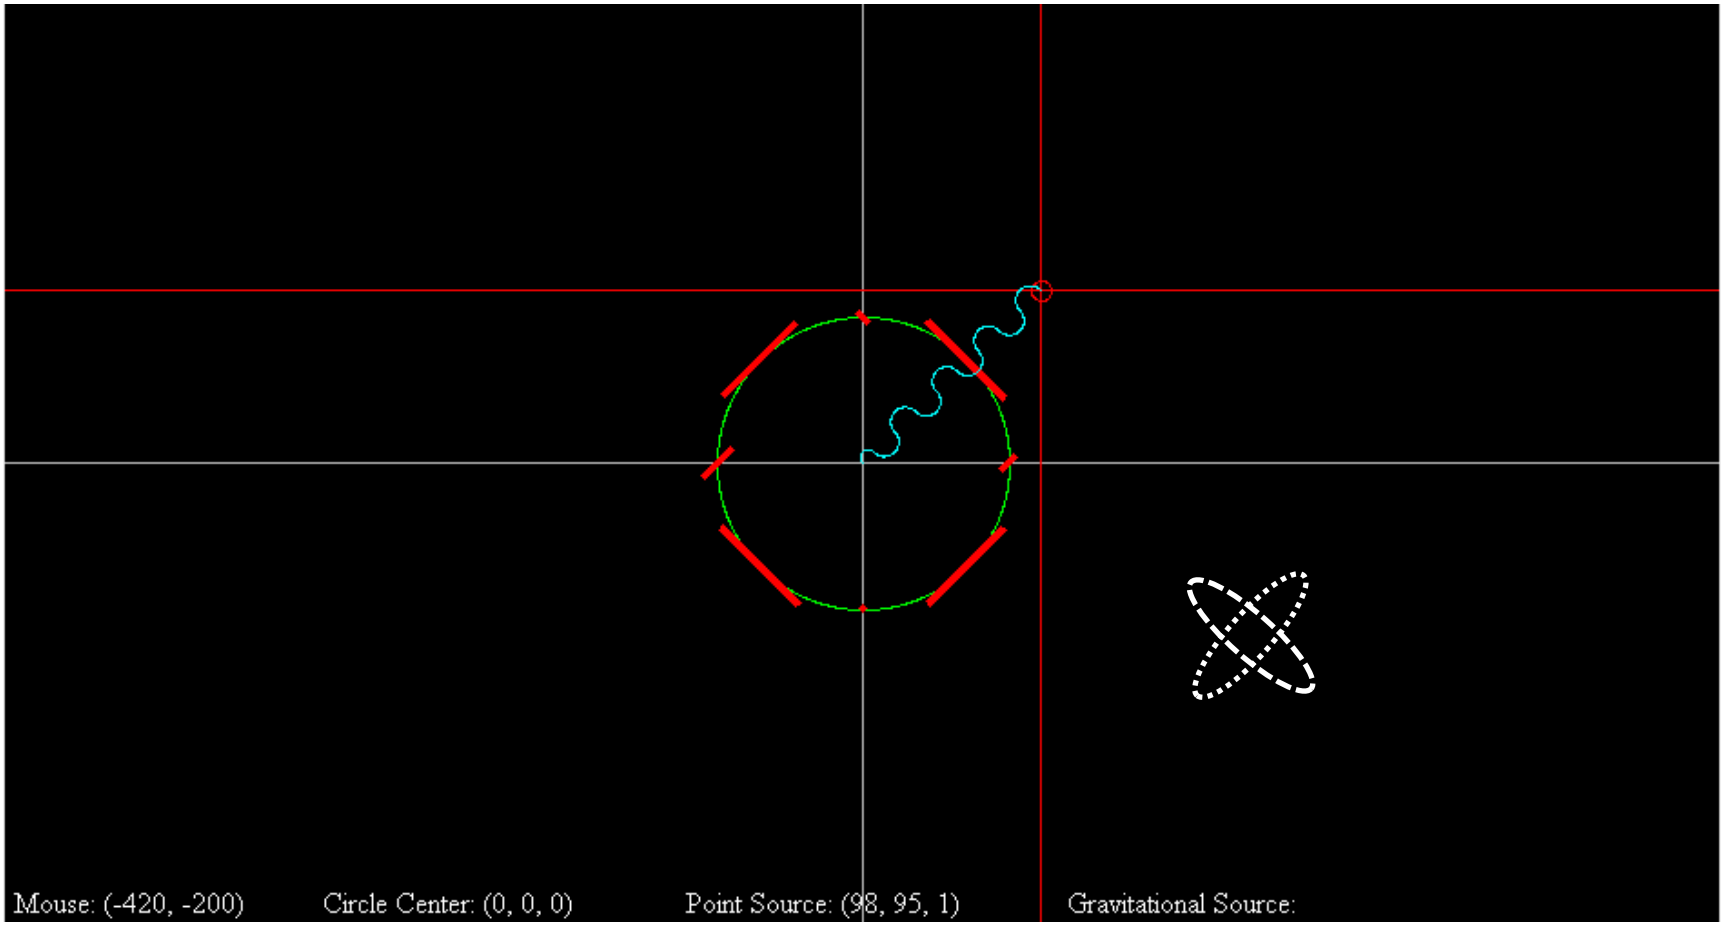


Polarization pattern caused by Rayleigh scattering is E-mode

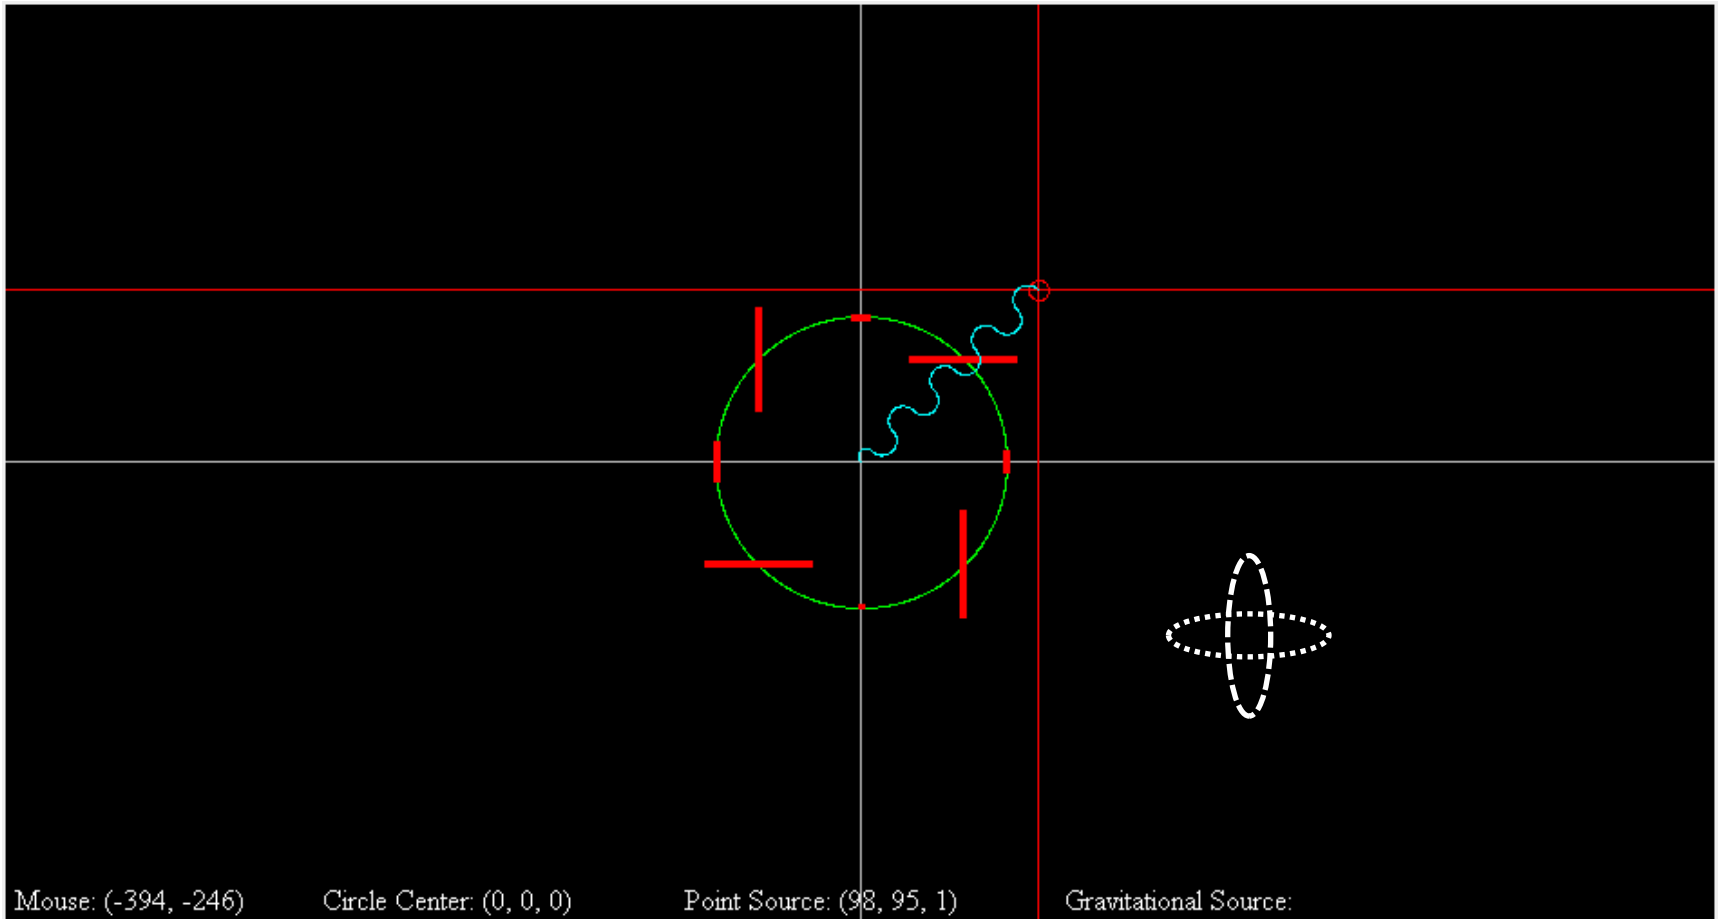


Polarization pattern caused by Rayleigh scattering is NOT B-mode

Gravitational waves generate *E*-mode polarization



Gravitational waves generate *B*-mode polarization



!!!

The polarization pattern is unique, but small

Vertical / Horizontal

Splits the 4 boresight rotations

Amplifies differential pointing in comparison to fully added data. Important check of deprojection. See later slides.

Splits by time

Checks for contamination on long (“Tag Split”) and short (“Scan Dir”) timescales. Short timescales probe detector transfer functions.

Splits by channel selection

Checks for contamination in channel subgroups, divided by focal plane location, tile location, and readout electronics grouping

Splits by possible external contamination

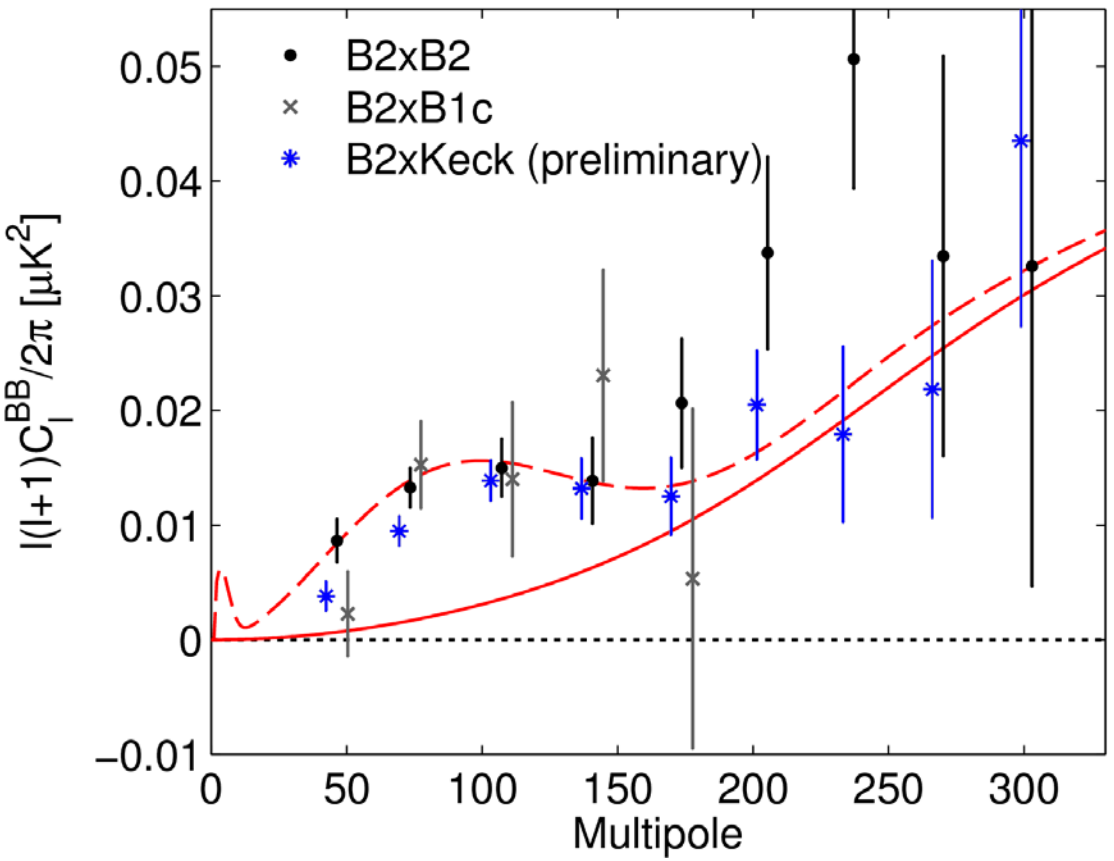
Checks for contamination from ground-fixed signals, such as polarized sky or magnetic fields, or the moon

Splits to check intrinsic detector properties

Checks for contamination from detectors with best/worst differential pointing. “Tile/dk” divides the data by the orientation of the detector on the sky.

Additional Cross Spectra

Form cross spectrum between BICEP2 and BICEP1 combined (100 + 150 GHz):

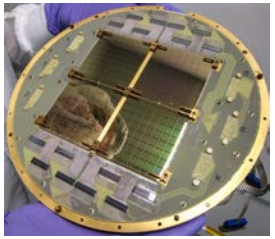


BICEP2 auto spectrum compatible with B2xB1c cross spectrum

~3σ evidence of excess power in the cross spectrum

Additionally form cross spectrum with 2 years of data from *Keck Array*, the successor to BICEP2

Excess power is also evident in the B2xKeck cross spectrum



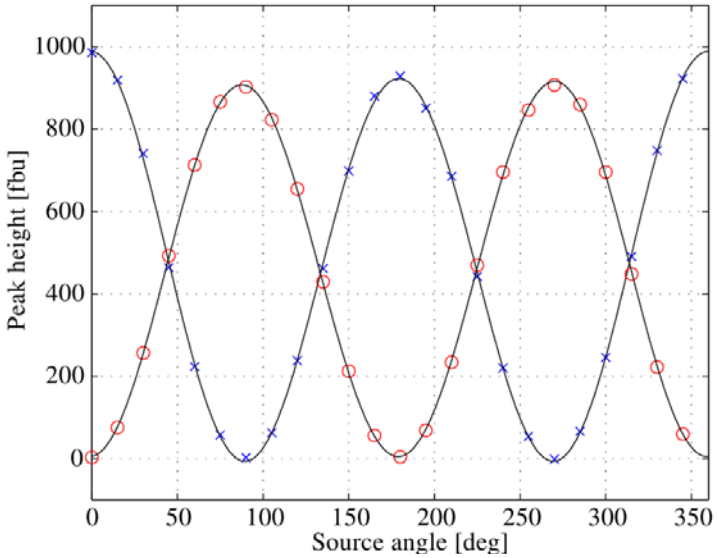
Cross spectra:
Powerful additional evidence against a systematic origin of the apparent signal

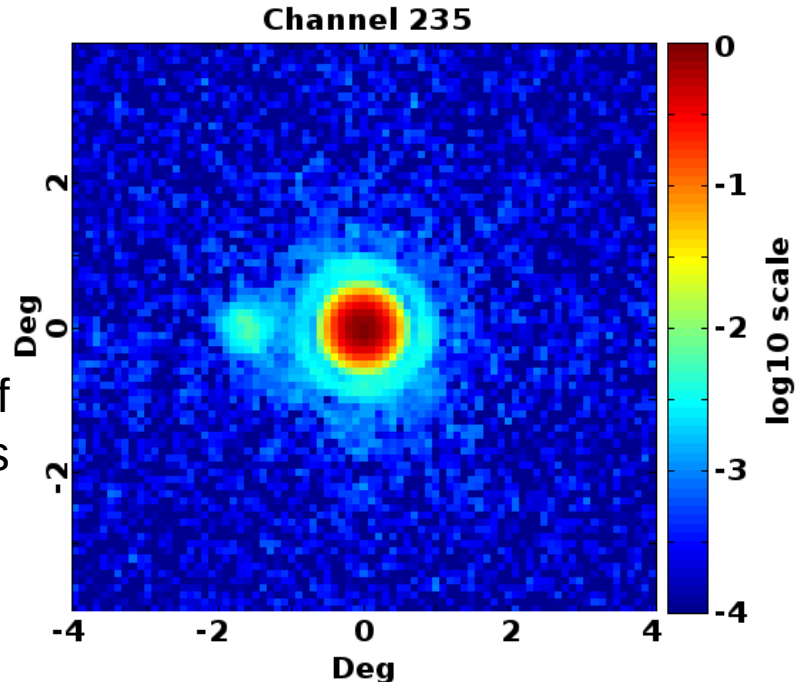
Calibration Measurements

For instance...

Far field beam mapping

Detector Polarization Calibration

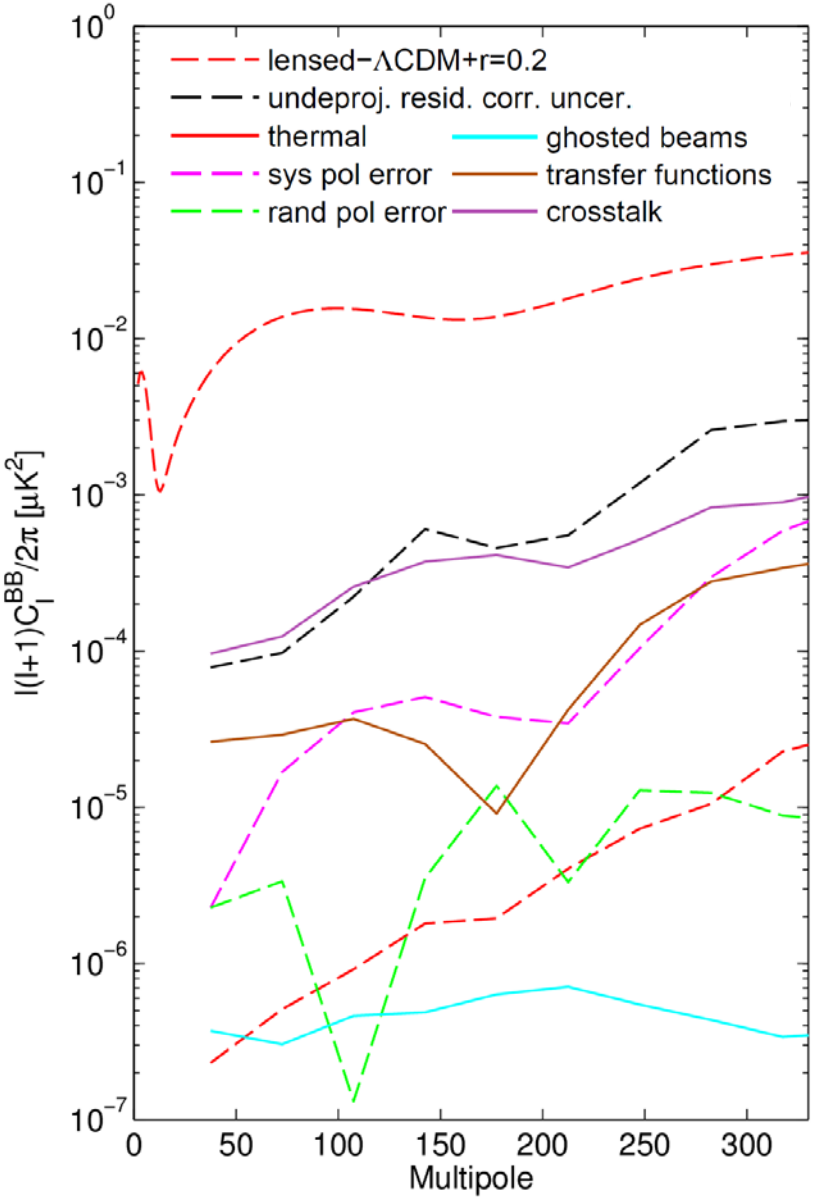




Hi-Fi beam maps of individual detectors

Detailed description in companion Instrument Paper

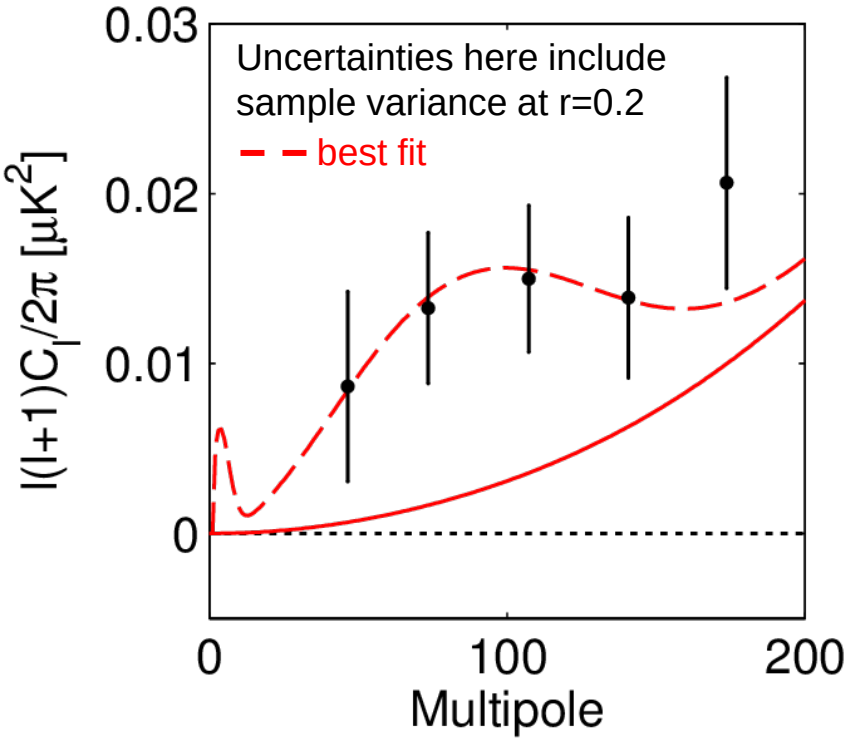
Systematics beyond Beam imperfections



All systematic effects that we could imagine were investigated!

We find with high confidence that the apparent signal *cannot be explained* by instrumental systematics!

Constraint on Tensor-to-scalar Ratio r



Substantial excess power in the region where the inflationary gravitational wave signal is expected to peak

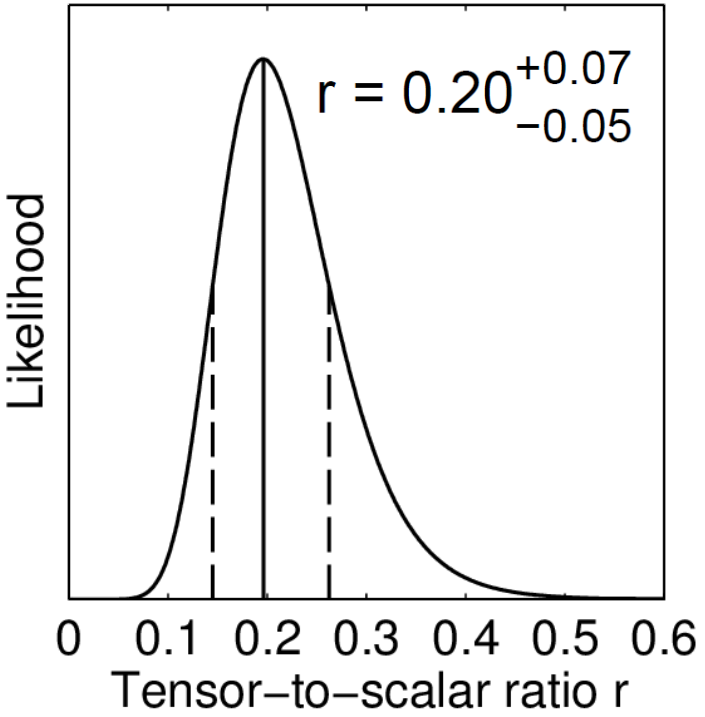
Find the most likely value of the tensor-to-scalar ratio r

Apply "direct likelihood" method, uses:

→ lensed-ΛCDM + noise simulations

→ weighted version of the 5 bandpowers

→ B-mode sims scaled to various levels of r (n_T=0)



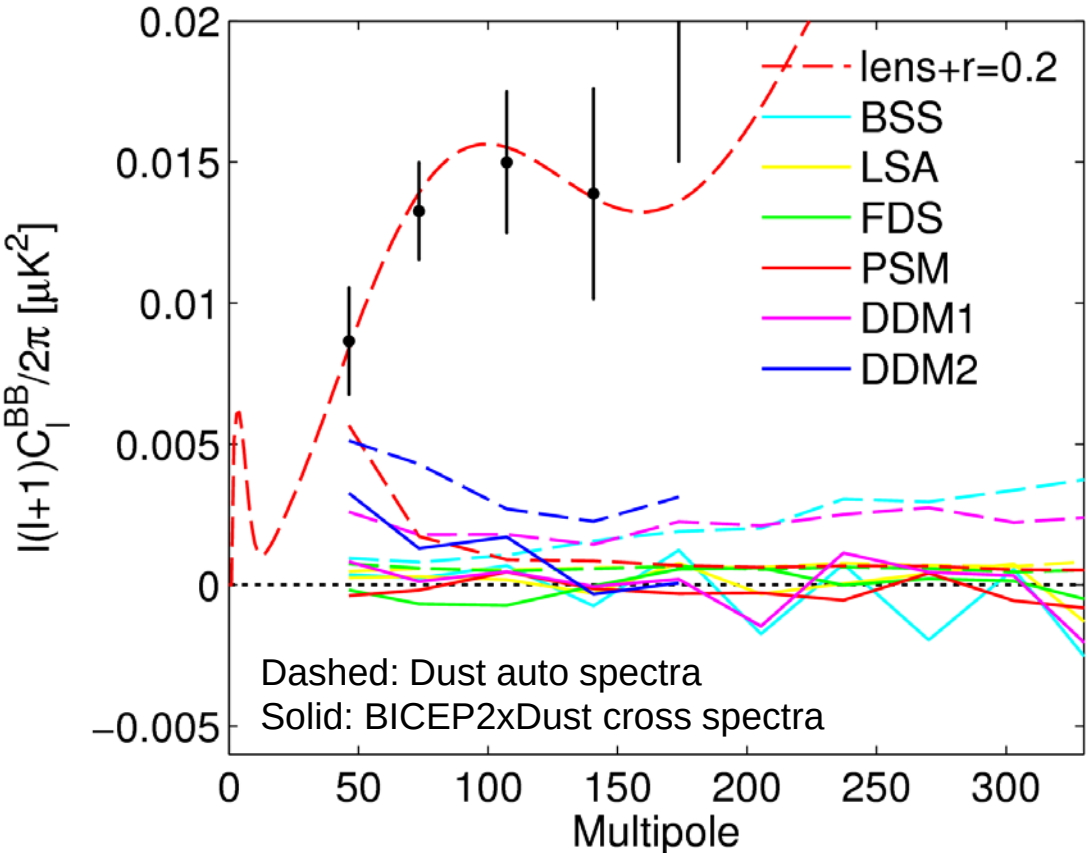
Within this simplistic model we find:

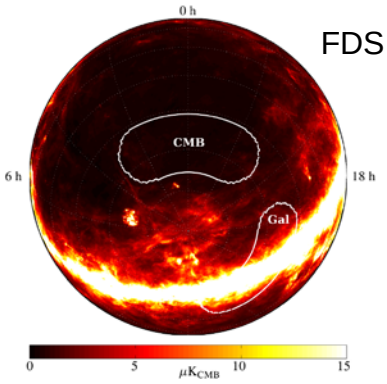
r = 0.2 with uncertainties dominated by sample variance

PTE of fit to data: 0.9
→ model is perfectly acceptable fit to the data

r=0 ruled out at 7.0σ

Polarized Dust Foreground Projections





FDS Model

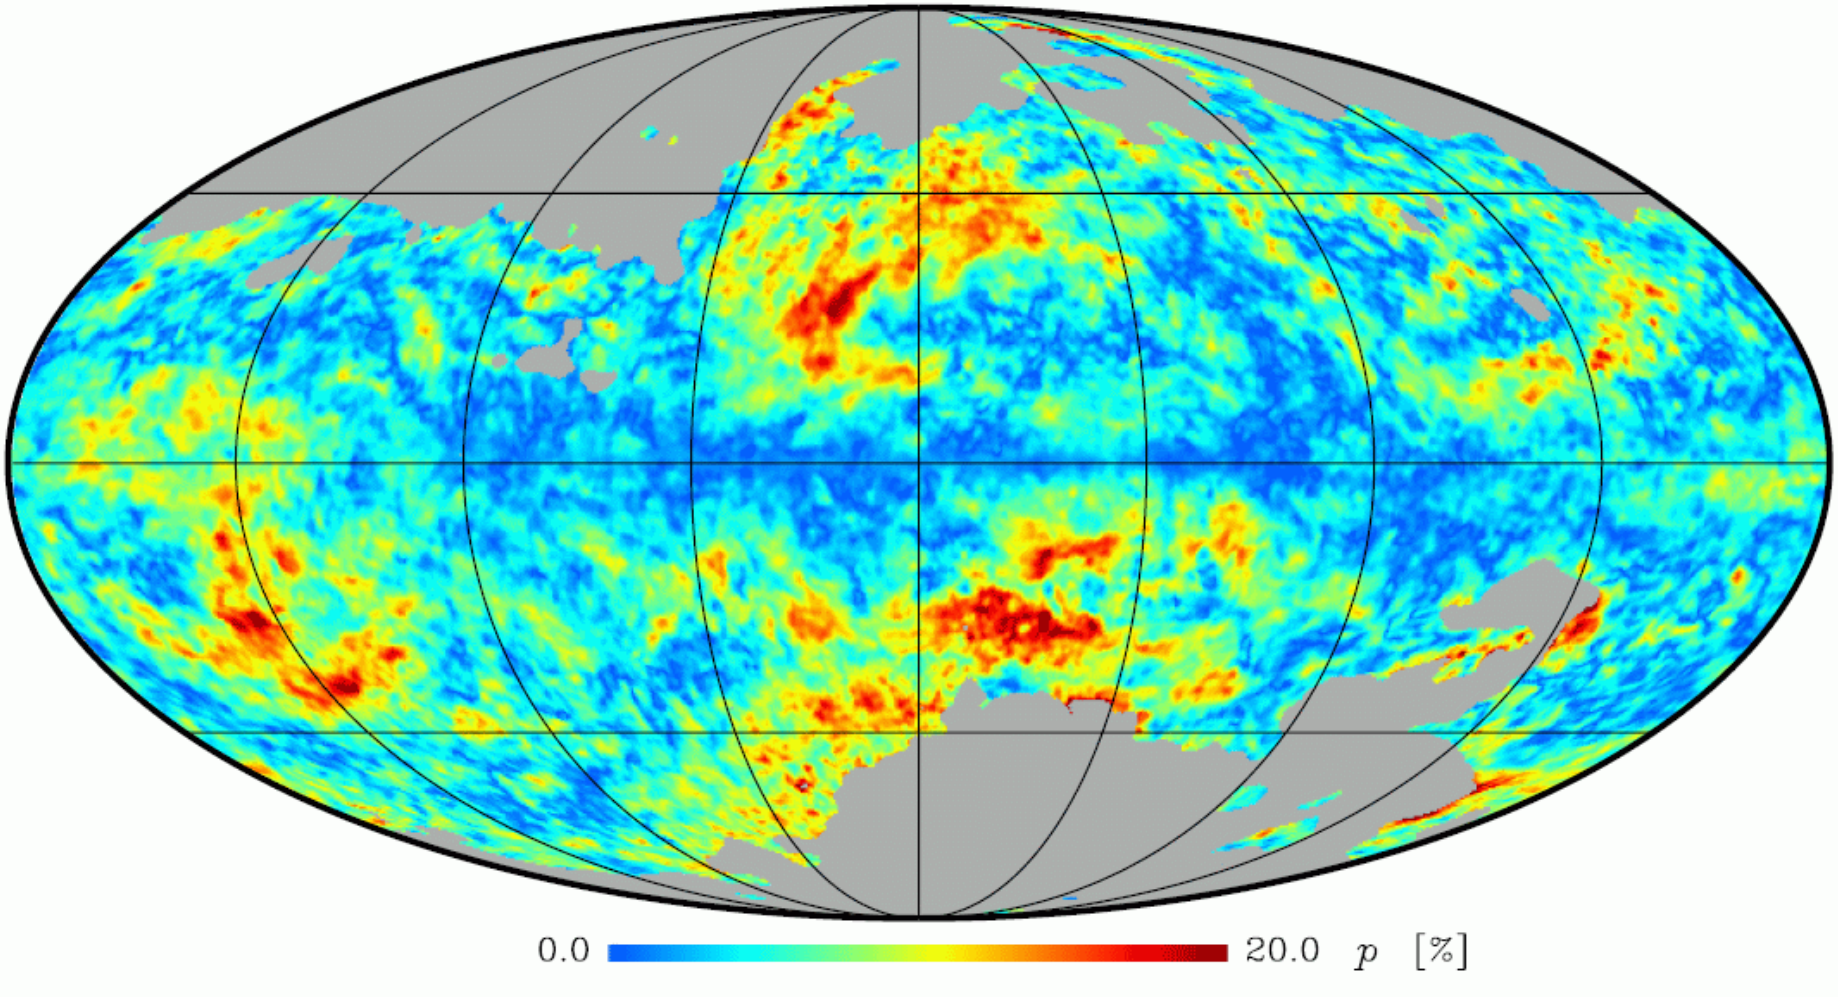
The BICEP2 region is chosen to have extremely low foreground emission.

Use various models of polarized dust emission to estimate foregrounds.

All dust auto spectra well below observed signal level.

Cross spectra consistent with zero.

Polarization fraction from *Planck XIX* (May 6)



The Bicep2 Collaboration

Polarization fraction from *Planck XIX* (May 6)

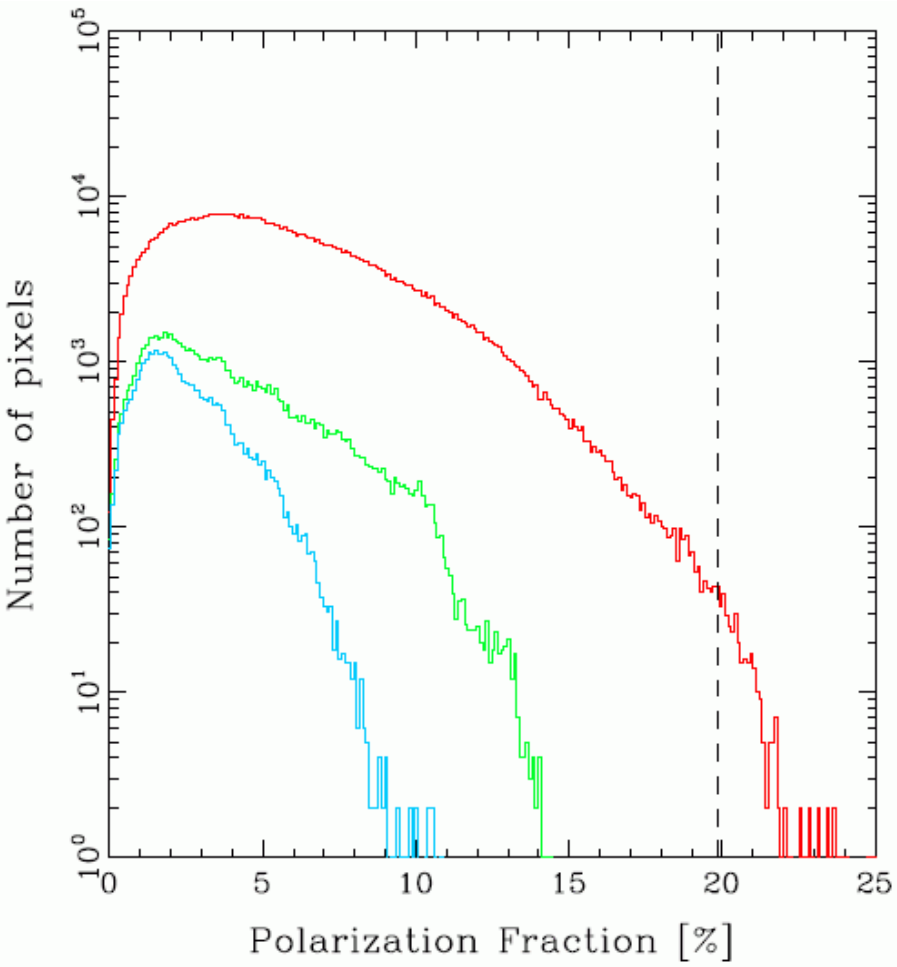


Fig. 7. Histograms of the observed polarization fraction at 1° resolution for the whole sky shown in Fig. 1 (*red*), the Galactic plane within $|b_{II}| < 5°$ (*green*) and the inner Galactic plane within $|b_{II}| < 5°$ and $|\ell_{II}| < 90°$ (*blue*).

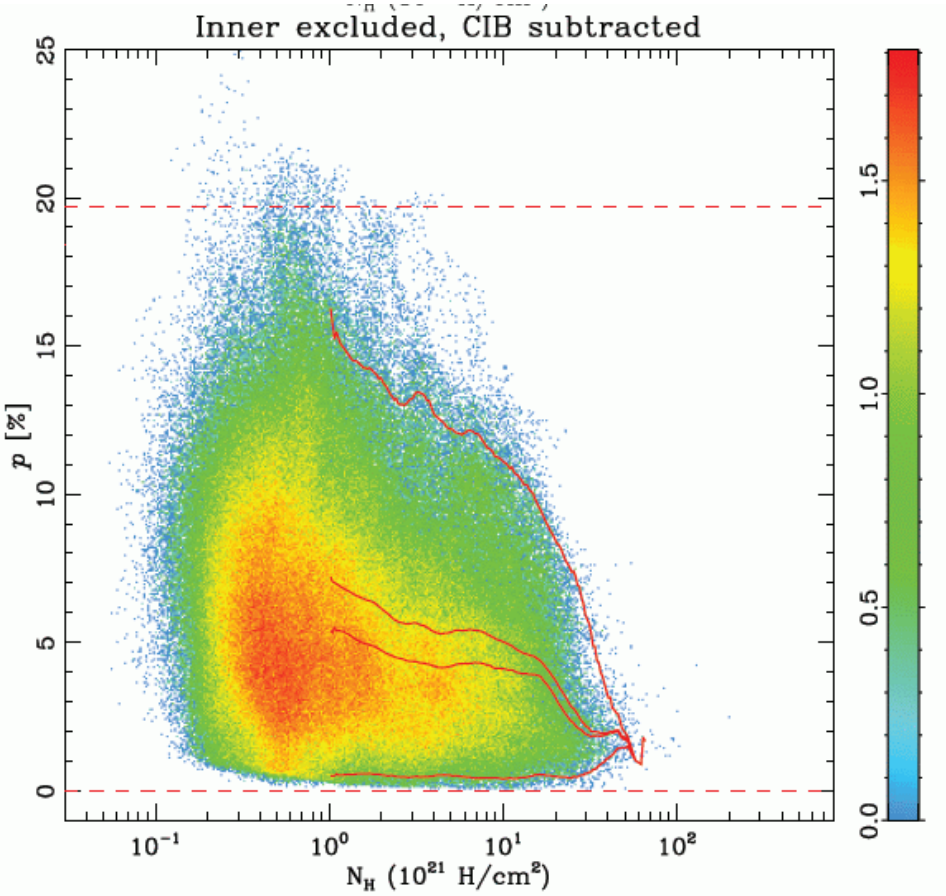
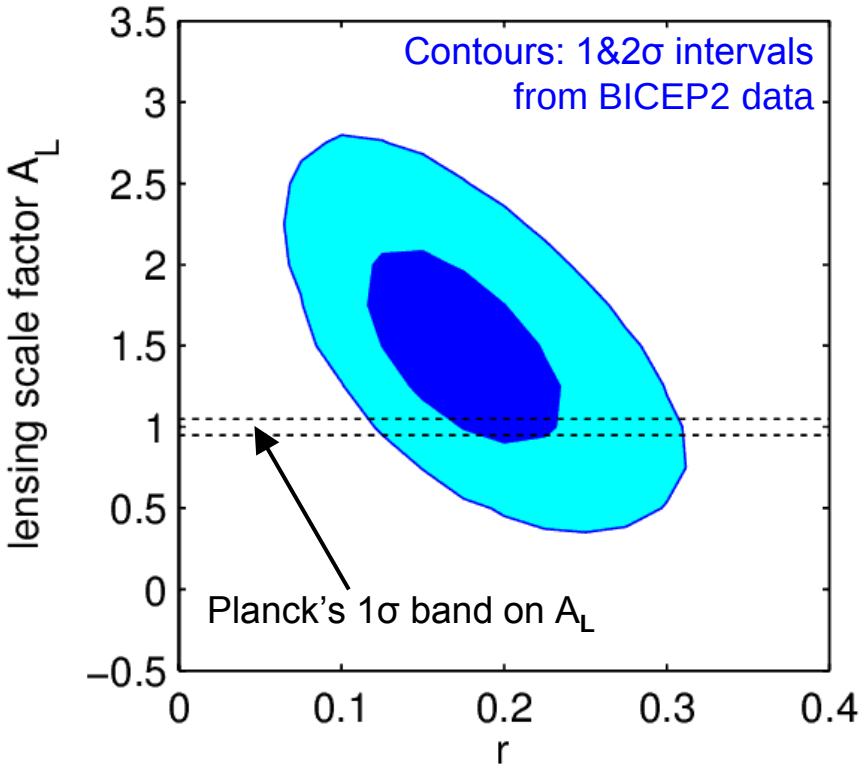


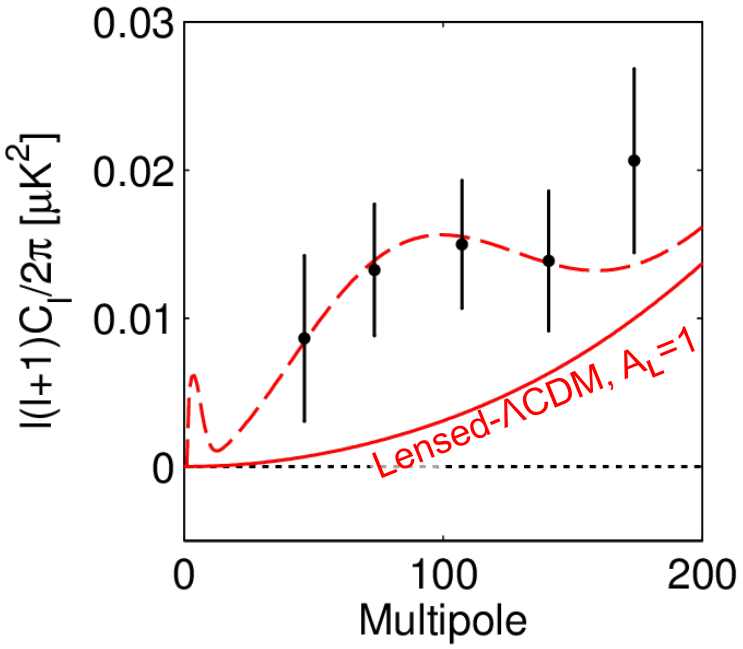
The Bicep2 Collaboration

Joint Constraint on r and Lensing Scale Factor

Lensing deflects CMB photons, slightly mixing the dominant E-modes into B-modes -- dominant at high multipoles

Planck data constrain the amplitude of the lensing effect to $A_L = 0.99 \pm 0.05$.





In the joint constraint on r and A_L we find:

BICEP2 data is perfectly compatible with a lensing amplitude of A = 1.

Marginalizing over r, we detect lensing B-modes at 2.7σ

Compatibility with Indirect Limits on r

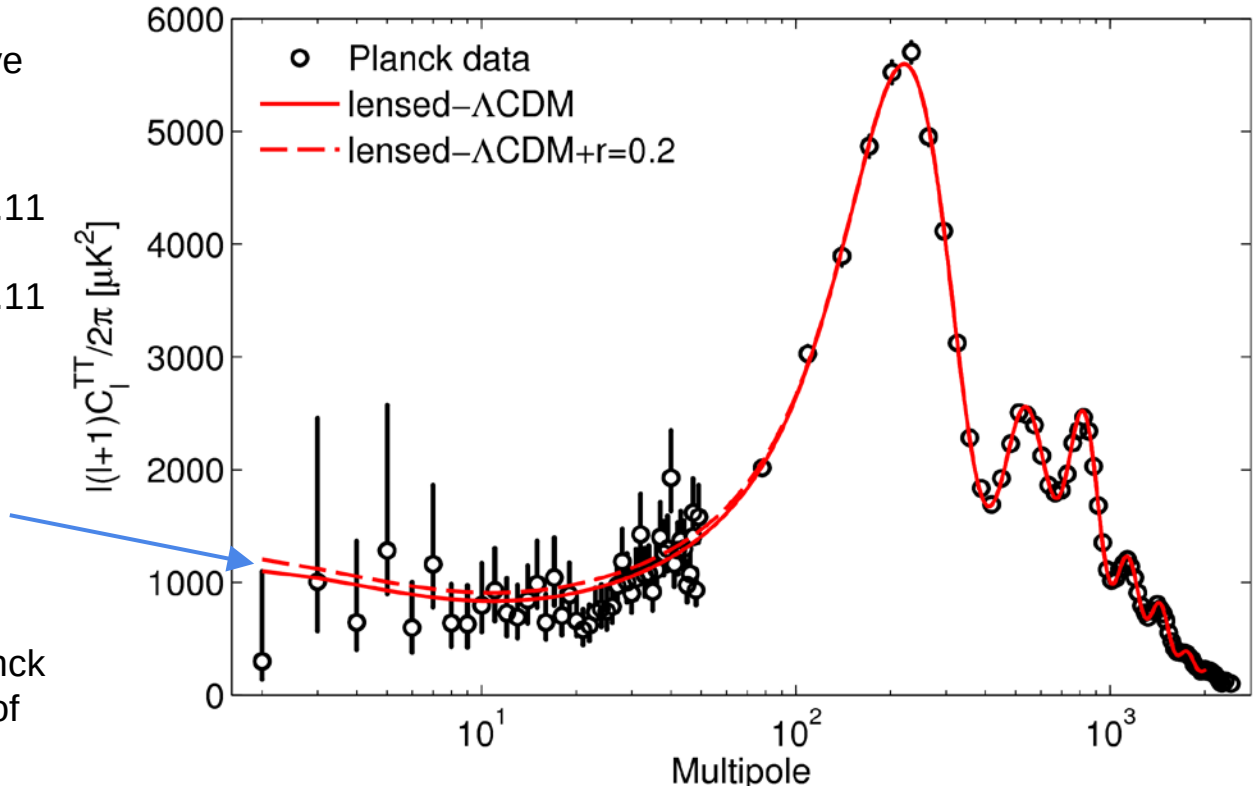
Using temperature data over a wide range of angular scales limits on r have been set:

SPT+WMAP+BAO+H_0 : $r < 0.11$

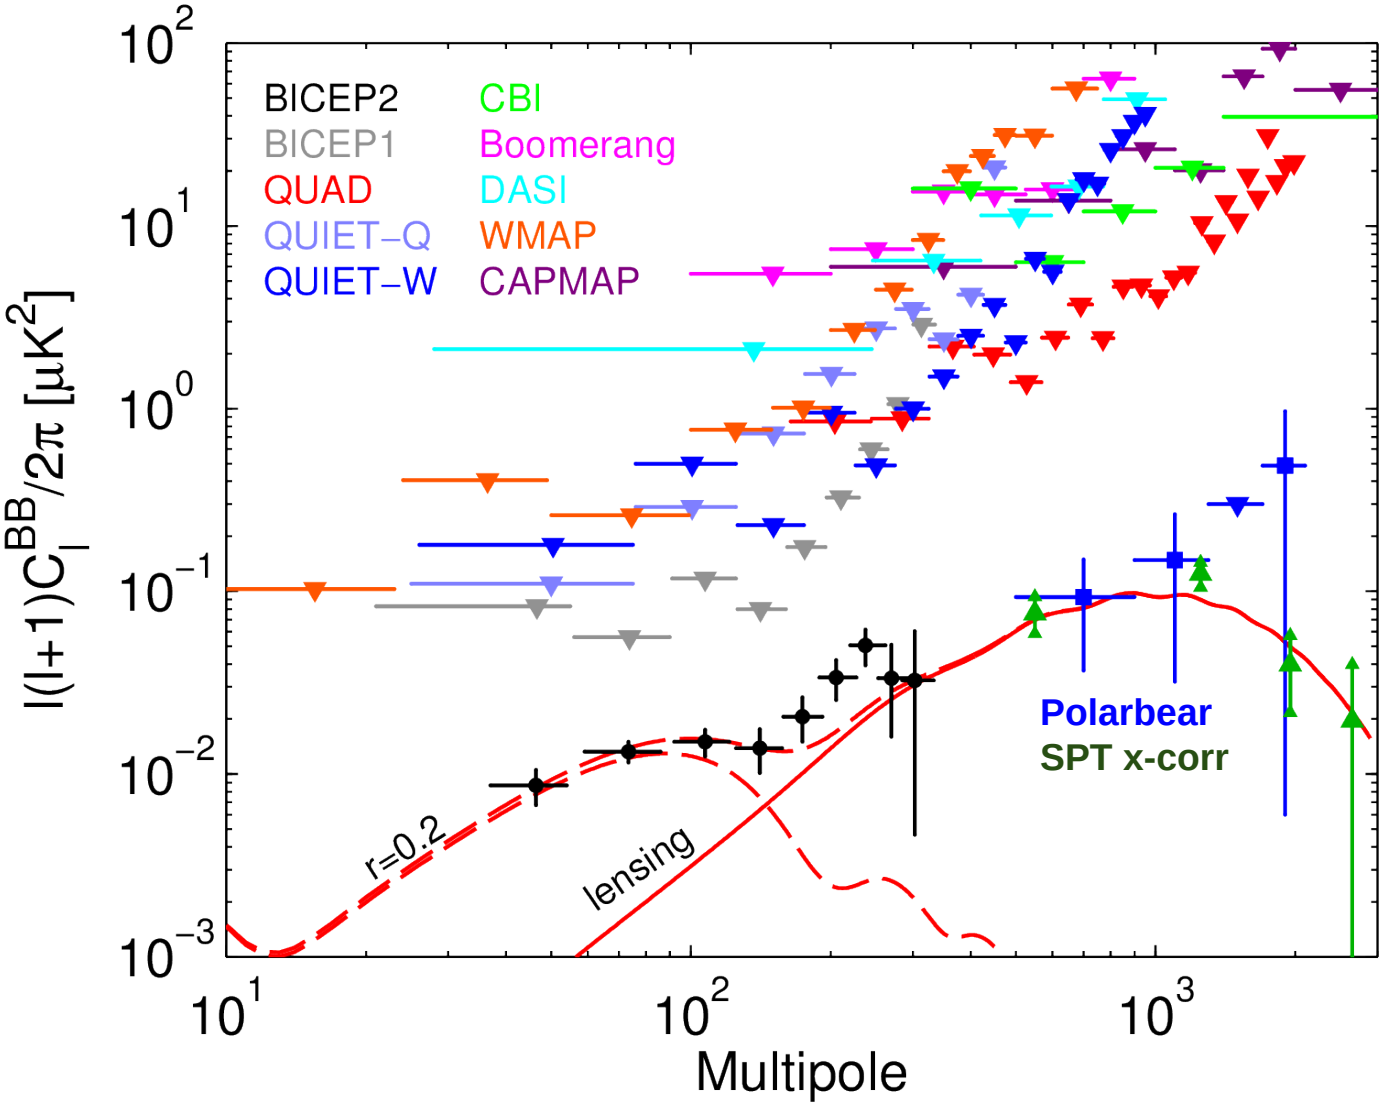
Planck+SPT+ACT+$WMAP_{pol}$: $r < 0.11$

r=0.2 makes a small change to the temperature spectrum.

(In this plot r=0.2 simply added to Planck best fit model with no re-optimization of other parameters)



BICEP2 and upper limits from other experiments:



Future

- We really want to confirm the signal (Keck-100, BICEP3, SPTpol, Planck, …)
- Increase the frequency and sky coverage
- Test the scale invariance of B-modes (n_T)
  - All sky survey
  - delensing with large aperture telescopes
- Test the Gaussianity of B-modes
- Search for the (tensor) reionization bump
- Can we fit tensor into TT spectrum ?

(Dated: February 18, 2014)

In this follow-up work to the High Energy Physics Community Summer Study 2013 (HEP CSS 2013, a.k.a. SNOWMASS), we explore the scientific capabilities of a future Stage-IV Cosmic Microwave Background polarization experiment (CMB-S4) under various assumptions on detector count, resolution, and sky coverage. We use the Fisher matrix technique to calculate the expected uncertainties in cosmological parameters in $\nu\Lambda$CDM that are especially relevant to the physics of fundamental interactions, including neutrino masses, effective number of relativistic species, dark-energy equation of state, dark-matter annihilation, and inflationary parameters. To further chart the landscape of future cosmology probes, we include forecasted results from the Baryon Acoustic Oscillation (BAO) signal as measured by DESI to constrain parameters that would benefit from low redshift information. We find the following best 1-σ constraints: $\sigma(M_\nu) = 15$ meV, $\sigma(N_{\rm eff}) = 0.0156$, Dark energy Figure of Merit $= 303$, $\sigma(p_{ann}) = 0.00588 \times 3 \times 10^{-26}$ cm^3/s/GeV, $\sigma(\Omega_K) = 0.00074$, $\sigma(n_s) = 0.00110$, $\sigma(\alpha_s) = 0.00145$, and $\sigma(r) = 0.00009$. We also detail the dependences of the parameter constraints on detector count, resolution, and sky coverage.

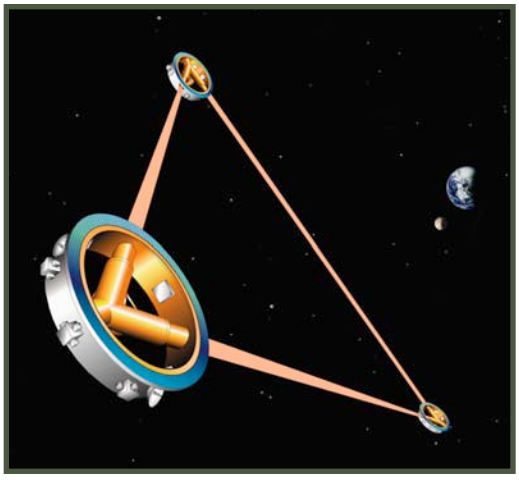
Executive Summary

The New Science of Gravitational Waves

Einstein's theory of spacetime and gravity, general relativity, predicts that motions of mass produce propagating vibrations that travel through spacetime at the speed of light. These gravitational waves (as the vibrations are called) are produced abundantly in the Universe and permeate all of space[1]. Measuring them will add an altogether new way to explore what is happening in the Universe: rather than studying the propagation and transformation of conventional particles and fields in spacetime, as all science has done up to now, we will sense vibrations of the fabric of spacetime itself. Studying this new form of energy will convey rich new information about the behavior, structure, and history of the physical universe, and about physics itself. When gravitational waves become observable they will provide a new and uniquely powerful probe of the extremes of spacetime, from the Big Bang to black holes, to address the deep questions that have emerged in Einstein's vision of the cosmos: what powered the Big Bang, what happens to space and time in black holes and what is the mysterious dark energy accelerating the expansion of the Universe?

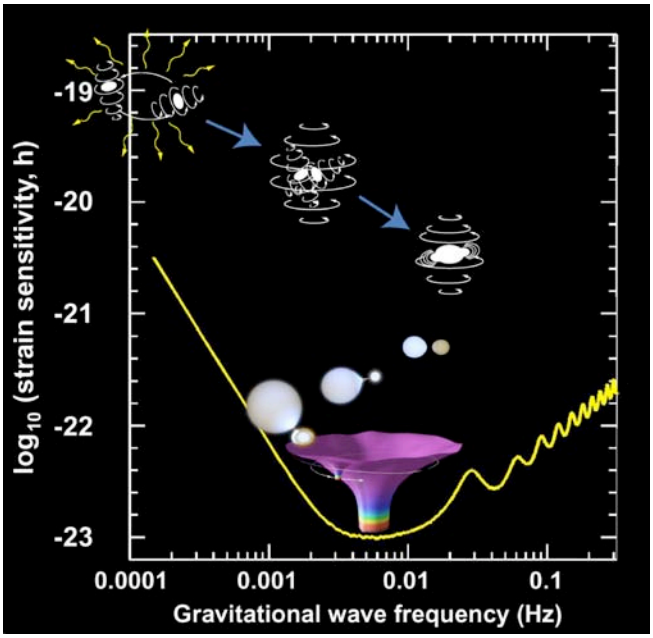
LISA is a space mission designed to measure gravitational radiation over a broad band at low frequencies, from about 0.03 to 100 millihertz, a band where the Universe is richly populated in strong sources of gravitational waves. It measures signals from a wide range of different sources: massive black holes merging in galaxies at all distances; massive black holes consuming smaller compact objects; known binary compact stars and stellar remnants; members of known populations of more distant binaries; and probably other sources, possibly including relics of the extremely early Big Bang, which are as yet unknown.



[1] Gravitational waves have never been directly detected. Nevertheless, the existence of gravitational waves is in little doubt as their effects have been measured precisely, if indirectly. Any theory of gravity consistent with special relativity will exhibit gravitational waves, and the predictions of general relativity should be quantitatively reliable for LISA because the long standing best evidence for of gravitational waves is the orbital decay of the Hulse-Taylor binary pulsar, which radiates at frequencies only marginally below LISA's operating band. Moreover, LISA is sensitive to any time-dependent tidal gravitational force, even to those of Newtonian theory produced by, say, the Sun. Therefore LISA will be able to detect the gravitational waves predicted by any reasonable theory of gravity.

These strong signals convey detailed information addressing a wide range of science: the history of galaxies and black holes in the Universe; general relativity itself and the behavior of spacetime; precision measurements of the Universe as a whole; the physics of dense matter and stellar remnants; and possibly new physics associated with events in the early Universe or relics predicted in string theory.

In the same way that electromagnetic radiation accompanies acceleration of electric charges, gravitational radiation accompanies quadrupolar acceleration of any kind of mass or energy. Quadrupolar motion in a system with mass M and size R at a distance D typically perturbs spacetime with a dimensionless metric-strain amplitude (fractional variation in proper spatial separations) of about $h \approx \left(GM/(Rc^2)\right)^2 (R/D)$. LISA senses this by monitoring the changes in the distances between inertial proof masses. LISA uses precision laser interferometry across a vast distance of space to compare separations among proof masses that are protected by the spacecraft from non-gravitational disturbances. Over a separation of $L \approx 5$ million kilometers, LISA's ability to measure variations of $\Delta L \approx 0.05$ picometers (rms over one year observation) corresponds to a strain amplitude sensitivity of about $h \approx \Delta L/L \approx 10^{-23}$. LISA *coherently* measures spacetime strain variations, including frequency, phase, and polarization, all of which reflect large-scale properties of the systems that produce them and are therefore direct traces of the motions of distant matter.



The LISA strain sensitivity curve showing approximate frequency range and strain amplitude of three categories of sources: massive black hole inspiral, ringdown, and merger (uppermost source); ultra-compact Galactic binaries (middle source); capture of stellar mass compact object by massive black holes (lower source).

LISA is an astronomical observatory of unprecedented versatility and range. Its all-sky field of view ensures that it misses nothing. Its coherent mode of observing allows it to resolve and distinguish overlapping signals and locate them on the sky. Its dynamic range of 10^5 or more in amplitude (10^{10} in energy) allows it to study sources within the Galaxy and out to the edge of the Universe. Finally, LISA's wide frequency band (more than three decades) allows it to study similar sources of widely different masses and cosmological redshifts. Because gravitational waves penetrate all regions of time and space with almost no attenuation, LISA can sense waves from the densest regions of matter, the earliest stages of the Big Bang, and the most extreme warpings of spacetime near black holes.

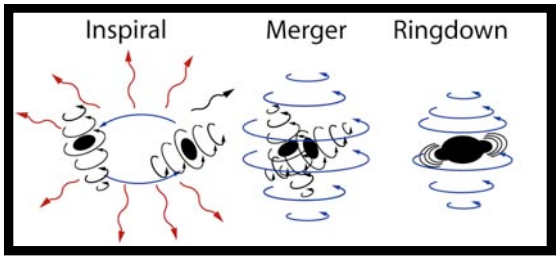
Survey of LISA Science

We now provide a brief survey of the key scientific measurements that LISA will perform. These measurements address the basic scientific goals of the LISA mission, which are captured formally in the LISA Science Objectives listed in the first appendix. The scientific background for the LISA science measurements and objectives is discussed extensively in the various sections of this document.

LISA records the inspirals and mergers of binary black holes, the most powerful transformations of energy in the Universe, allowing precision measurements of systems composed only of pure dynamical spacetime.

The strongest gravitational waves are generated by systems with the largest gravitational fields GM/R, hence large masses and small sizes. The strongest of all are generated by interactions of black holes, dense knots of pure spacetime energy with $GM/Rc^2 \approx 1$. At LISA frequencies the strongest sources are massive black hole binaries with about 10^4 to 10^7 times the mass of the sun. Two black holes orbit each other, spiral together as they lose energy by radiation, and finally merge. The waves from these events — many cycles over a long inspiral, climaxing in a brief series of powerful waves during a violent merger, and a final ringdown to a quiescent single black hole — record dynamical general relativity not only in its purest form but also in its most violent, nonlinear behavior: a maximally warped vacuum spacetime interacting with itself.

The black hole binaries start with wide orbits at low frequencies. As they lose energy their frequency increases and their radiation strengthens. A typical source enters the LISA band a year or more before the final merger so many orbits are recorded, encoding details of the system properties and behavior, position on the sky, and absolute distance. The coherent phase and polarization information obtained over LISA's solar-orbit baseline (and variable inclination) can often pinpoint where a source is in the sky to better than a degree. In the last hours or minutes the signal-to-noise ratio grows very high, often into the hundreds to thousands depending on distance. At its peak luminosity, around the moment of merger, a black hole binary is the most extreme transformation of mass-energy of any kind in the Universe, radiating a power $\approx 10^{-3}c^5/G$ (or ~10^{49} watts), in a few wave cycles, for a time of about 100 GM/c^3. This peak radiated power is about 1000 times more than all the stars in the visible Universe. The merger throes of a million solar mass binary black hole merger last about 500 seconds. Massive black hole binary inspiral and merger

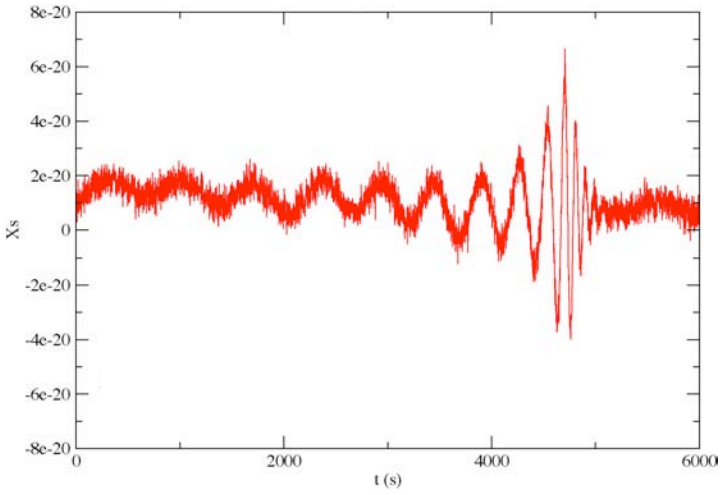


events are such powerful radiators that LISA can detect them anywhere, out to the largest redshifts where galaxies might exist.

The detailed study of waveforms from black hole binaries provides a rich testbed for general relativity. Recent breakthroughs now allow numerical computation of Einstein's field equations throughout the entire inspiral and merger event, yielding a detailed map of the predicted gravitational waveform that will be the first detailed test of dynamical, strong-field general relativity. Waveforms coherently correlated over many orbits (from ≈ 10 to ≈ 1000 depending on mass and redshift) recorded in the LISA signal stream, and detection of events with a signal to noise of a thousand or more, allow precise tests of the theory as well as precise measurements of system parameters to a precision of order 10^{-2} to 10^{-3}. Comparison with the computed details of the inspiral and merger waveform will provide a powerful test of the binary black hole model assumed for these systems.

LISA will map isolated black holes with high precision, verifying whether they are the stationary "no hair" spacetime configurations described by the Kerr metric, completely specified by four numbers: the mass and three components of spin.

In general relativity the final isolated spinning black hole is described mathematically as a particular, precisely specified spacetime shape called a Kerr metric, that depends only on the physics of gravity and not at all on the history or environment of the black hole. Comparison of the ringdown waveform with theory can verify that the final black hole which arises from a merger is indeed described by the Kerr solution, and satisfies the "no hair" theorem of general relativity that states that an isolated, stationary black hole is completely specified by its mass, charge and angular momentum. The LISA signals during the merger phase are so strong that the signal-to-noise ratio is often greater than 100 even in one oscillation cycle: signal waveforms are visible on an oscilloscope type display of raw data even to the naked eye, so even if general relativity were to be wrong at the levels allowed by our existing tests (*e.g.* the double binary pulsar J07037 -3039) we would be able to use LISA data to make sense of what is happening.



Gravitational wave signal for the final few orbits, plunge, merger and ringdown of a massive black hole binary. The signal is the sum of the gravitational waveform and simulated LISA noise. Note that the waveform stands up well above the noise and is visible in fine detail. A merger event such as that shown here can have a total signal to noise of 200 even at a redshift, z = 15.

A small compact object orbiting a spinning massive black hole.

LISA also uses a second type of source to explore the spacetime near a massive black hole. Driven by chance encounters, a much smaller mass compact objects — such as a degenerate dwarf, neutron star or stellar-mass black hole — sometimes finds itself captured by the massive black hole, after which it orbits many times until it finally plunges into the horizon and disappears. The gravitational waves from these extreme mass ratio inspirals (EMRIs) encode a detailed map of a relatively unperturbed massive black hole, predicted to be a pure Kerr knot of highly curved, spinning spacetime. About 10^5 wave cycles are measured for each source, emitted from orbital paths exploring deep into different parts of the relativistic region near the massive black hole. The specific mass quadrupole and higher moments predicted by the Kerr solution are measured with a precision of about 10^{-4}, and precision tests of small variations about the equilibrium Kerr solution — the small amounts of "hair" added by the perturbing object — are measured at the one percent level. Gravitational waves from these events map in exquisite detail the cleanest and most accurately predicted structures in all of astrophysics, whose mathematical elegance Chandrasekhar once likened to that of atoms.

LISA directly observes how massive black holes form, grow, and interact over the entire history of galaxy formation.

Optical, radio and x-ray astronomy have produced abundant evidence that nearly all galaxies have massive black holes in their central nuclei (and indeed that some recently merged galaxies even have two black holes). These nuclear black holes have a profound effect on galaxy formation; the influence of black hole powered jets on the intergalactic gas out of which galaxies form is in some cases directly observed. There is a circumstantial case, but no direct evidence, that the formation of this population of black holes was associated with a multistage process of binary inspiral and merger, together with accretion. LISA will obtain direct and conclusive evidence and study details of this process via gravitational radiation.

In standard concordance cosmology, the first massive black holes naturally arise from the very first, supermassive stars. In this scenario, black hole binaries begin to form from a high redshift, $z \approx 20$, when galaxies start to assemble by a series of (hundreds to thousands of) hierarchical mergers of smaller protogalaxies. When two galaxies merge into one, their central black holes sink to the center of the new galaxy, find each other, inspiral and merge. There are so many galaxies forming in the Universe observed by LISA that mergers happen quite frequently: estimates based on standard galaxy formation theory suggest that if black holes indeed grew by hierarchical merging, LISA detects a merger event about once or twice every week on average, from a wide range of redshifts extending back to massive binaries in early protogalaxies at $z \approx 15$. At any given time, in addition to the actual mergers, these models predict

that LISA observes inspiral signals from hundreds of binaries in the final years before their merger. LISA digs directly and intimately into the detailed evolution of galactic nuclei: the large sample of binaries provides a direct record of the whole history of galaxy formation in the observable Universe, and of the processes that grew their central black holes and shaped their nuclei.

In addition to mergers of massive black holes, LISA will also observe the inspiral of stellar mass black holes into the massive black holes in the centers of normal galaxies. These are the extreme mass ratio inspiral events (EMRIs) mentioned earlier. The parameters measured from extreme mass ratio events yield a census of isolated massive black hole spins and masses in many galaxies today, a revealing relic of black hole history. The local universe also produces observable inspirals of less compact stars and stellar remnants that probe the rich astrophysics near the massive central black holes as they consume piecemeal the various stellar populations in their vicinity.

LISA measures precise, gravitationally-calibrated absolute luminosity distances to high redshift, with the potential of contributing uniquely to measurement of the Hubble constant and dark energy.

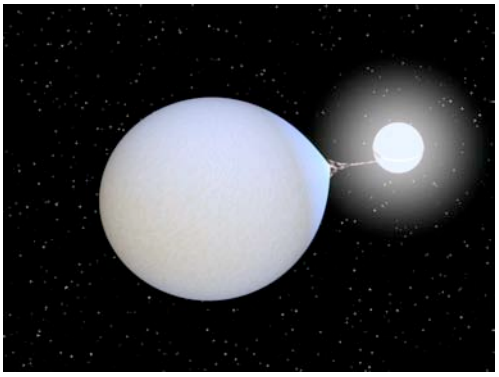
Because the inspiral leading up to the merger is a clean, pure vacuum spacetime system of two black holes, properties of the radiation can be computed exactly in general relativity, so that the black hole masses, spins, orientations and even the exact distance can be reconstructed from LISA data. (Roughly speaking, the final wave cycle period tells the final absolute Schwarzschild radius, and the ratio of that length to the distance is the metric strain, h.) These inspiral distances are both individually precise and absolutely calibrated, using only pure gravitational physics, and they cover a wide range of redshift. In the absence of lensing effects the absolute physical luminosity distance to a single LISA inspiral event is typically estimated from the waveform alone with on the order of one percent precision, and in some cases with as good as 0.1% precision. If identification of the host galaxy[2] allows an independent redshift determination, the redshift-distance relation is also measured with high precision. Black hole binaries thus represent a unique and independent new capability for precision cosmology that complements other techniques. Even a small number of sources at moderate redshift calibrates the distance scale and Hubble constant an order of magnitude better than any current method — a powerful constraint on dark energy models in combination with microwave background data. The expected large sample of high redshift inspiral events may lead to measurements of dark energy

[2] LISA's waveform fitting can often pinpoint the direction of a source to much better than a degree, and the distance estimate also narrows the redshift range considerably; nevertheless there may be many thousands of galaxies in the LISA "error box" for a given source. Models suggest that the host may be identified from a telltale nuclear starburst associated with the merger, or from variability associated with the disrupted disks around the merging holes, but galaxy nuclei are too little understood to make a firm prediction. Study of LISA electromagnetic counterparts may provide an exploratory bonanza for wide field synoptic imaging and spectroscopy across the electromagnetic spectrum, but it is also possible that identification of hosts will prove elusive.

parameters comparable in precision to other methods, but with independent calibration and completely different systematic errors. The main source of error, especially at high redshift, is the noise induced by cosmic weak gravitational lensing along the line of sight, but in a statistical sample this is controllable, and indeed provides unique new information about the nature and clustering of dark matter over time.

LISA studies in detail thousands of compact binary stars in the Galaxy, providing a new window into matter at the extreme endpoints of stellar evolution.

In addition to mergers and meals of distant black holes, LISA detects many lower mass binary systems in our galaxy, mostly very compact remnants of normal stars, called white dwarfs. Very soon after turning on, LISA will quickly detect a handful of nearby binary compact stars already studied and named. These "verification binaries" provide sources with known positions and periods ensuring particular, predictable LISA signals. Signals are also certain to appear from populations in our galaxy of numerous and various remnants, including white dwarfs and neutron stars, which are known to exist from some that emit electromagnetically. Simple extrapolation of known nearby samples to the whole Galaxy predicts that LISA will detect thousands of binaries. The most compact binaries (those at high frequency) will be measured in detail as individual sources from across the Galaxy, while at lower frequencies only the nearby ones will be individually distinguished; millions of others from across the Galaxy will blend together into a confusion background. LISA provides distances and detailed orbital and mass parameters for hundreds of the most compact binaries, a rich trove of information for detailed mapping and reconstruction of the history of stars in our galaxy, and a source of information about tidal and other non-gravitational influences on orbits associated with the internal physics of the compact remnants themselves. LISA may also detect at high frequencies the background signal from compact binaries in all the other galaxies.



LISA may find entirely new phenomena of nature not detected using light or other particles.

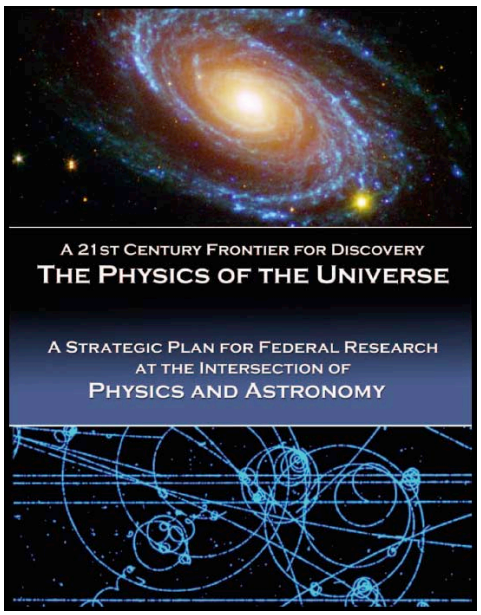
Given that all forms of mass and energy couple to gravity, other sources of gravitational waves may exist that are not known from extrapolating current electromagnetic observations. LISA's frequency band can indeed be extrapolated to very high redshift where we do not yet have any direct observations, and to a regime where LISA itself will be our first information of any kind about the nonlinear behavior and motion of matter. For example, the LISA frequency band in the relativistic early Universe corresponds to horizon scales at the Terascale frontier, where phase transitions of new forces of nature or extra dimensions of space may have caused catastrophic, explosive bubble growth and efficient gravitational wave production. LISA is capable of detecting a stochastic background from such events from about 100 GeV to about

1000 TeV, if gravitational waves in the LISA band were produced with an overall efficiency more than about 10^{-7}, a typical estimate from a moderately strong relativistic first-order phase transition. This corresponds to times about 3×10^{-18} to 3×10^{-10} seconds after the start of the Big Bang, a period not directly accessible with any other technique. Reaching much further still beyond the range of any particle accelerator, LISA also deeply probes possible new forms of energy such as cosmic superstrings, relics of the early Universe predicted in some versions of string theory, that are invisible in all ways except by the gravitational waves they emit. In principle, their signature could provide direct evidence for new ideas unifying all forms of mass and energy, and possibly even spacetime itself.

LISA and the Key Questions of Astronomy and Physics

LISA addresses forcefully and directly a broad cross-section of the research priorities and key questions raised by recent astronomy and physics decadal, community, agency and White House reports. These include National Research Council reports such as *Astronomy and Astrophysics in the New Millenium* and *Connecting Quarks with the Cosmos*, as well as the National Science and Technology Council report *A 21st Century Frontier of Discovery: The Physics of the Universe*.

LISA approaches many deep questions set forth in these documents in a new and unique way not possible with any other space- or ground-based observatory. Indeed, LISA has the potential to transform much of physics and astronomy: it senses the remote Universe in an entirely new way, and explores many new kinds of phenomena that can be explored in no other way. Its discoveries are likely to expand the scope of both astronomy and physics significantly and to reshape the science questions of the future. By directly sensing the dynamical activity of spacetime, LISA feels the beating heart of Einstein's cosmos. The new science of gravitational waves provides the most direct way to advance the goals of NASA's Beyond Einstein program.



1. Gravitational Waves: An Overview

Most everything we know about the Universe we have learned from *light*: since ancient times, electromagnetic waves have been messengers from the cosmos to our eyes, and later to our telescopes and our antennas. More recently, we have begun to parse the messages of more exotic carriers: like the elusive neutrinos from the Sun and beyond. We are now ready to add an altogether new modality to science: sensing vibrations of the very fabric of spacetime. *Gravitational waves* will add a many-voiced soundtrack to the rich imagery of the cosmos (see Hogan 2006).

In Einstein's 1915 theory of general relativity, the geometry of spacetime is not a passive setting for the dynamics of matter and energy, but an equally dynamic player. Matter and energy cause spacetime curvature, which in its turn guides the free fall of matter and energy. Remarkably, spacetime can support curvature without any matter: *black holes*, the densest masses in the Universe, are objects of pure spacetime wrapped around itself; *gravitational waves* are self-sustaining, undulatory excitations of spacetime, carrying energy and traveling at the speed of light. Unlike electromagnetic radiation (but much like neutrinos) gravitational waves interact very weakly with matter, and can penetrate anything without losing intensity. This makes them powerful probes of faraway regions and extreme conditions, but it also makes them very hard to detect. Only recently has technology advanced to the point of

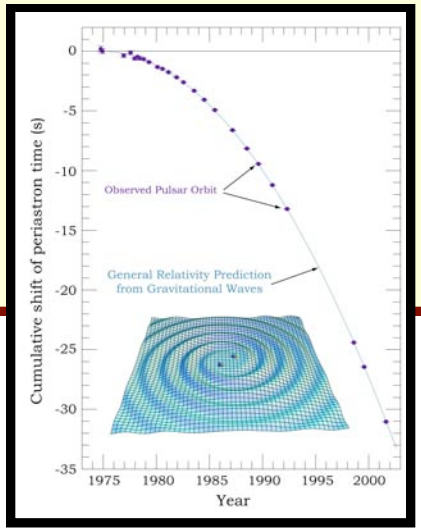
In 1967, the first radio pulsar was discovered by Jocelyn Bell and Anthony Hewish (for which Hewish received the Nobel Prize in 1974). Pulsars were quickly identified as neutron stars, the incredibly compressed remnants of the supernova explosions of stars.

In 1974, Russel Hulse and Joseph Taylor discovered the first binary pulsar, PSR 1913+16. This system consists of two neutron stars (of which only one emits as a pulsar) with an orbital period of eight hours. The general theory of relativity predicts that the orbiting stars stir spacetime around them, losing energy by emitting gravitational waves and therefore spiraling closer together.

In 1993, Taylor and Hulse received the Nobel prize for showing that the orbital period of PSR 1913+16 is decreasing at exactly the rate predicted by Einstein's "quadrupole formula" for the emission of gravitational waves in binaries.

In 2004 an international team of astronomers announced the discovery of PSR J0737-3039A/B, a *double* binary pulsar of two neutron stars, both of which emit detectable radiation. This system is a unique general-relativistic laboratory: timing studies of its emissions over 2.5 years have already improved on some of the most stringent tests on general relativity from other binary pulsars and from Solar-system dynamics (Kramer *et al.* 2006).

The gravitational waves from neutron binary stars await direct detection by LISA and by ground-based detectors.



Precession of periastron in PSR 1913+16 as measured in 27 years of radio data and as predicted by general relativity.

building apparatus sensitive enough to measure the minute effects of gravitational waves on matter.

Gravitational waves will reveal the most violent events in the Universe, the collision and coalescence of two black holes. In the final minutes before the merger, the power radiated in gravitational waves reaches 10^{49} W, a thousand times more luminous than all the stars in all the galaxies in the visible Universe put together. These mergers will allow us to test how well Einstein's equations work in such extreme conditions, offering us insight into the strongest and most violently dynamical spacetimes Nature has produced since the Big Bang.

Gravitational waves produce tiny oscillations in the distance between *freely-floating* masses isolated from all forces other than gravity; these oscillations can be monitored using laser interferometry. This principle is implemented in the ground-based Laser Interferometer Gravity-wave Observatory (LIGO), funded by NSF. LIGO and similar observatories worldwide will likely make the first detection of gravitational waves at relatively high frequencies, between 1 and 1000 Hz. The *Beyond Einstein* Great Observatory LISA will be sensitive in a broad band at much lower frequencies, between 10^{-4} and 0.1 Hz. It will detect entirely different sources, in great numbers, and with exquisite precision.

With LISA we will observe the coalescence of the supermassive black holes at the centers of merging galaxies; the radiation from thousands of individual ultra-compact binaries in our galaxy; the infall of small black holes, neutrons stars, and white dwarfs into the supermassive black holes at galactic centers. These sources will provide rich astrophysical information about the evolution of galaxies and stars, and they will serve as unique laboratories for precision measurements that may lead to new insights into fundamental physics and cosmology. In addition to these well-known astrophysical sources, LISA will search for gravitational waves from the very early Universe, as well as Big Bang remnants such as cosmic superstrings.

What are Gravitational Waves?

Electromagnetic (EM) waves are self-sustaining oscillations of the electric and magnetic fields, propagating through spacetime. By contrast, gravitational waves (GWs) are oscillations of spacetime itself (see Thorne 1987 and Flanagan & Hughes 2005 for reviews). Einstein predicted GWs shortly after developing his theory of general relativity (GR), but the first experimental verification of their existence had to wait over 60 years, until the binary pulsar observations by Hulse and Taylor starting in 1974 (see sidebar).

According to GR, GWs propagate at the speed of light, acting *tidally* by stretching and squeezing any extended distribution of matter or energy through which they pass. This warping action is transverse to the direction of wave propagation. GWs contain two dynamical degrees of freedom, which can be identified in the "+" (plus) and " $\times$" (cross) polarizations, corresponding to the axes associated with the stretching and squeezing. For instance, as depicted in Figure 1-1, a pure "+" polarization squeezes along the x axis and stretches along the y axis, and then vice-versa one half-cycle later.

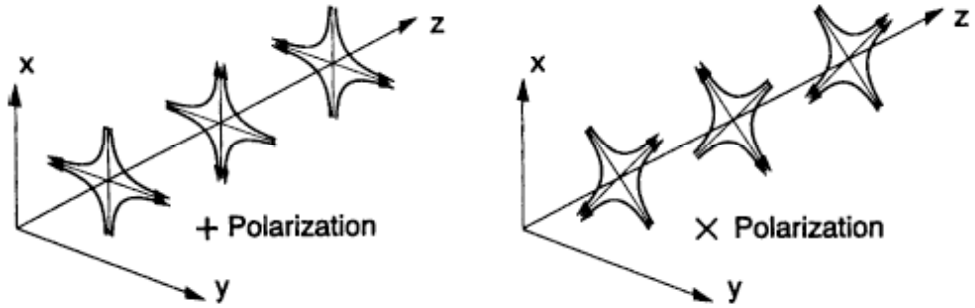


Figure 1-1: The effect of linearly polarized gravitational waves is to alternately stretch and squeeze the intervening matter and energy in perpendicular directions, as visualized here by the motions of a set of freely-floating *test* particles (*i.e.*, bodies small enough that their own gravitational field is negligible).

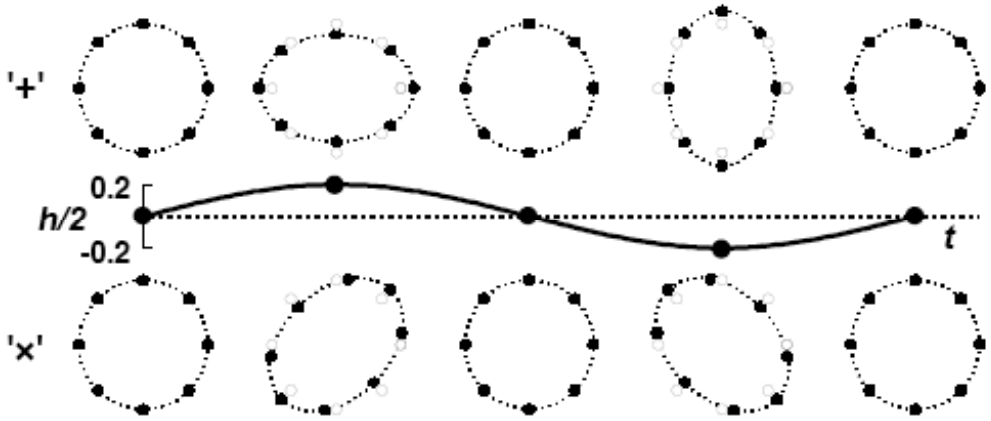

Just as EM waves are generated by accelerated charges, GWs are generated by accelerated masses. Because of charge conservation, an oscillating charge dipole is the lowest-order time-dependent distribution that can produce EM waves; because of mass and momentum (*i.e.*, mass dipole) conservation, a variable mass *quadrupole* is needed to produce GWs. (Technically it is the second time derivative of the transverse-traceless part of the quadrupole moment that generates GWs.)

EM waves arise from the interactions of atoms, nuclei, or other particles within astrophysical sources. EM waves are typically generated in numerous individual emitting volumes, much smaller than the astrophysical object of interest, so the wavelength of radiation is also much smaller than the object. For this reason, EM waves permit us to image the object if it is close enough or big enough. But the short wavelength has a disadvantage: we typically receive an incoherent superposition of radiation from many independent regions in the source, and if the source is not close enough to resolve then it is often a difficult and uncertain job to model the emission process well enough to go from the information we get about many different wavelength-scale regions up to the much larger scale of the entire astrophysical system.

By contrast, GWs are generated by the bulk mass distribution of the objects, so the wavelength of GW radiation is typically comparable to or larger than the size of the entire emitting region. (For instance, for two black holes orbiting each other and losing energy by gravitational radiation, the wavelength of the GW radiation is 10 or 20 times the radius of the orbit.) Thus, GW observations do not generally allow imaging, and the extraction of information from waveforms proceeds with audio-like methods such as time–frequency analysis. Because GW radiation is emitted coherently from the entirety of the astrophysical object, it provides *direct* information about the object's large-scale structure. Moreover, GW observations allow us to extract information from the *phase* of the wave as well as its amplitude or intensity. The phase evolution often carries more information about the detailed dynamics of the emitter than the amplitude does.

An astronomical observatory for GWs has very different characteristics from observatories of EM radiation. It will help to understand the range and versatility of LISA's observations as described in this document if we make some of these differences explicit.

First, LISA has a large intrinsic dynamic range: it could in principle measure accurately signals over an amplitude range of 10^5 or an energy range of 10^{10}. This is because it measures tiny changes in separations between the proof masses and therefore always operates in a linear regime. LISA is designed to study sources well below its mean noise level (extracted by matched filtering) up to the strongest expected sources in the Universe.

Second, LISA has a very large frequency range, spanning four decades, limited by its size and by the difficulty of isolating the proof masses at low frequencies. This means that, unlike optical, ultraviolet, or infrared observatories, LISA is less likely to miss distant sources because they are cosmologically redshifted to lower frequencies: it will be able to study homogeneously populations of objects out to the highest redshifts.

Third, LISA has all-sky acceptance of signals; it sweeps three different quadrupolar antenna patterns across the sky as it orbits the Sun, so that its sensitivity for all but the shortest transient sources is fairly isotropic. Unlike any imaging EM observatory, LISA is not pointed, so it does not miss any signals if they are above its noise level. This is particularly important because it allows LISA to detect strong transient events like black hole coalescences without having to point at the source; the strongest events in the Universe are necessarily transient, because they radiate far too much energy to be sustained in a steady state. Although LISA is an all-sky detector, it can nevertheless reconstruct event positions through its data analysis, by using phase modulation (Doppler effects) and amplitude modulation, which are available to it because it makes coherent observations. LISA can also separate thousands of simultaneously superimposed signals because it uses phase information to resolve them, so its all-sky acceptance does not lead to confusion except where there are really huge numbers of sources.

Finally, because GWs interact very weakly with matter, LISA is not troubled by absorption, scattering, or obscuration in any of its observations. The best illustration of this is in its search for a cosmological background of radiation from inflation: it can in principle see right back to the end of the inflationary epoch, through all stages of decoupling, symmetry breaking, and particle creation. GWs will give us our deepest views of the interiors of very dense environments, our

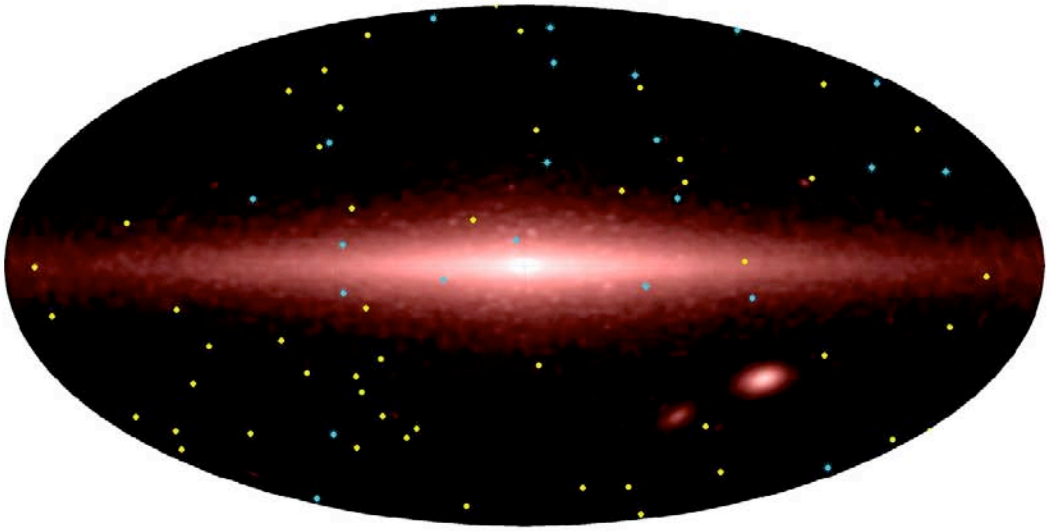

Figure 1-2: Simulation of the gravitational wave sky in the LISA band. The plane of the Galaxy is clearly visible as a horizontal band of emission from the population of compact white dwarf binaries. Also visible are the Magellanic clouds. Massive black hole mergers and capture of compact objects by massive black holes, which are temporary events, are indicated by yellow

only direct information about black holes, leading to their unequivocal identification and our first possibility to observe any possible structures in the electrically uncharged dark matter in the Universe.

We also note that the GW observable is the amplitude of the wave (or *wave strain*) h, the fractional amount of the stretching and squeezing discussed above. The amplitude h falls off only as $1/r$. A consequence is that strong sources of GWs (such as the binary inspirals of massive black holes, which LISA will see with amplitude signal-to-noise ratios ~ 1000 at a redshift $z = 1$), can essentially be detected out to arbitrarily large redshifts.

The distinctive characteristics of GWs ensure that they will provide a unique new channel to study the Universe, complementing information gathered over decades from EM channels, and probing previously inaccessible dense and dark regions of the Universe. The potential for discovery and surprise is great.

The Gravitational-Wave Universe in the LISA band

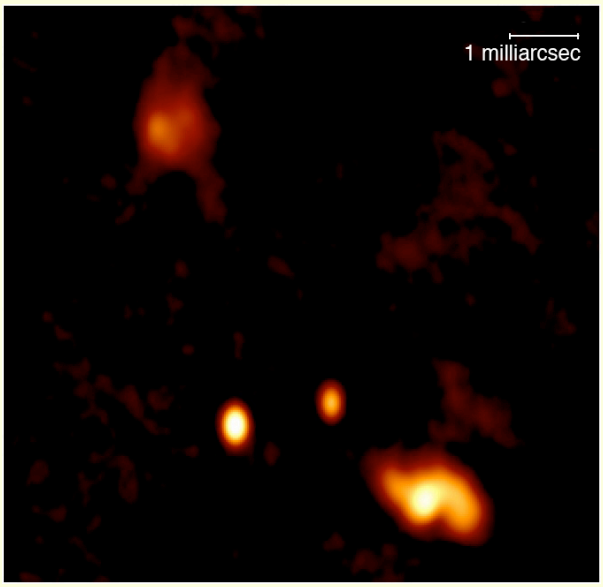
Although GWs have not been detected yet, we know enough about the contents of the Universe to make reasonably accurate guesses about some of the GW sources that LISA will observe (see Hughes 2003 & 2006 for reviews). As discussed earlier, in the same way that accelerated electric charges generate EM radiation, accelerated mass and energy of any kind generate gravitational radiation. The periodic motion of a system of mass M and size R creates GWs at a distance D with a strain amplitude of about $h \approx \left(GM/(Rc^2)\right)^2 (R/D)$, with frequency determined by the frequency of the motion. The shapes and strengths of the observed waves give us details about the structure and behavior of the system that produced them.

The strongest waves are generated by the systems with the largest gravitational fields GM/R, which correspond to large masses and small sizes. The strongest of all are generated by the interactions of black holes, which have $GM/Rc^2 \approx 1$. The lightest black holes (remnants of single stars, with about ten times the mass of the Sun) emit at the highest frequencies, in the 100-Hz band accessible to ground-based detectors.

By contrast, the strongest sources in the far lower LISA band (between 0.1 to 100 mHz) are the *super*massive black holes (SMBHs)

A supermassive black hole binary with parsec-scale orbital separation

Massive black hole binaries with parsec-scale orbital separation are expected to be quite common in the Universe. Since however the corresponding angular separations are very small, it is hard to image the binary components separately, and until recently the only known massive black-hole binaries had kiloparsec-scale separation. Recently, radio imaging with the Very Long Baseline Array has revealed a supermassive black-hole binary (0402+379) with an angular separation of just 7 milliarcseconds, corresponding to a projected spatial separation of 7.3 parsecs (Rodriguez *et al.* 2006). The binary sits in an elliptical galaxy, and its total mass is estimated to be about 10^8 Solar masses. The radio map of this amazing system is shown in the figure and consists of two compact cores associated with the two supermassive black holes, as well as two extended radio lobes. The radio lobes are estimated to be only about 1000 years old, indicating very recent activity associated with one of the two black holes. While this particular system is not necessarily expected to coalesce in a Hubble time because of its large mass, it demonstrates the existence of binary black holes resembling the progenitors of the coalescing systems that will be observed by LISA. There are so many galaxies in the observable volume that mergers are estimated to occur about once or twice a week, and signals from multiple binaries will be observed at any given time.



15 GHz VLBA image of 0402+379 (courtesy of Greg Taylor)

at the centers of galaxies; these are the remnants of the process of galaxy formation, with about 10^4 to 10^7 times the mass of the Sun. Optical, radio, and X-ray astronomy have produced abundant evidence that nearly all galaxies have massive black holes in their central nucleus, and that some of them even have two (see sidebar).

Mergers of SMBHs happen frequently: galaxies are continually forming, in a hierarchical fashion, from the mergers of smaller galaxies, and whenever two galaxies merge their central black holes sink to the center and find each other. SMBH mergers are so powerful that LISA can see them out to a wide range of redshifts, extending back to the first protogalaxies at $z \approx 15$. Estimates from standard galaxy formation theory suggest that LISA will detect SMBH mergers about once or twice every week (Volonteri 2006), but predictions are very uncertain at the high-redshift end, which sits beyond the reach of EM observations. LISA will lift the veil of these cosmic "dark ages", providing a direct record of the history of galaxy formation and central black hole growth in the observable Universe.

Smaller galactic objects can also be captured (and eventually consumed) by the central black hole. Compact objects such as degenerate dwarfs, neutron stars, and black holes will sometimes be driven by chance encounters into a close orbit around the massive black hole: a dance of death that they will repeat many times until they finally plunge into the black hole event horizon. The GWs from these extreme–mass-ratio inspirals (EMRIs) encode a detailed map of spacetime geometry around the SMBH. The history and environment of the black hole leave no imprint on this geometry, which is a very pure and beautiful solution (the *Kerr metric*) of the equations of general relativity. Thus, EMRI signals will test Einstein's theory by probing the most accurately predicted structures in all of astrophysics, whose mathematical elegance Chandrasekhar once likened to that of atoms.

In addition to black holes, many other known systems in our Universe can produce GWs in LISA's frequency band. Soon after it is turned on, LISA will quickly detect a handful of nearby binary stars, which have known periods and positions (and even assigned names), and which will appear in the LISA data with predictable, distinctive signatures.

A numerous Galactic population of *undiscovered* degenerate-dwarf binaries will be observed all across the LISA band; we know that such objects exists from EM observations in our vicinity, but LISA will detect thousands of individual binaries throughout the Galaxy. At low frequencies millions binaries more from across the Galaxy will blend together into a confusion background in the LISA data which will nevertheless teach us about the statistics of their population. At higher frequencies, the binaries have more powerful signals, and are farther apart in frequency space, allowing LISA to characterize each individually. At high frequencies, LISA may also detect the background signal from the degenerate binaries in other distant galaxies, allowing us to place constraints on cosmic star formation rates.

Given that all forms of matter and energy couple to gravity, it seems likely that the Universe will treat LISA to yet other GW sources that we cannot anticipate on the basis of our EM observations. This is especially true for observations at very high redshifts, where LISA may give us the very first clues to the unknown conditions of matter and energy in the very early Universe.

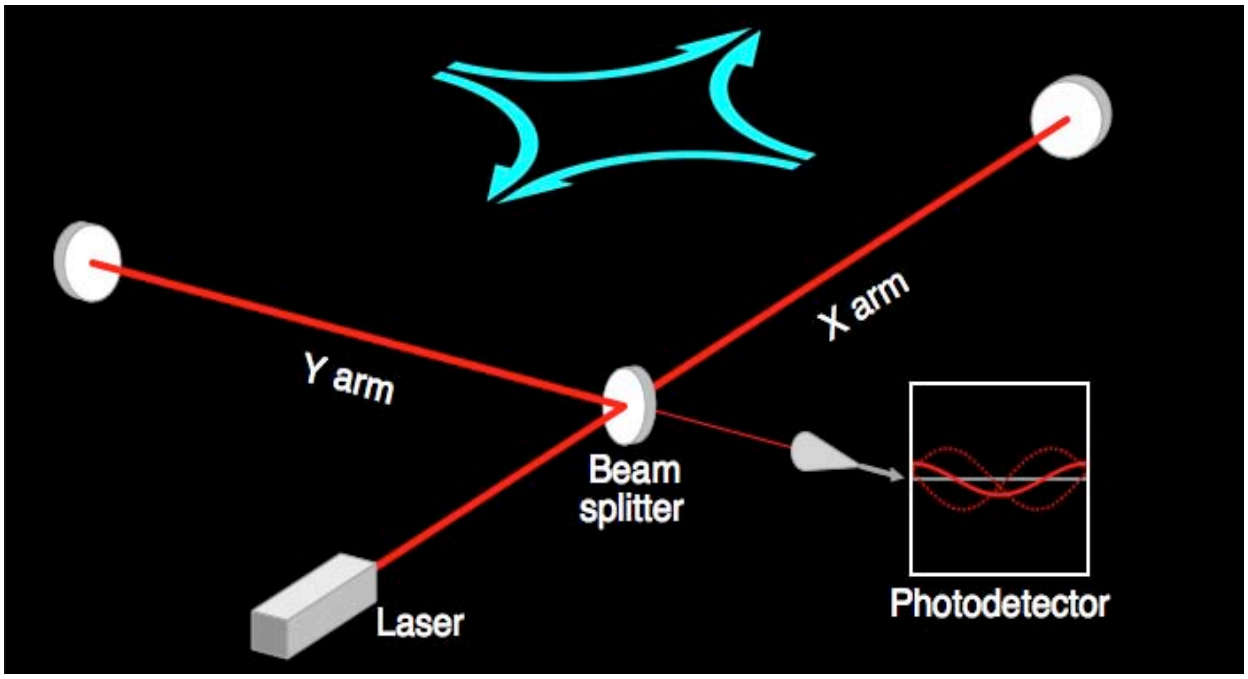


Figure 1-3: Idealized Michelson interferometer with laser, beam splitter, end mirrors, and photodetector at the exit port. the blue arrows represent a perpendicularly propagating polarized gravitational wave.

In the relativistic early Universe, the LISA frequency band corresponds to the *Terascale frontier*, where the phase transitions of exotic fields or extra spatial dimensions may have caused catastrophic and explosive bubble growth, with efficient GW production. LISA will also probe *superstrings*, relics of the early Universe predicted in some versions of string theory. These exotic structures, which are completely invisible except for the GWs they emit, could produce strong, distinctive LISA signatures; they could provide direct evidence that all forms of matter and energy, and possibly even spacetime itself, are ultimately made of quantum strings.

How are Gravitational Waves Detected?

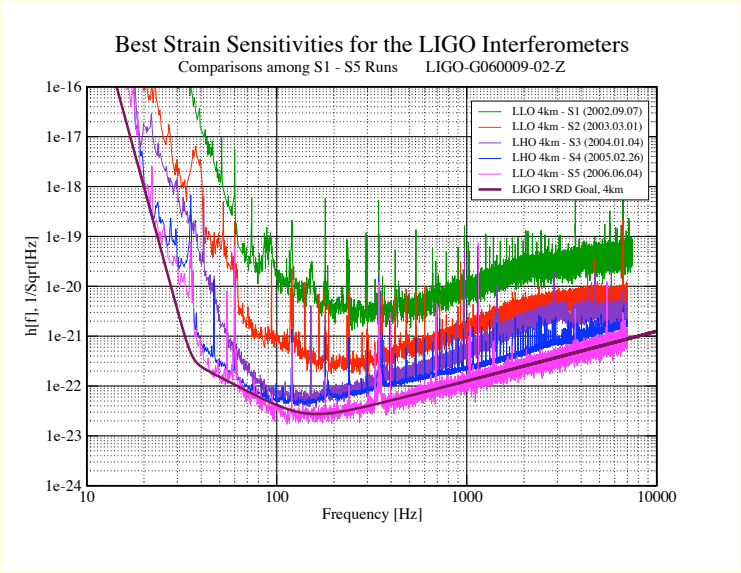
Einstein's great epiphany was that gravity is the manifestation of the curvature of spacetime, the background for all the interactions of matter and energy. Freely-falling *test* bodies (small compared to spacetime curvature and undisturbed by other forces) thread spacetime along *geodesics*, the straightest paths possible through this curved arena. Nearby, approximately parallel geodesics are pushed together and pulled apart by spacetime curvature. Indeed, GWs are waves of spacetime curvature, experienced by test bodies as an oscillating change in their relative distance.

To understand how this principle is used to detect GWs, it is useful to visualize an idealized Michelson laser interferometer (see Figure 1-3) whose components are floating freely in space, at

LIGO reaches its design sensitivity

The absolute accuracies required by GW observations may at first seem unachievable. The LIGO design sensitivity (black line) implies measurements of the change in distance between interferometer mirrors that are accurate to better than one part in 10^{22} in the relevant frequency band. Yet, as shown in this figure by the progression of experimental noise curves for the LIGO Hanford 4 km interferometer (colored lines), the dedication and ingenuity of countless scientists and engineers has made these measurements possible.

Because of LISA's much longer arm length, the metrology accuracy required locally at each spacecraft is much less exacting than the LIGO requirement, by a factor of about one half million .



rest with each other, and far removed from any gravitating bodies. The power measured by a photodetector at the exit port of the interferometer is a simple function of the phase difference of the two light beams that are divided at the beamsplitter, propagated across the two arms, and recombined at the exit port. Incoming GWs (consider for simplicity a plane GW, propagating perpendicularly to the plane of the interferometer, with "+" polarization aligned with the two arms) alternately increase the distance experienced by light traveling along one arm and decrease the distance along the other, creating oscillations in the power measured at the exit port.

The currently operating ground-based GW detectors such as LIGO (Abramovici *et al.* 1992) implement much more sophisticated versions of this setup (for instance, in LIGO light is made to bounce several times along cavities in each arm, enhancing the phase-accumulation effect). The free fall of interferometer components is approximated, along the "sensitive" axes, by suspending them from pendulums that are carefully isolated from the environment.

The sensitivity and frequency range of ground-based interferometers is set by their size (with armlength ranging from a few hundred meters to 4 km for LIGO), and by various noise sources, including photon shot noise in the phase-difference measurement, and thermal noise in the suspensions and optical components. To detect an amplitude of $h \approx 10^{-22}$ LIGO must measure displacements of the order of 10^{-19} m, an extremely challenging target. At frequencies below 10 Hz, seismic noise from terrestrial sources is especially challenging to the mechanical isolation systems. Below about 1 Hz, another terrestrial noise begins to be larger than expected astronomical signals: gravity-gradient noise from time-dependent changes in the local Newtonian gravitational field. No GW detector can be isolated from these tidal gravitational fields, so that detection in the LISA frequency band requires a detector far from the Earth.

LISA brings the Michelson measurement concept to the grander scale and much quieter environment of space. While ground-based detectors are naturally limited by the Earth's curvature to km armlengths, LISA can be more than a million times larger. Longer arms magnify the effect of GWs, so LISA can achieve 10^{-22} strain accuracy by measuring displacements of the order of fractions of a picometer, a million times larger than those LIGO has to cope with. When this is combined with the absence of seismic and gravity-gradient noise, LISA can achieve remarkable sensitivity to the lower-frequency GWs emitted by larger, more massive systems. Thus, while advanced ground-based detectors may observe neutron stars or stellar-mass black holes coalescing out to distances of hundreds of megaparsecs, LISA will be sensitive to supermassive black hole coalescences out to redshifts greater than 10, allowing it to plumb the earliest stages of galaxy formation.

While LISA can be thought of as a "Michelson interferometer in space", its actual implementation is quite different from a conventional Michelson interferometer. The experimental approach is closer to that of spacecraft Doppler tracking, in which the observed quantity is the frequency change in the signal from a distant spacecraft. In LISA, each spacecraft sends a beam of laser light to each of the other two distant spacecraft and in turn receives a beam from each of the two spacecraft. The received laser light is coherently combined at a photodetector with the light from an onboard reference laser and the frequency difference is recorded as a beat signal. The beat signals recorded at each of the three spacecraft are delayed in time and recombined in a technique called "Time Delay Interferometry" (Tinto 2005), which essentially creates three virtual Michelson interferometers whose output signals represent the basic LISA science data stream.

2. LISA Mission Overview

The LISA mission uses three identical spacecraft whose positions mark the vertices of an equilateral triangle five million km on a side, in orbit around the Sun. LISA can be thought of as a giant Michelson interferometer in space, with a third arm that provides independent information on the two gravitational wave (GW) polarizations as well as redundancy. The spacecraft separation — the interferometer arm length — sets the range of GW frequencies LISA can observe (from about 0.1 mHz to above 0.1 Hz). This range was chosen to reveal some of the most interesting sources – mergers of supermassive black holes, ultra-compact binaries, and the inspirals of stellar-mass black holes into supermassive black holes. The center of the LISA triangle traces an orbit in the ecliptic plane, 1 AU from the Sun and 20° behind Earth, and the plane of the triangle is inclined at 60° to the ecliptic (see Figures 2-1 and 2-2). The natural free-fall orbits of the three spacecraft around the Sun maintain this triangular formation throughout the year, with the triangle appearing to rotate about its center once per year.

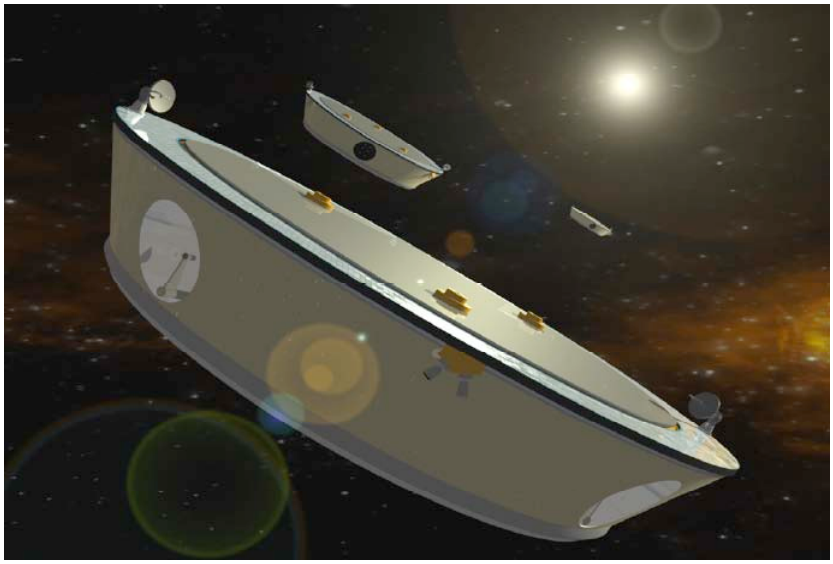


Figure 2-1: The LISA constellation of three spacecraft separated from one another by five million km (0.03 AU), with the Sun visible in the distance at 1 AU.

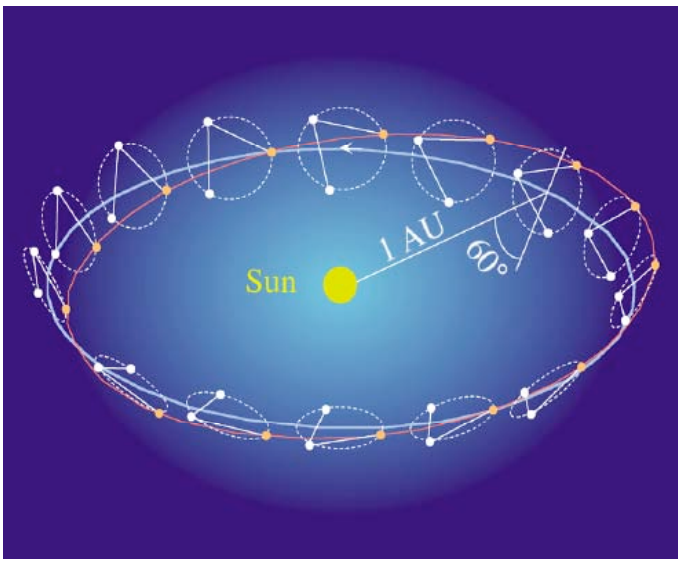

Figure 2-2: The LISA constellation's heliocentric 1-AU–radius orbit, with the plane of the triangle inclined at 60° to the ecliptic. The triangle appears to rotate once around its center in the course of a year's revolution around the Sun.

Rather than a physical Michelson interferometer, the actual implementation used for LISA resembles the technique known as spacecraft Doppler tracking, but realized with infrared laser light instead of radio waves. The laser light going out from one spacecraft to the other corners is not reflected back directly,

because diffraction losses over such long distances would be too great. Instead, in analogy with an RF-transponder scheme, the laser on the distant spacecraft is phase-locked to the incoming light and transmitted back at full intensity. When the transponded laser light arrives back at the original spacecraft, it is superposed with a portion of the original laser beam, which serves as the local oscillator in a standard heterodyne detection scheme. This relative phase measurement gives information about the length of that interferometer arm, modulo an integer number of wavelengths of the laser light. The difference between the phase measurements for the two arms gives information about the relative changes in the two arms — the gravitational-wave signal.

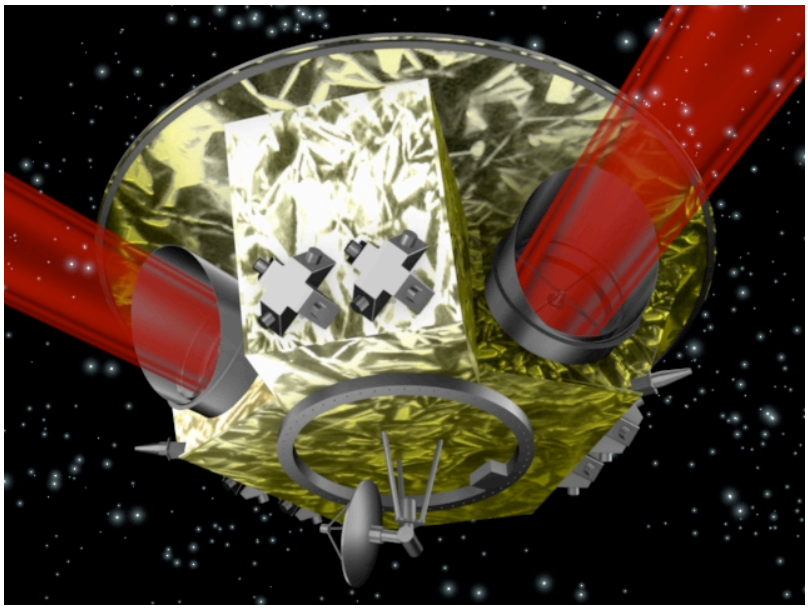

Figure 2-3: View of the exterior of one LISA spacecraft, showing the two telescope assemblies, two of the six thruster packages, and the telemetry antenna.

A two-arm interferometer can be prone to phase errors due to laser frequency fluctuations. If the arms were exactly equal in length, then laser frequency fluctuations would cancel perfectly in the arm length difference measurement. Unfortunately, annual variations in the LISA spacecraft orbits prevent perfect cancellation of laser noise. To minimize the measurement error from laser phase noise the lasers are frequency stabilized — first to an optical cavity, and then to the 5-million-km interferometer arm (Sheard *et al.* 2003, Herz 2005). Any residual laser frequency noise in the LISA measurements will be removed by post-processing on the ground using a technique called Time Delay Interferometry (TDI; Tinto *et al*. 2003, Tinto & Dhurandar 2005).

Each spacecraft contains a pair of optical assemblies oriented at roughly 60° to each other (see Figure 2-3). Each assembly is pointing toward a similar one on the corresponding distant spacecraft, to form a (non-orthogonal) Michelson interferometer. Through a 40-cm aperture telescope on each assembly, a laser beam from a 1.064-μm Nd:YAG master laser and 1-W Yb fiber amplifier is transmitted to the corresponding remote spacecraft. The same telescope is used to collect the very weak incoming beam (around 100 pW) from the distant spacecraft and direct it to a sensitive photodetector, where it is combined with a local-oscillator beam derived from the original local laser light. At the heart of each assembly is a vacuum enclosure containing a free-flying polished platinum-gold cube, 4 cm in size — the "proof mass" that serves as an inertial reference for the local optical assembly (see Figure 2-4). A passing gravitational wave will produce a relative strain in this large "optical truss," causing an increase in the optical path

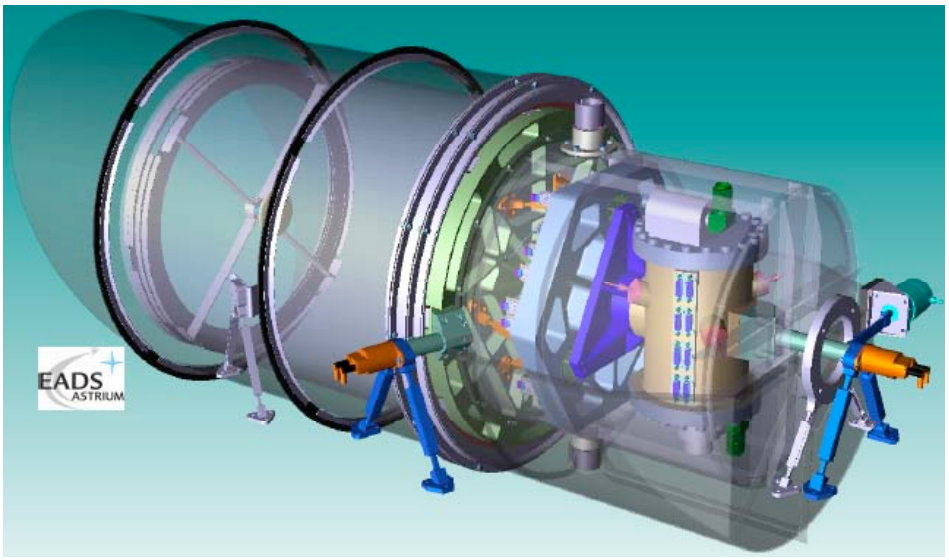

Figure 2-4: Optical assembly containing (from left to right) the telescope assembly, the optical bench, and the proof mass vacuum enclosure.

length between the proof masses forming one arm while causing a decrease for the other arm. These length changes are measured interferometrically with sub-Angstrom precision. In this way, LISA will be sensitive enough to detect gravitational-wave induced strains of amplitude $h = \Delta l / l \sim 10^{-23}$ in one year of observation, with a signal-to-noise ratio of 5.

The spacecraft surrounding each pair of optical assemblies serves primarily to shield the proof masses from the adverse effects of solar radiation pressure fluctuations; the spacecraft positions do not enter directly into the measurements. Nevertheless, in order to minimize disturbances to the proof masses from fluctuating forces in their vicinities, each spacecraft must be kept moderately centered around the proof masses (to about 10 nm/$\sqrt{\text{Hz}}$ in the measurement band). This is achieved by a “drag-free" control system based on small electric thrusters and displacement sensors. Specifically, both capacitive and optical sensors are used to measure the displacements and rotations of the proof masses relative to the spacecraft. These offset signals are then fed back to control micro-Newton thrusters, which force the spacecraft to follow its proof masses. The thrusters are also used to control the attitude of the spacecraft relative to the incoming optical wavefronts, using signals derived from quadrant photodiodes. Capacitive actuation is used to adjust the positions or orientations of the proof masses when needed.

Each of the three LISA spacecraft has a launch mass allocation of about 480 kg (including margin) including the payload, propulsion module, and the spacecraft adapter. The propulsion modules use a chemical propulsion system to transfer each spacecraft from the Earth orbit to the final position in interplanetary orbit. All three spacecraft can be launched together by a single Atlas V (531). Each spacecraft carries a small, steerable antenna used for transmitting the science and engineering data, in the Ka-band to the NASA Deep Space Network. The nominal mission lifetime is five years. Additional information about the LISA mission can be found in Hammesfahr (2001) and Cramer *et al.* (2003).

LISA Capabilities

Sensitivity

The sensitivity of LISA is shown in Figure 2-5 together with a comparable sensitivity curve for the future ground-based Advanced LIGO. Sensitivity over a logarithmic frequency interval is shown here in terms of the dimensionless strain $\sqrt{f}\sqrt{S_{\rm h}(f)}$ (where $\sqrt{S_{\rm h}(f)}$ is the 1-σ level of strain noise spectral amplitude), in order to facilitate comparison with the much higher measurement frequencies of LIGO. The LISA sensitivity curve divides into three regions: a low-frequency region where proof-mass acceleration noise dominates, a mid-frequency region where shot noise and optical-path measurement errors dominate, and a high-frequency region where the sensitivity curve rises as the wavelength of the GW becomes shorter than the LISA arm length. Additionally, a diffuse background of unresolved galactic binaries is expected to contribute to the measured strain level in the frequency range from 0.1 - 1 mHz; this component is indicated in Figure 2-5.

Figure 2-5 illustrates also the different astrophysical sources that LISA will study, contrasted with those studied by ground-based interferometers such as LIGO. In general, a ground-based

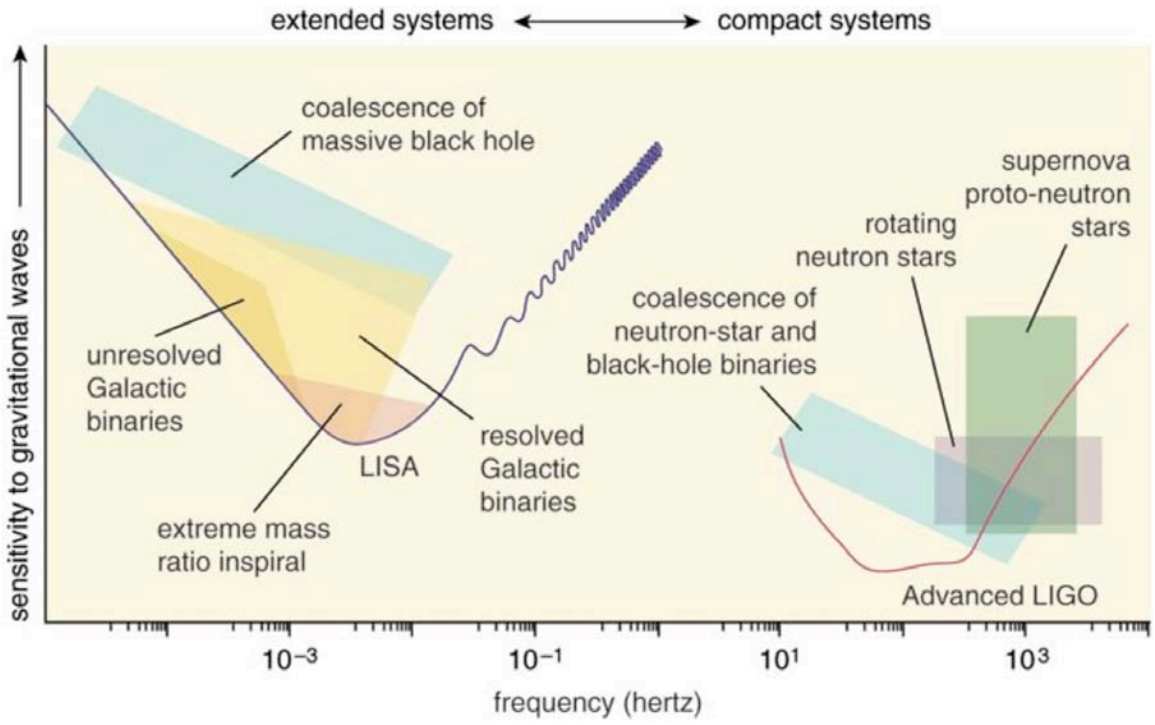

Figure 2-5: Strain sensitivities predicted for LISA and Advanced LIGO. The curve is plotted in units of ($\sqrt{fS_{\rm h}(f)}$), where $S_{\rm h}(f)$ is the LISA noise power spectrum with $\sqrt{S_h(f)}$ representing the 1-σ noise level. The units of ($\sqrt{fS_{\rm h}(f)}$) are the natural units for plotting sensitivity per logarithmic frequency interval.

interferometer is limited to frequencies above about 10 Hz because of seismic noise, corresponding to wavelengths less than about 30,000 km. The sources it studies will therefore generally be very compact sources, *e.g.*, with orbital separations comparable to the wavelength. Such sources include neutron-star binaries and stellar-mass black hole binaries just before merger. In contrast, LISA will see most of its sources in the frequency range below about 10 mHz, corresponding to wavelengths greater than about 30 million km. This is the characteristic size of systems involving massive black holes, as well as compact white-dwarf binaries.

Sky Position Determination

LISA can determine a source's position in the sky using techniques that are similar to those used in the radio frequency domain, namely AM and FM modulation. For higher frequencies, above about 1 mHz, LISA will use a technique similar to the localization of pulsars *via* pulsar timing, *i.e.*, observing the phase or Doppler shifts of the GW signal as a function of the position of LISA in its orbit about the Sun. At low frequencies the wavelengths are too long to do positioning using frequency modulation. Consequently, the position is determined from the modulation of the amplitude of the GW signal as the LISA constellation changes aspect in its orbit about the Sun. Both of these methods can provide sub-degree location accuracy for strong GW sources.

Distance Determination

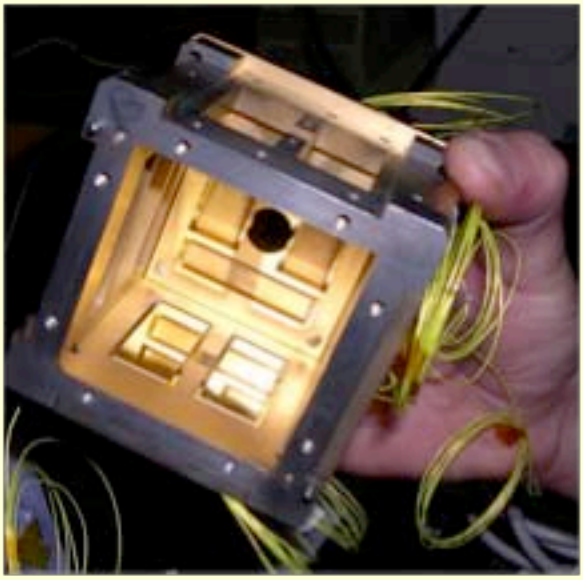
A unique feature of gravitational wave measurements of astrophysical systems is the capability of determining precise distances for many GW sources. A coalescing binary has a characteristic frequency of emission which is twice the orbital frequency and which increases in time due to the loss of energy to GW emission. The rate of increase of the frequency, *df/dt*, depends on the so-called "chirp mass", $M_{\rm chirp} = (1+z)(M_1 M_2)^{3/5}(M_1+M_2)^{1/5}$, where z is the redshift and M_1 and M_2 are the masses of the two members of the binary. The amplitude of the GW signal at the detector depends both on the chirp mass and on the distance. By determining the chirp mass from the rate of increase of the frequency the signal amplitude can then be used to determine the distance. LISA will typically be able to measure the distance to a coalescing massive black hole binary to a few-percent accuracy. In contrast, the redshift z is not independently determined from GW observations. Dimensionful system parameters such as mass and spin enter the system's dynamical evolution as timescales. For distant sources, these timescales acquire a redshift factor $(1 + z)$; as a consequence, the inferred system parameters likewise acquire factors of $(1 + z)$. Redshift is always degenerate with a measured system's intrinsic parameters; it must be determined by associating a merging system with a host galaxy. We thus have the situation that for electromagnetic (EM) observations distance determination is typically difficult, but redshift determination reasonable straightforward, while the opposite is true for GW observations. The excellent distance determination capability of LISA is extremely

LISA Pathfinder: Flight Test of Key LISA Technologies

The European Space Agency is preparing a flight validation of the LISA drag-free and interferometry systems on the LISA Pathfinder (LPF) mission, planned for 2011. LPF will provide validation and risk reduction for key LISA technologies by carrying two drag-free proof masses and an interferometer to measure their relative displacements using heterodyne techniques as planned for LISA. Essentially, LPF shrinks one LISA arm down to fit inside a single spacecraft; it thereby loses its sensitivity to gravitational waves but tests the LISA sensitivity to relative proof-mass displacements.

The picometer displacement sensitivity required of LISA's interferometer is not particularly challenging: it is about one-million times more relaxed than LIGO currently achieves on the ground, and it is only a thousand times more stringent than Albert Michelson achieved in his original interferometer 125 years ago. LPF will demonstrate that this can be achieved in space, but the primary reason for launching LPF is to validate the drag-free system. LPF will demonstrate a proof-mass assembly that can survive launch vibration and still provide the required degree of isolation from external disturbances in space. LPF will also carry two independent microthruster hardware and control systems, one supplied by ESA and the other by NASA. It will provide an opportunity to compare the stability, reliability, and precision of these key components of the drag-free system.

The LPF design, incorporating any lessons learned from the mission, will form the basis of the LISA drag-free and interferometry systems. ESA plans to give LISA the final go-ahead for Phase C/D once the results of LPF have been evaluated.



The LISA pathfinder engineering model of the drag-free sensor housing, showing the capacitive sensors.

important for determining the number density of BH mergers versus epoch, for possible H_0 and dark energy measurements, and for determining the distribution of ultra-compact binaries in the Galaxy.

Science Operations

LISA will deliver a rich and diverse scientific data set providing numerous opportunities for guest investigations associated with LISA observations. Opportunities will include: complementary EM observations during flight and pre- and post-flight, development of analysis techniques for LISA data, analysis of the LISA data for detection and characterization of sources of gravitational waves, and use of LISA generated source lists, waveforms, catalogues for physics and astrophysics research investigations and theoretical investigations. These are discussed further in a later section.

The starting point for most science analysis of LISA data will be the construction of three science data channels, the so-called "Time-Delay Interferometry (TDI) variables". A full discussion of the TDI data is beyond the scope of this

document and further information can be found in Tinto & Dhurandar (2005). Basically, the three TDI data channels can be thought of as containing the information about the "+" and "×" gravitational wave polarizations, as well as a third channel of information, the "Symmetrized Sagnac" channel, which is relatively insensitive to gravitational waves and can be used as a monitor of LISA instrumental noise, very important for LISA measurements of the diffuse GW background.

LISA data are expected to contain the signals from many sources simultaneously. Well-developed techniques exist to detect and characterize multiple sources. Thus, in addition to the calibrated TDI channels, a data product will be produced that will be a "model" for the LISA data providing at any time the best estimate for the source content of the LISA data, including waveform estimates, effectively providing three source-subtracted LISA data channels for use by researchers interested in searching for new sources.

In addition to the actual scientific data channels, LISA will provide "alerts" of specific events, in particular predictions of merger times and locations of massive black hole binaries as well as catalogues and ephemerides for detected sources: extra-galactic black hole binaries, ultra-compact galactic binaries, inspiral of stellar-mass compact objects into massive black holes in external galaxies, *etc*. These data products will provide a wealth of opportunities for follow-up ground- and space-based astronomical facilities as well as opportunities for theoretical research.

Status of LISA Data Analysis

There is already a robust community effort in development and demonstration of LISA data analysis including publication of over 250 papers. LISA has an active program of data simulation and "mock data challenges" to refine the understanding of the science capabilities of LISA (Arnaud *et al.* 2006). Techniques have been developed for detection and parameter estimation for all classes of LISA sources: massive binary black hole coalescence, galactic white-dwarf binaries, extreme mass ratio inspirals, and stochastic background. These techniques have a rich heritage, not only from ground-based gravitational wave detectors, but also from related analysis fields such as sonar, radar, seismology, radio astronomy, and voice recognition. Activity is underway to perform detailed simulations and demonstrations for the various sources and analysis techniques.

LISA mission quick facts

LISA Pathfinder: The joint ESA-NASA LISA Pathfinder/ST-7 mission will demonstrate the core technologies needed for both LISA's interferometers and for the 'drag-free' spacecraft control that protects LISA's proof masses from disturbance.

LISA: The Laser Interferometer Space Antenna is a joint mission of NASA and ESA. Specifications below are per the baseline of design of 2006 but are subject to change.

Launch and cruise: A single Atlas-V rocket lifts all three spacecraft, each with its own propulsion module. They reach their final solar orbits after a 13-month cruise.

Orbits: Each drag-free spacecraft is in an independent heliocentric orbit, trailing Earth by about 20 degrees.

Station-keeping: There is no station-keeping. The orbits are chosen to keep the spacecraft at the corners of a nearly equilateral triangle throughout the mission life.

Inter-spacecraft separation: About 5 million kilometers (0.03 Earth-Sun distance, or 17 light-seconds).

Spacecraft:
Size: 2.7-m diameter, 0.7-m thick
Mass: 575 kg
Orientation: 60 degrees to the Sun, constant.
Power: 820W per spacecraft, from solar cells.
Attitude and drag-free control: six micro-Newton thrusters, 4 to 30 μN each
Telemetry: X-band, DSN, under 10 kbps

Payload (per spacecraft):
Lasers (two): 1-W diode-pumped 1064-nm Nd:YAG lasers, frequency-stabilized to an onboard reference cavity and also to the inter-spacecraft arms.

Proof masses (two): 2-kg Au-Pt cubical proof masses. Electrostatic actuation perpendicular to the measurement axes. Charge control by UV illumination.

Telescopes (two): 40-cm diameter, f/12, used both to transmit and receive.

Measurement and error budget:

Measurement: Optical heterodyne: The received laser beam (about 10^{-10} W) is mixed with about 1mW of local laser light on a quadrant photodiode. Measurements from all three pairs of spacecraft are combined using time-delay interferometry to synthesis two independent Michelson interferometers and a third independent Sagnac interferometer.

Optical-path errors: Caused by detector shot noise, pointing jitter etc., total not to exceed 2 x 10^{-11} m/√(Hz) over the LISA bandwidth.

Acceleration errors: Caused by unmeasured residual forces on proof masses. Total not to exceed 3 x 10^{-15} $(m/s^2)/\sqrt{(Hz)}$ from 0.1 to 1 mHz. Divide by $(2\pi f)^2$ for resulting displacement error.

Strain sensitivity: Primary sensitivity to gravitational waves of frequency 0.03 mHz – 0.1 Hz.

Source localization in space: Below 1 mHz or lifetime < months: degrees
Above 10 mHz, lifetime > months: arcminutes

3. Black Hole Astrophysics: Supermassive Black Holes in Galactic Nuclei

There is now abundant evidence that nearly all galaxies have massive black holes in their central nuclei. These nuclear black holes can have profound effects on galaxy formation, releasing huge amounts of energy into the galaxy *via* accretion-powered jets. The formation of this population of massive black holes is thought to be associated with a multistage process of binary inspiral and merger, together with accretion. LISA will detect the merger events directly, thus tracing the growth and merger history of massive black holes and their host galaxies. LISA will search for a population of seed black holes at early epochs and use precise measurements of black-hole spins to help determine the relative importance of black-hole growth mechanisms. LISA will also probe the rich astrophysics in the nuclei of normal galaxies by observing the inspiral of compact objects into the massive black holes in their centers.

Key science questions

- When did the massive black holes in galactic nuclei form, and how did they grow?
- What fraction of proto-galaxies contained massive black holes in their cores, as a function of redshift?
- What are the mass and spin distributions of the supermassive black holes in galactic nuclei?
- What is the role of black hole mergers in early hierarchical structure assembly?
- What are dynamics of stars near massive black holes in galactic nuclei?

Evidence for supermassive black holes in galactic nuclei

Supermassive black holes accreting gas in galactic nuclei were first proposed in the 1960s (Salpeter 1964; Zel'dovich & Novikov 1964) to explain the enormous luminosities of the newly discovered quasars. Refinements of this idea have become the generally accepted explanation for the electromagnetic and kinetic emissions from all active galactic nuclei (AGN; see, *e.g.*, Krolik 1999).

The disks of gas around accreting black holes (mass $M_\bullet$) in active galaxies are inferred to have luminosities approaching the Eddington limit (at which radiation pressure on the Thomson cross section σ_T of electrons balances the gravitational attraction on them and the protons from which they were stripped):

$$L_{\rm Edd} = 4GcM_\bullet m_p/\sigma_T = 10^{46}\ {\rm erg\ s^{-1}}(M_\bullet/10^8 M_\odot)\ .$$

Thus, the black holes in AGN, producing radiation from accreted rest-mass with efficiency $\varepsilon \equiv 0.1\varepsilon_{0.1}$ must be increasing in mass by accretion with an e-folding time known as the Salpeter time,

$$t_S = \varepsilon M_\bullet c^2/L_{\rm Edd} = 4\times 10^7 \varepsilon_{0.1}\ {\rm yr}\ .$$

Since t_s is about one percent of the age of the Universe at redshift $z = 1$, at most about one percent of black holes can be radiating at near the Eddington limit; the rest must be quiescent. This crude estimate is consistent with observations: the deepest images from the Hubble Space Telescope (HST) show nearly 10^6 galaxies per square degree. Only about one percent have the variable nuclei characteristic of AGN (Cohen *et al.* 2006). In its longest exposures, the Chandra X-ray observatory also detects about 10^4 active galactic nuclei in each square degree of sky (Brandt & Hasinger 2005). We might expect, then, that the deep Universe is populated by billions of invisible black holes, representing 99% of the total population. Gravitational wave observatories such as LISA can reveal these hidden objects.

As Lynden-Bell pointed out, another consequence of the ~ 1% "duty cycle" is that a large fraction of local galaxies must have been quasars in their youth, and must today harbor relic black holes in their nuclei (Lynden-Bell 1969). A 1% duty cycle could mean that 1% of galaxies host a black hole that is active for most of its life or, at the other extreme, that most galaxies host black holes that are active only 1% of the time. The latter interpretation has recently been confirmed spectacularly by the discovery that in the centers of almost all bright nearby galaxies (including our own Milky Way) the velocities of stars and gas begin to rise in the Keplerian fashion expected if there were a central point mass dominating the central potential (Ferrarese & Ford 2005; see Figure 3-1).

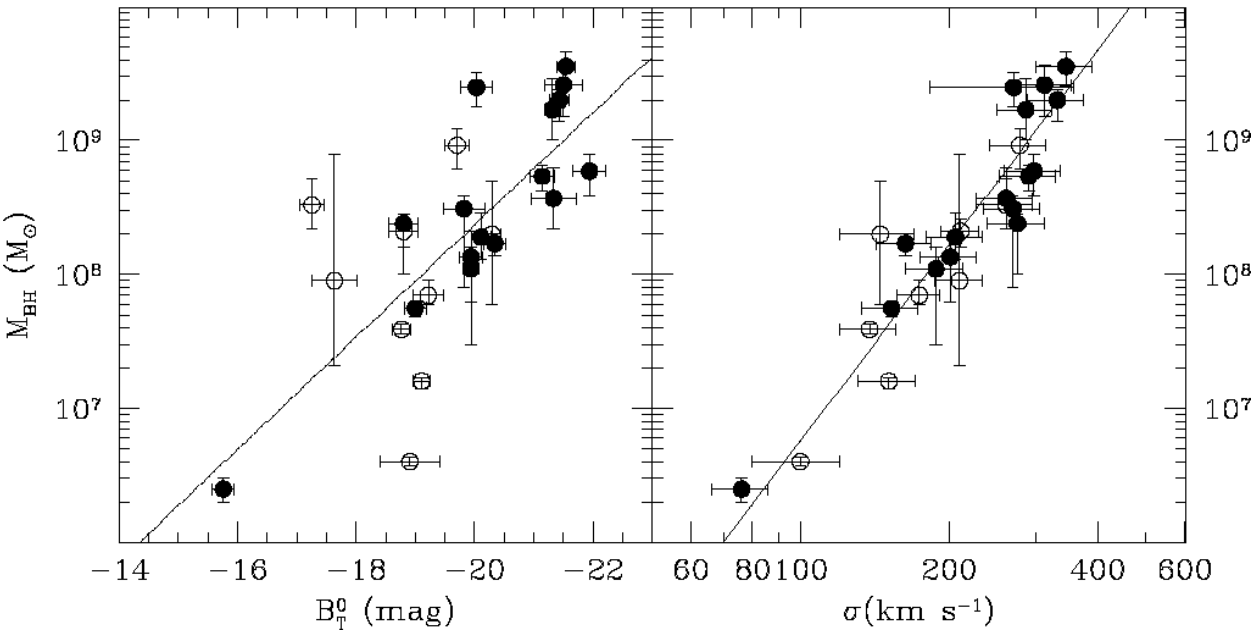


Figure 3-1: The correlation between black hole mass *M*• and the luminosity of the host galaxy's stellar bulge (left) and between *M*• and the host galaxy's bulge velocity dispersion σ (right) for all detections in galaxies near enough that current instruments resolve the region in which the black hole dominates the dynamics. Filled symbols show elliptical galaxies; open symbols show spiral and lenticular galaxies (from Ferrarese & Ford 2005; see also Gebhardt *et al.* 2000).

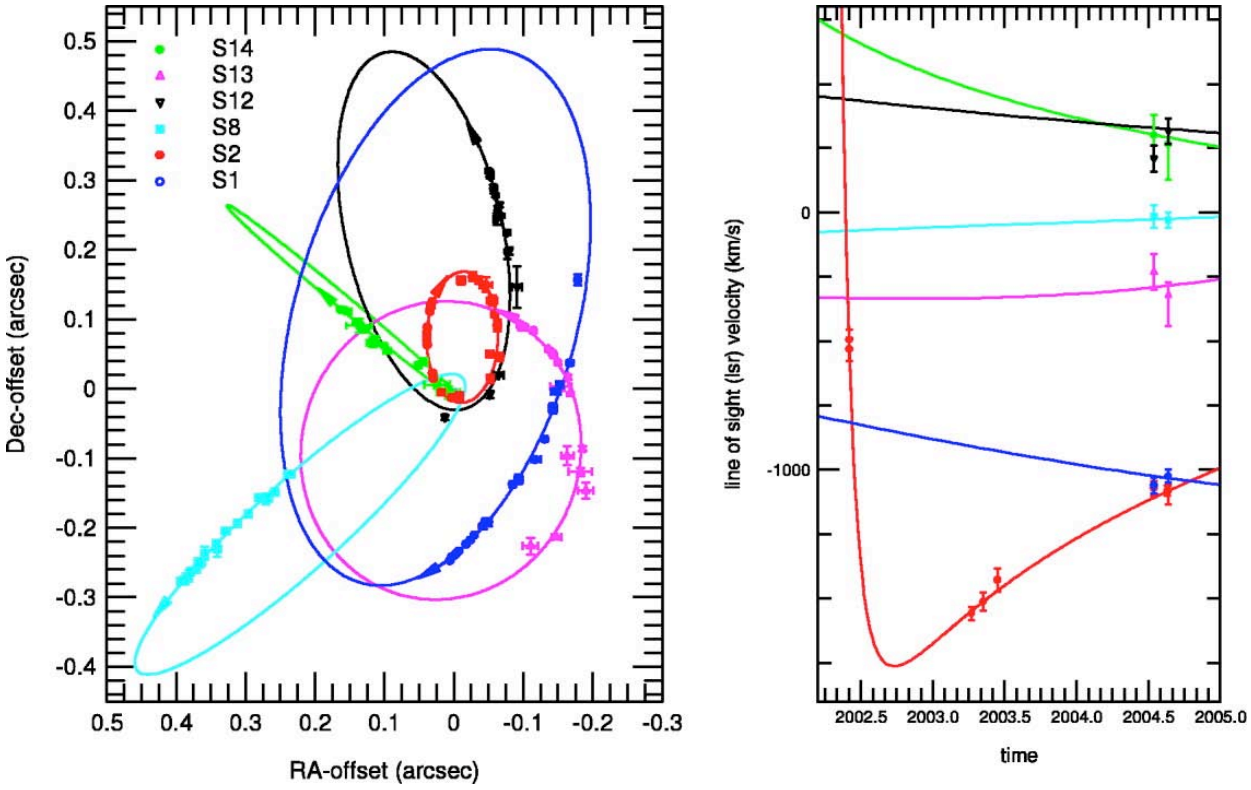

Figure 3-2: The orbits on the sky, and radial velocity measurements of six stars close to the central point mass in the Milky Way. At their peribothrons, stars S2 and S14 pass within 5×10^{-4} pc = 100 AU = 1300 Schwarzschild radii of the central black hole, of mass $4 \times 10^6 M_\odot$ (from Eisenhauer *et al.* 2005).

Hubble Space Telescope press releases consistently call these central masses black holes, and we follow that practice here. But one of the most important questions LISA will address is whether these masses are actually the Kerr black holes of Einstein's relativity. In almost all cases, current measurements cannot probe regions closer than $\sim 10^5$ times the Schwarzschild radius of the inferred black hole, so other astrophysical models (*e.g.*, dense clusters of stellar-mass black holes) are not conclusively ruled out. But in the notable case of our own Milky Way, one can measure the orbits of stars passing as close as 1300 Schwarzschild radii from the $4 \times 10^6 M_\odot$ central mass (Ghez *et al.* 2005; Eisenhauer *et al.* 2005), and one can rule out even contrived astrophysical alternatives to black holes (Maoz 1998),

Massive or Supermassive?

The terms "massive black hole" and "supermassive black hole" often are used almost interchangeably to refer to the massive objects in the centers of galaxies. In this document we generally will use the following definitions:

Supermassive Black Hole (SMBH): $10^7 M_\odot < M_{BH}$

Massive Black Hole (MBH): $10^4 M_\odot < M_{BH} < 10^7 M_\odot$

Intermediate Mass Black Hole (IMBH): $10^2 M_\odot < M_{BH} < 10^4 M_\odot$

though not exotic models invoking new physics such as soliton stars with radii of less than a few Schwarzschild radii. See Figure 3-2.

The black hole mass estimates derived from the kinematics of stars and gas in the nuclei of nearby representative galaxies also allow one to estimate the space density of local black holes (Figure 3-1). These estimates give

$$\rho_\bullet = 2\text{-}5 \times 10^5 M_\odot \ \mathrm{Mpc}^{-3}$$

(for $H_0 = 70$ km s^{-1} Mpc^{-1}; Aller & Richstone 2002; Marconi *et al.* 2004). The uncertainty in $\rho_\bullet$ results principally from uncertainties and dispersion in the correlations between black hole mass and galaxy luminosity or between black hole mass and velocity dispersion (*c.f.* Lauer *et al.* 2006, Tundo *et al.* 2006).

Figure 3-3: Snapshots from a simulation of a collision of two spiral galaxies, similar to the Milky Way, containing $10^5 M_\odot$ seed black holes at their centers. The images show only the gas in the galaxies. Color indicates temperature and brightness gas density. The collision drives both star formation in the galaxy and gas accretion onto the black holes, causing them to merge. The resulting quasar expels most of the gas from the galaxy, leaving a gas-poor galaxy containing a $\sim 10^8 M_\odot$ black hole (from Di Matteo *et al*. 2005).

One can compare $\rho_\bullet$ to the total increase in the mass density of black holes derived from the total radiation density emitted by AGN, an argument suggested by Soltan in 1982. If the total radiation density emitted by AGN were produced by accretion onto black holes with an efficiency ε of converting accreted rest-mass to radiation, then it must have increased the mass-density of supermassive black holes by

$$\Delta\rho_\bullet \approx 3.5 \times 10^5 \varepsilon_{0.1}^{-1} M_\odot \ \mathrm{Mpc}^{-3}$$

where $\varepsilon_{0.1} \equiv \varepsilon/0.1$ (Marconi *et al*. 2004; Soltan 1982). Most of this radiation comes from AGN with redshifts between 0.5 and 3. There is probably a 50% uncertainty in $\Delta\rho_\bullet$ due to uncertainties in the bolometric corrections and in corrections for obscured AGN and faint high-redshift AGN.

The striking correlation shown

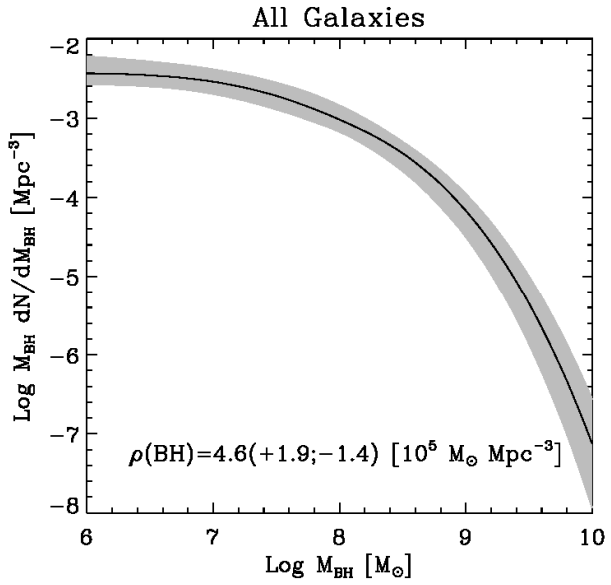

Figure 3-4: The local space density of black holes in galactic nuclei as a function of black hole mass, inferred from measurements of the kinematics of stars and gas in the nuclei of nearby galaxies (from Marconi *et al*. 2004).

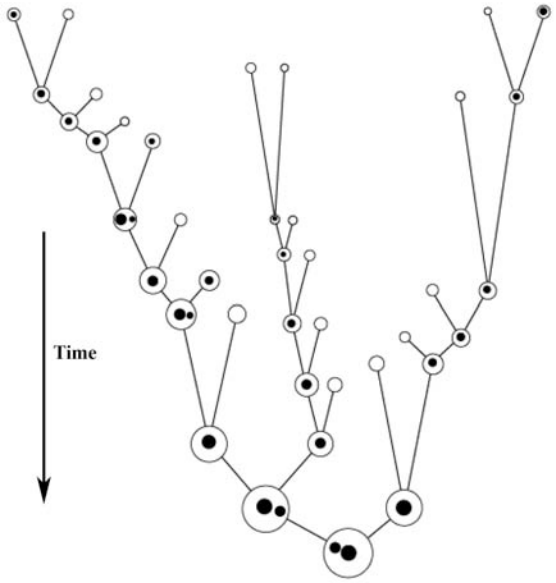

Figure 3-5: A cartoon of the merger-tree history of the assembly of a galaxy and its central black hole in cold-dark matter cosmology. Time increases from top to bottom, and the horizontal axis is a spatial direction. In this case the final galaxy is assembled from the merger of twenty smaller galaxies, containing a total of four seed black holes, and results in four mergers of binary black holes.

in Figure 3-1 between the mass of a galaxy's nuclear black hole and the galaxy's stellar mass and velocity dispersion (and hence the depth of its gravitational potential well) has convinced astronomers that throughout cosmic history, the growths of galaxies and their nuclear black holes have been tightly coupled (Gebhardt *et al.* 2000; Tremaine *et al.* 2002). Events in the galaxy decide the rates of the black hole's accretion, stellar capture, and merger; and jets and radiation from the black hole's accretion disk can remove gas from the galaxy and its surroundings (Figure 3-3).

The estimates for the growth in black hole mass, $\Delta\rho_\bullet$, can be compared to the estimate for the local density of black holes. Most of the contribution to the local black hole mass density comes from black holes with masses between 10^8 and 10^9 $M_\odot$ (Figure 3-4). Similarly, the main contribution to $\Delta\rho_\bullet$ comes from black holes in the same mass range at z = 2 - 3 (Merloni 2004). Since these billion-solar-mass black holes have grown in mass mainly through accretion, by a few orders of magnitude from z = 3 to now, the high-redshift Universe must have been dominated by black holes of a smaller variety, $10^6 - 10^7 M_\odot$. Were the smaller black holes quietly growing by mergers, while the supermassive ones were growing by accretion? Here lies a great potential for discovery by LISA, which will detect mergers of mass 10^5 - 10^7 $M_\odot$ with high signal-to-noise out to redshift $z \sim 20$ or higher.

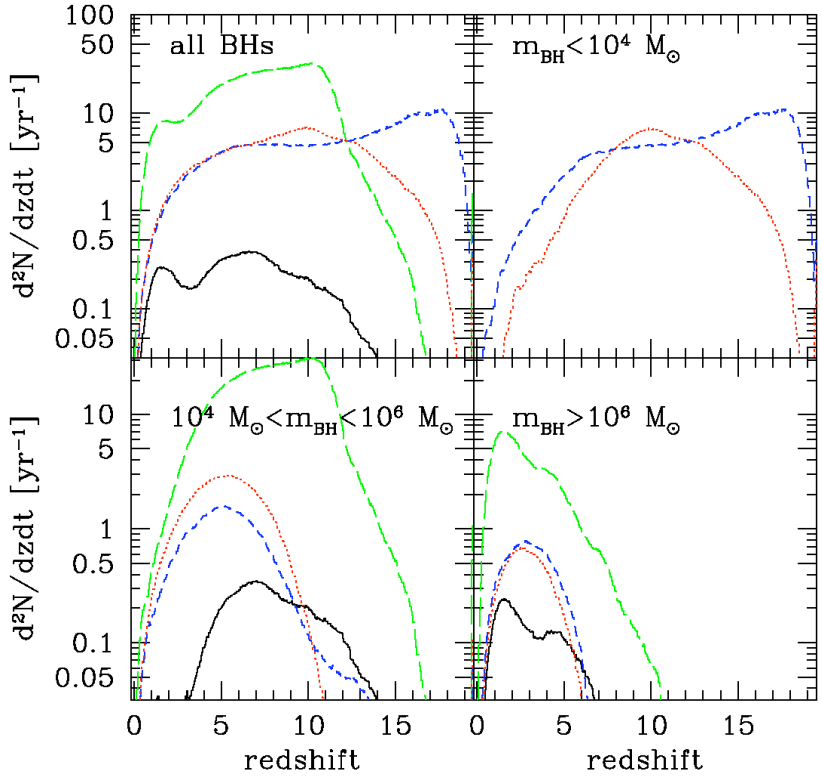

Figure 3-6: Predicted rates of massive black hole binary coalescences observable by LISA. Red, blue curves: scenarios with 150 $M_\odot$ black hole seeds resulting from the collapse of the first stars formed at $z > 20$, with black hole growth occurring by gas accretion during galaxy mergers. The black hole mergers are assumed to be driven initially by spherical stellar dynamics alone (red) or to be prompt (blue, *e.g.*, driven by gas drag). Black, green curves: scenarios with heavy seed black holes ~ 10^4-10^5 $M_\odot$. The green curve assumes the heavy seeds were produced in all dark halos with masses > 10^8 $M_\odot$ by $z = 15$. These merge to produce today's black holes (Koushiappas *et al.* 2004) The black curve assumes a much smaller number of similarly substantial seeds only in dark halos of > 10^{10} $M_\odot$, and requires that today's black holes grew mainly by gas accretion (from Volonteri 2006).

Growth and merger history of massive black holes

Expected merger rates

There is a simple argument bounding the number of mergers of supermassive black holes that LISA is likely to see. Hubble Space Telescope observes more than 10^{10} galaxies. Most bright local galaxies contain central supermassive black holes. Fossil evidence for mergers among local galaxies implies that about 70% of these have undergone a merger during the 0.8×10^{10} years since redshift $z = 1$ (Toomre 1977; Bell *et al.* 2006). Therefore, the galaxy merger rate at $z < 1$ must be close to one per year, and if the black holes in merging galaxies merge in turn, the merger rate of supermassive black holes should also be at least one per year.

Observations show that our Universe is dominated by cold dark matter, and that its initial spectrum of perturbations was such that the first objects to collapse under their self-gravity were tiny systems the size of dwarf galaxies. These then fell into each other to create larger ones (see Figure 3-5). Present-day galaxies like our Milky Way grew by the merger of more than 1000 subunits, which started forming already at redshift higher than 20. If each of these subunits initially contained a seed black hole of $10^4 M_\odot$, the merger rate seen by LISA could be as high as one thousand per year!

These elementary arguments suggest strongly that the merger rate of binary black holes that LISA will see lies in the range 1 - 1000 yr^{-1} (see Figure 3-6). The actual rate is proportional to: (1) the fraction of proto-galactic fragments that contain seed black holes massive enough for LISA to detect their mergers, multiplied by (2) the fraction of galaxy mergers that lead to black hole mergers. Our theoretical understanding of these fractions is limited and neither is well constrained observationally. LISA's measurements offer our best hope of determining them.

Seed black holes

The number densities and masses of the seed black holes largely determine their merger history. The similarity between $\rho_\bullet$ (the current best estimate for the mass density in black holes) and $\Delta\rho_\bullet$ (the density of rest mass that must have been accreted in order to produce the observed AGN) suggests that accretion does play a large part in the building of supermassive black holes. However, the estimates are also consistent with a significant fraction of the present black hole mass density being already present as black hole "seeds" by z = 10 - 20 (Koushiappas *et al.* 2004). In this scenario only a few of the seeds have grown through accretion to a billion solar masses, and these make up most of the mass we detect in supermassive black holes today and explain most of the accretion luminosity. The majority of seeds did not grow to high mass by accretion, so their presence and evolution is best traced by observing their mergers directly through gravitational radiation.

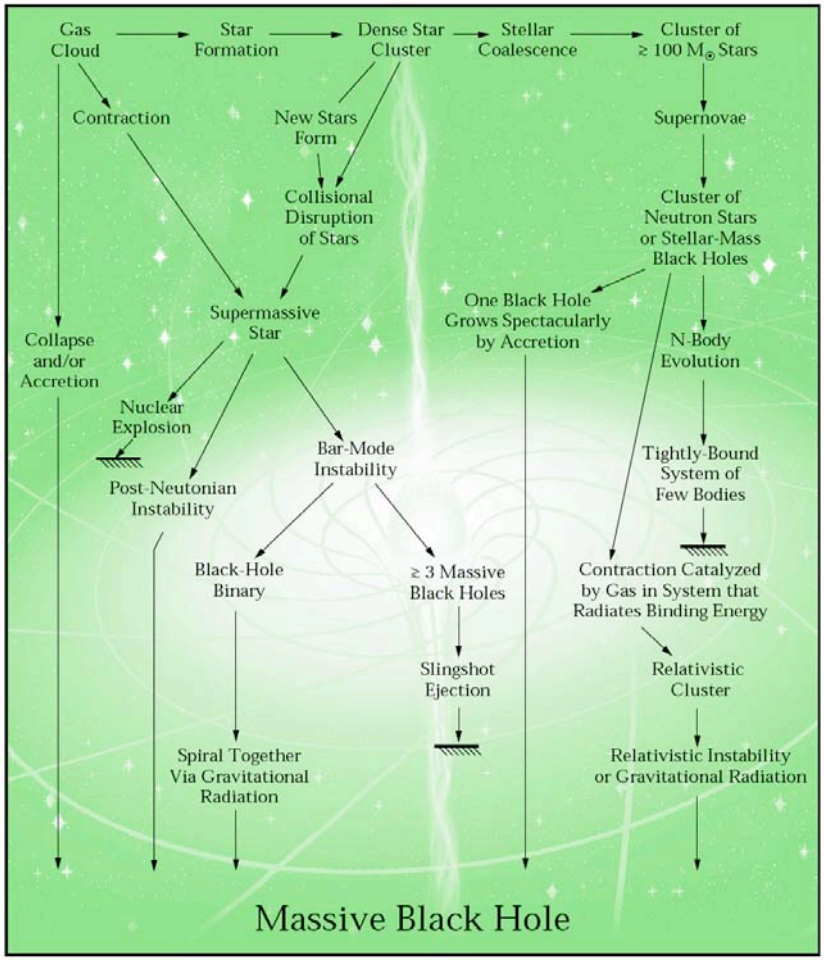

Figure 3-7: Scenarios for the formation of a massive black hole out of dense gas in the center of galaxies. From http://www.slac.stanford.edu/pubs/beamline/31/1/31-1-trimble.pdf (after Rees 1978).

Broadly, there are two

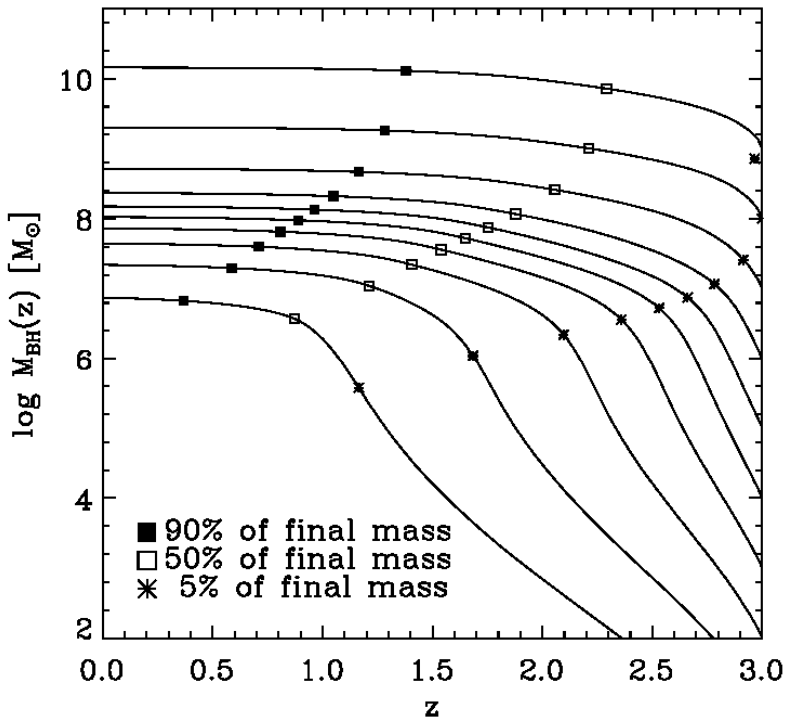

Figure 3-8: One possible growth history of black holes in active galaxies due to gas accretion, as a function of redshift and black hole mass, inferred from an X-ray selected sample of active galactic nuclei, assuming near-Eddington accretion (from Marconi *et al.* 2004).

currently popular scenarios for these "seeds". The first supposes that they are the ~100 $M_\odot$ black hole remnants of the first stars to form from primordial gas in the Universe (so-called Population III stars: Abel *et al*. 2002; Bromm *et al.* 2002; Bromm & Larson 2004; Madau & Rees 2001).

The second scenario is motivated in part by the existence of quasars at z = 5 - 6 (when the Universe was not even one billion years old) so luminous as to require black holes $> 10^9 M_\odot$ even at that early time. This second scenario supposes that much more massive seeds (10^4-$10^5 M_\odot$) could grow either by direct collapse of radiation-dominated massive star-like objects (Rees 1978; Bond *et al.* 1984), or by rapid accretion at super-Eddington rates (Begelman *et al.* 2006). See Figures 3-7 and 3-8.

Understanding how black hole seeds formed is a challenging observational task. There may be a population of "mini-quasars" at high redshift powered by accretion onto seed black holes, but if the mass of the seeds is below $\sim 10^6 M_\odot$ their flux, diluted by the large distance light has to travel from the formation redshifts ($z \sim 10$ - 30), is too weak for single sources to be detected electromagnetically. There is however evidence for a nearby population of low-mass AGN at $z <$ 0.2 (Barth *et al*. 2005). Seeds of mass $\sim 10^4 M_\odot$ can nevertheless be identified at high redshift during their mergers by observing their emission of gravitational radiation with LISA. Mergers may in fact play a much more important role in the higher-redshift Universe, because at $z > 5$ the merger rate is not limited by the Soltan-type argument that constrains the number of mergers at z < 3. Furthermore, constraints derived from the X-ray background actually limit the overall growth by accretion for black holes at $z > 6$.

The role of massive black holes in the evolution of early cosmic structure.

Active galactic nuclei powered by supermassive black holes keep the Universe ionized at $z < 4$, structure the intergalactic medium (IGM), and probably regulate star formation in their host galaxies. Intermediate mass black holes accreting gas from the surrounding medium may shine as "miniquasars" at redshifts as high as $z \sim 20$, with dramatic effects on the thermodynamics of the IGM (Kuhlen & Madau 2005). There are significant uncertainties about this key period in structure formation, from the fate of first stars (Abel, Bryan, & Norman 2002; Bromm *et al*. 2002; Bromm & Larson 2004) to the growth of $M > 10^9\ M_\odot$ black holes from seed black hole precursors in redshift $z > 6$ quasars (Madau & Rees 2001; Bromm & Loeb 2003) to the role of black holes in the reheating and reionization of the Universe (Madau *et al.* 2004) to the establishment at early epochs of the currently observed tight correlation between black hole mass and galactic bulge properties (Ferrarese & Merritt 2000; Gebhardt *et al.* 2000; Tremaine *et al*. 2002; Ferrarese & Ford 2005).

Models of hierarchical structure assembly predict that galaxy-sized dark matter halos will start to be common at redshifts $z \sim 10$ - 20 (see, *e.g.,* Mo & White (2002) for a pedagogical summary). This is also the epoch in which stars and galaxies first form in abundance, hence it is the beginning of the nonlinear phase of the Universe. However, electromagnetic observations of the properties and interactions of these early galaxies will be extremely challenging, because the first ones will be under-luminous dwarfs and because the surface brightness decreases as $(1 + z)^{-4}$.

In contrast, LISA observations of massive black hole coalescences from this epoch will be uniquely powerful in probing the halo mergers required in current models. The central black holes in many early halos are expected to have masses $M \sim 10^4$ - $10^6\ M_\odot$, corresponding to the redshifted mass range $10^5\ M_\odot < M(1+z) < 10^7\ M_\odot$ to which LISA will be most sensitive. The best current models predict tens of detected mergers per year at redshifts $z > 10$ (*e.g.,* Sesana *et al.* 2004). This is enough to characterize the redshift and mass distributions and discriminate between classes of structure formation models, in a crucial realm that is otherwise inaccessible to observation.

What happens when black holes collide and merge?

When two galaxies collide, the gravitational interactions between their stars and dark matter merge them into a ball of stars in $\sim 10^8$ yr. If both galaxies contain nuclear black holes, the black holes orbit within the ball of stars, and lose energy by deflecting the orbits of stars that pass near them. Within several orbital periods, the two black holes eject all the stars in their vicinity, and the rate of subsequent shrinking of their orbits is controlled by whatever stars and gas dribble in from larger radii, plus gravitational radiation (Merritt & Milosavljevic 2005). For black holes with mass $< 10^7 M_\odot$ (the ones to which LISA is sensitive), which live in galaxies with bulges smaller than the Milky Way's, gravitational radiation alone will merge the black holes in less than

10^{10} yr (Yu 2002). In more massive galaxies, the larger pair of black holes can eject all their surrounding stars before the pair is close enough for gravitational radiation to merge them. Then, without a further dribble of stars or gas, the black holes could be left orbiting each other for longer than the age of the Universe, at orbital separations of 0.1 - 1 pc and orbital periods of 10^2 - 10^4 yr. However, it appears that many galaxies have sufficiently flattened or tri-axial bulges of stars, or enough gas that the continuing supply of material for the pair to eject continues to cause the pair's orbit to shrink. The black holes are eventually driven close enough together that gravitational radiation takes over and merges them on a fairly short timescale. Observational evidence, too, favors prompt mergers even among the massive black holes. If the close pairs were long lived, a third merger would frequently lead to a third black hole interacting with the pair, leading to ejection of all three black holes from the nucleus of the galaxy, contrary to observation (Haehnelt & Kauffmann 2002). Furthermore, the most compelling explanation for X-shaped and double-double radio galaxies is that they result from reorientation of the black hole spin following a merger (Zier 2006 and references therein).

Black Hole Spins

No hair and no naked singularities

In general relativity, astrophysical black holes are predicted to be completely described by exactly two parameters: mass and *spin* (vacuum relativity also allows an electric charge, but this is quickly shorted out to gravitationally insignificant levels in the real world). This is the famous theorem that "black holes have no hair " (Thorne 1995). The total spin angular momentum S is usually specified in terms of the angular momentum per unit mass $a = S/M$ or the dimensionless $a_\bullet = S/(GM^2/c) = S/M^2 = a/M$ (the last two equalities being true only in relativists' units where $G = c = 1$). For a specified mass M, a black hole described by relativity cannot have $a_* > 1$ without showing a naked *singularity i.e.* one uncloaked by an event horizon (and this would generally be forbidden by the Cosmic Censorship conjecture). The simple non-rotating Schwarzschild black hole has $a_* = 0$.

Predicted spins from formation and growth

So what values $0 < a_* < 1$ do astronomers now expect for astrophysical black holes? Rotating gas clouds and stars have $a_* > 1$, so black holes that form from their collapse have high spin ($a_* = 0.75$), and leave much of their angular momentum in a residual disk that could accrete and raise a_* still more (Shibata & Shapiro 2002; Gammie *et al.* 2004). However, as discussed above in the context of seed black holes, most of the black holes in galactic nuclei have masses well above likely seed masses. Doubling the mass of a black hole is also enough to change a_* by of

order unity, so the values of a_* probably depend more on the growth history than on the original spins of the seeds (Hughes & Blandford 2003, Gammie *et al.* 2004, Volonteri *et al.* 2005). One possible evolutionary path involves rapid disk accretion of interstellar gas onto the black hole. Evidently this was the dominant path for the rare quasar black holes, which are too large to be probed by LISA. Another possible path involves a combination of gas accretion with many generations of black hole mergers. A third possibility for the growth of black holes is the random accretion of small packets of less dense material, such as material from tidally disrupted individual stars.

Merging binary black holes of comparable masses also have orbital angular momentum much larger than the maximum allowed for the merged black hole. However, recent numerical relativity simulations of the merger of equal mass, non-spinning black holes show that enough angular momentum is radiated to avoid a naked singularity, and the final steady-state merged black hole has $a_* = 0.7$ (Pretorius 2005). Simulations of the mergers of equal-mass rapidly rotating Kerr holes suggest it is unlikely to create a maximally rotating hole in this way; a maximum final value of $a/M = 0.89$ was produced from two holes with individual spin parameters $S/M^2 = 0.757$ aligned with the orbit (Campanelli *et al.* 2006).

By contrast, growing a black hole by accreting small companions (*e.g.*, stars or stellar mass black holes of mass M_c) which fall in on isotropically distributed orbits causes a secular decrease $a_\bullet$. If $M \gg M_c$, the angular momentum is essentially determined by a random walk, and $a_* \sim (M_c/M)^{1/2} \sim 10^{-3}$. This mechanism of black hole growth is most plausible for lower luminosity AGN and black holes of $< 10^7 M_\odot$ (Milosavljevic *et al.* 2006). In nuclear clusters dense and massive enough to supply enough stars to grow black holes of 10^8-$10^9 M_\odot$, stars collide (Figure 3-7; Rauch 1999). The subsequent evolution is hard to model, and there is no compelling evidence for the existence of such massive clusters.

Accreting unmagnetized gas in a thin disk with a steady direction of angular momentum drives a black hole to $a_* = 0.998$ after the accretion has increased its mass by a factor of 2.5 (Thorne 1974). Magnetized accretion disks are less effective at spinning up black

Table 3-1 Black hole spin characteristics for different growth scenarios (a-e), and representative efficiencies in converting accreted mass into radiation. Here efficiencies are calculated assuming no torque inside the innermost circular orbit, and corrected for the radiation emitted by the disk and swallowed by the hole (Thorne 1974).

holes, since they also lose angular momentum electromagnetically through disk winds, torques in the region where the gas begins to plunge into the black hole, and through magnetically-mediated extraction directly from the black hole. Simulations suggest that these effects may limit the final spins to $a_* \sim 0.9$, in contrast to the $a_* = 0.998$ of an unmagnetized thin disk (Krolik *et al.* 2005; Hawley & Krolik 2006). These results are summarized Table 3-1.

Although massive black holes could form by any combination of these processes, numerical astrophysics and relativity have show that these different mechanisms can produce very different distributions of black hole spins, skewing the distribution to high or low spins or spreading it evenly over a wide range of spins. No other astronomical observable can provide such a direct probe into the history of a key structural constituent of the Universe, and LISA will be able to measure such spins to better than 1% accuracy.

Merging massive black holes: Open questions and LISA's answers

There is strong evidence from electromagnetic observations that the many diverse phenomena of active galactic nuclei, ranging from giant radio jets to quasars, ultra-luminous infrared galaxies, the X-ray background and gamma-rays from blazars are all caused by accretion onto black holes. There is also strong evidence that galaxies grow by mergers, and that those mergers cause inflow of gas into the nuclear regions, exciting starbursts and feeding the central black holes. The winds and radiation from the stars and accreting black holes in turn expel the remaining gas, and determine the structure of the galaxy (Begelman 2003; Murray *et al*. 2005; Hopkins *et al*. 2006). While this evidence from electromagnetic observations is compelling, it is incomplete. Many fundamental questions about black holes and the galaxies they inhabit remain, which LISA will address:

- Except in a very small number of cases, the masses of the black holes in both quiescent and active galaxies are uncertain by factors of at least a few (due to the difficulty of constraining observationally the complications of stellar and gas dynamics). This prevents us from improving our understanding of accretion disk structure and dynamics. LISA observations of merging MBHs will reveal both their masses to typically less than 1% (Lang & Hughes 2006).

- Today, almost nothing is known observationally about the high-redshift merger tree that led to the galaxies we see today (see Figure 3-7). LISA observations of merging MBHs represent one of our best chances of observing this complex history. LISA can determine the binary's luminosity distance, typically to within a several percent. Assuming the standard concordance cosmology, this distance gives us the binary's redshift. Thus one can deduce the MBH merger rate as a function of z, and so trace the early history of galaxy mergers and the build-up of MBH masses over time (at least for those of solar masses). Today, the fraction of low-luminosity galaxies with black holes at $< 10^6 M_\odot$ is unknown at all redshifts.

- The spins of both quiescent and active black holes are poorly known. The distribution of spins will be strongly diagnostic of the mechanism of black hole growth (see discussion above on predicted spins). And the spins themselves are vital to many models of electromagnetic

phenomena: jet formation, jet twists, accretion efficiency, tidal disruption events. LISA observations of MBH mergers will reveal the spin parameters a_* of the merging BHs to within 1% (Lang & Hughes 2006). EMRI detections (see below) should typically reveal the MBH spin a_* to within ~ 0.01% (Barack & Cutler 2004).

Direct gravitational wave observations of these objects, which we now assume to be black holes, whether through their mergers or their capture of compact stellar-mass companions, should resolve these questions with a precision and certainty unachievable by other modes of observation.

Stellar captures and the dynamics of galactic nuclei

Some of the most exciting astrophysics with LISA will come from observing the gravitational waves produced by inspirals of stellar-mass compact objects into massive black holes. There is compelling indirect evidence that these inspirals are common throughout the Universe and occur about once per 10 million years in galaxies like the Milky Way (Freitag 2003, Hopman & Alexander 2006). Because the mass ratio for these binaries is typically ~ 10^{-5}, these sources are commonly referred to as extreme mass ratio inspirals, or EMRIs.

White dwarfs, neutron stars, and stellar-mass black holes all share the property that they reach the last stable orbit around the massive black hole (MBH) before they are tidally disrupted; hence all three types of compact stars can in principle lead to observable EMRI signals. However, black holes (BHs), being more massive, are expected to dominate the observed rate for LISA, for two reasons: mass segregation tends to concentrate the heavier compact stars nearer the MBH, and BH inspirals have higher signal-to-noise, and so can be seen within a much larger volume.

There are currently about 20 confirmed stellar-mass black holes, with estimated masses in the range ~ 5 - 15 $M_\odot$. However, it is generally believed that there are tens of millions of them in our galaxy, since they are expected to be produced in the deaths of massive (greater than ~ 20 - 25 $M_\odot$) stars (Woosley *et al.* 2002). The mechanism of mass segregation insures that the fraction of stars that are black holes is much higher very near the central MBH than at a random spot in the galaxy. In the Milky Way, near Sgr A*, it is estimated that there are several thousand stellar-mass BHs in the innermost parsec (Miralda-Escudé & Gould 2000; Freitag *et al*. 2006) and that stellar-mass BHs dominate the total stellar mass within 0.01 parsec.

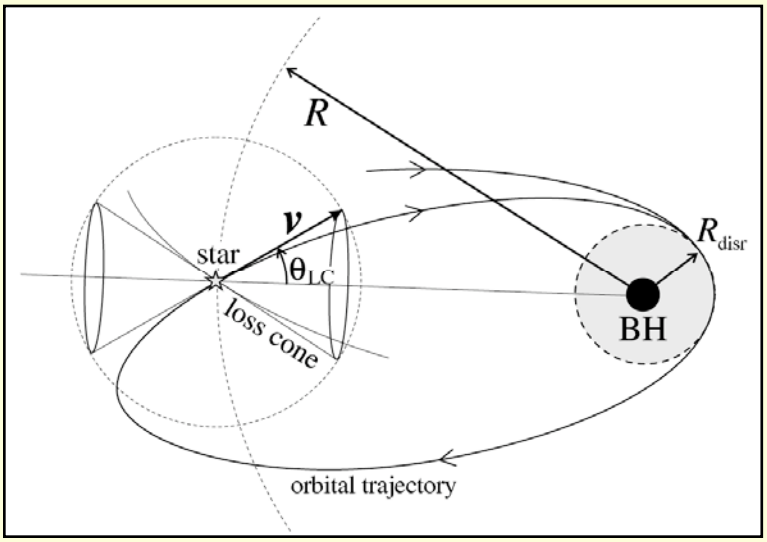
The oldest and best understood mechanism for creating EMRIs is that two-body encounters between stars in a dense stellar cluster near the MBH result in diffusion in each one's specific angular momentum, J. For non-rotating (Schwarzschild) MBHs, if J is reduced below about $4M$ (where M is the MBH mass), then the star plunges directly into the MBH. More interesting for LISA are the compact stars that diffuse into very high-eccentricity orbits, but that do not plunge directly. If the changes in J bring the value down to roughly $6M$, substantial energy starts to be lost due to gravitational radiation. The apocenter of the orbit shrinks as energy is radiated, and it

is possible for the apocenter to shrink enough that the compact star essentially ceases to interact with the other stars near the center of the galaxy, and gravitational radiation reaction completely drives the final evolution of the orbit.

Unfortunately, other scenarios can occur also. If J random-walks away from near zero before the BH-MBH system becomes substantially more tightly bound, then the losses due to gravitational radiation become negligible. Or, if J decreases to about $4M$ before much energy is radiated away, the black hole will plunge into the MBH rather than spiral in gradually. The gravitational wave signal then would not last long enough to produce a detectable signal-to-noise ratio. For a MBH of ~ 3 - 4 million solar masses (such as the one at the center of our Milky Way), gradual inspirals – the observable LISA sources – arise from the stars that are scattered towards the MBH from distances within a few times 0.01 parsec (Hopman & Alexander 2006). For such gradual inspirals, the last years of inspiral will typically be observable by LISA. Compact stars that are scattered into low-J orbits start out with orbital eccentricity very close to unity ($1 - e \sim 10^{-4}$), and their orbits remain moderately eccentric until the final plunge; median final eccentricities might be $e \sim 0.2$.

Mechanisms for Creating Extreme Mass Ratio Inspiral (EMRI) Events

Three different mechanisms for the production of EMRIs have been explored in the literature. The oldest and best-understood mechanism is the diffusion of stars in angular-momentum space, due to two-body scattering. Compact stars in the inner ~ 0.01 pc will sometimes diffuse onto very high eccentricity orbits, such that gravitational radiation will then shrink the orbit's semi-major axis and eventually drive the compact star into the MBH. This diffusion of stars into the "loss cone" is illustrated in the figure below.



Important physical effects setting the overall rate for this mechanism are mass segregation, which concentrates heavy, ~ 10 solar mass BHs close to the MBH, and resonant relaxation (the stars in the inner cusp are on nearly periodic orbits around the MBH, so the same two stars will interact with each other repeatedly), which increases the rate of diffusion (Hopman & Alexander 2006). The other two proposed mechanisms for producing EMRIs are tidal disruption of binaries that pass close to the MBH (Miller *et al.* 2005) and the creation of massive stars (and their rapid evolution into compact objects) in accretion disks surrounding MBHs (Levin 2006). It is not clear which mechanism will actually dominate the rate; indeed, all three could be roughly comparable.

It is estimated that most LISA detections of EMRIs will come from ~ 10 $M_\odot$ BHs spiraling into MBHs with masses in the range ~ 10^6 - $10^{6.5}$ $M_\odot$. The space density of MBHs in this mass range is ~ $1.7 \times 10^{-3}\,\mathrm{Mpc}^{-3}$, and LISA can detect such sources out to $z \sim 1$, corresponding to a co-moving volume of ~ 200 Gpc^3. The two-body scattering mechanism discussed above leads

to a rate (of observable inspirals) in Milky Way-type galaxies of $\sim 2.5 \times 10^{-7}\,\mathrm{yr}^{-1}$ (Hopman & Alexander 2006), which then implies a LISA detection rate ~ 85/yr (Gair *et al.* 2004). (The above estimate ignores "edge effects" related to the fact that inspirals ending in the first few months after LISA turns on will generally not be observable, since not enough signal-to-noise will have built up. Also EMRIs with unfavorable orientations will not be observable to $z = 1$, so a more conservative estimate would be ~ 50/yr.) The uncertainty in this rate is perhaps a factor of ~ 20.

In addition to the two-body scattering mechanism, other proposed channels for EMRIs are tidal disruption of binaries that pass close to the MBH (Miller *et al.* 2005) and creation of massive stars (and their rapid evolution into black holes) in the accretion disks surrounding MBHs (Levin 2006). Either of these channels could lead to a rate of the same order of magnitude as quoted above for two-body scattering, and this multiplicity of channels gives added confidence that at least one of them will produce a significant detection rate for LISA. Given a reasonable sample of detections, it should also be possible to infer the relative contributions from the different EMRI channels listed above. That is because two-body scattering leads to EMRIs that are moderately eccentric and have arbitrary inclination with respect to the MBH spin. In contrast, tidal disruptions of binaries lead to EMRIs that also have arbitrary inclination, but whose eccentricities are very close to zero; this is because tidal disruption results in orbits with (initially) much larger pericenter than for two body scattering, giving more time for radiation reaction to circularize the orbit before it becomes visible to LISA. Disk formation of EMRIs leads to sources with zero eccentricity and zero inclination (*i.e.*, orbital angular momentum parallel to the MBH's spin angular momentum). The orbital inclination and eccentricity can both be measured with very high accuracy from the LISA data (Barack & Cutler 2004).

During the last years before merger, the motion is highly relativistic, with speeds typically a third the speed of light. The period for precession of periapsis is comparable with the period for radial motion, and the orbital plane precesses just a few times less rapidly if the MBH has large spin. Thus the motion is quite complex, and correspondingly, the number of templates needed to do a brute force search for the signal is extremely high. Indeed, a brute force search for the signal over a year or more of data will not be possible, even with the computer power available in 2016.

Fortunately, Gair *et al.* (2004) were able to show that the search problem can be overcome by using shorter time intervals for the initial searches, and then combining the results incoherently. For three-week initial intervals, the computational resources required are reduced to reasonable levels. The main penalty of this approach is that the signal-to-noise ratio required for a successful search is increased from roughly 15 to 30-35. (That is, the source strength must be such that the combined, matched-filtering signal-to-noise using two independent LISA channels is 30-35.) Whether other search methods can be found that will avoid this increase in the required signal-to-noise ratio is now under investigation.

Recently, much more detailed simulations of EMRI events and of the stellar and compact object populations in galactic nuclei have been carried out by several different groups (Alexander & Hopman 2003; Freitag 2004; Hopman & Alexander 2005, 2006). As noted, there are still sub-

stantial uncertainties in the rates for EMRI events, because current observations simply do not impose strong constraints on models of the stellar swarms in galactic nuclei. The event rates for black hole EMRIs as a function of MBH mass will give detailed information on conditions in the galactic nuclei that probably cannot be obtained in other ways. The estimated event rates for white dwarf and neutron star EMRIs are considerably lower, but such events also are likely to contribute to clarifying conditions in the galactic nuclei.

Barack & Cutler (2004) showed that EMRI observations will permit measurement of the MBH spin parameter a_* with extremely high accuracy: $\Delta a_* \sim 10^{-4}$. Hence LISA is likely to provide a databank of hundreds or more black hole spins in the low-redshift ($z < 1$) Universe. As noted above, this spin distribution is highly sensitive to the evolutionary paths of the MBHs (Hughes & Blandford 2003, Gammie *et al*. 2004, Volonteri *et al.* 2005). No other astronomical observable provides such a direct probe into the history of MBHs, which chart the history of galaxies themselves.

LISA Science Objectives and Investigations relevant to this section (see Appendix 1)

1. Understand the formation of massive black holes

1.1. Search for a population of seed black holes at early epochs.

1.2. Search for remnants of the first (Pop III) stars through observation of intermediate-mass black hole captures, both at formation and at later epochs.

2. Trace the growth and merger history of massive black holes and their host galaxies

2.1. Determine the relative importance of different black hole growth mechanisms as a function of redshift.

2.2. Determine the merger history of 10^4 to 3×10^5 $M_\odot$ black holes before the era of the earliest known quasars ($z \sim 6$).

2.3. Determine the merger history of 3×10^5 to 10^7 $M_\odot$ black holes at later epochs ($z < 6$).

2.4. Determine the masses and spins of low-z massive black holes (MBH) using observations of extreme mass ratio inspiral (EMRI) events ($z \lesssim 1$).

2.5. Enable the search for electromagnetic counterparts to MBH mergers in order to determine the host galaxy.

3. Explore stellar populations and dynamics in galactic nuclei

3.1. Characterize the immediate environment of MBH in $z < 1$ galactic nuclei from EMRI capture signals.

3.2. Study intermediate-mass black holes from their capture signals.

3.3. Improve our understanding of stars and gas in the vicinity of Galactic black holes using coordinated gravitational and electromagnetic observations.

4. Black Hole Physics: Confronting General Relativity with Precision Measurements of Strong Gravity

Setting the stage

Key Science Questions

- Is the strong field gravity correctly described by GR?
- Are the massive dark central objects in galaxies really black holes?

General relativity (GR) is a theory of gravity, one of the fundamental forces of nature, in which gravitational fields are manifested as curvature of spacetime. GR was put forth by Albert Einstein nearly one hundred years ago as a remarkable marriage of physical insight and mathematical beauty. In its first experimental triumph, GR provided an elegant solution to an outstanding physical conundrum, the missing 43 seconds of arc per century in the precession of Mercury's perihelion that could not be accounted for by Newtonian gravity. The advances in our ability to measure such small effects during the latter part of the 19^{th} century provided this precision probe of the gravitational field near the Sun, and a confrontation with Newtonian gravity. Today, in the early years of the 21^{st} century, LISA provides the means to confront GR with experimental measurements at levels of precision and gravitational field strengths unimaginable a hundred years ago.

GR has no adjustable (or free) parameters and makes solid, specific predictions. While any test can therefore potentially be fatal, any failure of GR can point the way to new physics. Confronting GR with experimental measurements, particularly in strong gravitational fields, is an essential enterprise. And despite its great successes, we know that GR cannot be the final word on gravity, since it is a classical theory and so must break down at the Planck scale. As yet there is no complete, quantum theory of gravity, and gravitation is not yet unified with the other fundamental fields

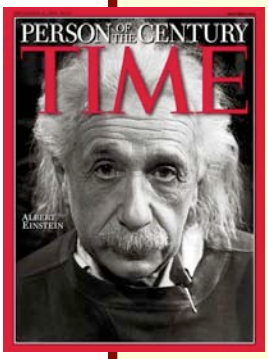
While so far GR has passed all the tests to which we have subjected it (Will 2006), most of these tests have been in the weak-field regime, which we can define by using the parameter $\varepsilon \sim v^2/c^2 \sim GM/(Rc^2)$. Here v is the typical velocity of the bodies, M their mass, and R their typical separation. In weak gravitational fields, $\varepsilon \ll 1$. For many astrophysical situations, such as Solar System dynamics, a fully general relativistic treatment is beyond our capabilities, but it is both practical and perfectly adequate to describe the dynamics using post-Newtonian (PN) equations, which are derived from the full general relativistic equations by systematically expanding them as a power series in ε. For the tests of GR that have been carried out in our Solar System, second-order corrections are of order $\varepsilon \sim 10^{-16}$, and so to-date it has been sufficient to model Solar System dynamics using first-order post-Newtonian equations. Solar

System tests have been completely consistent with general relativity, to this order of approximation.

Binary pulsars, which are essentially very stable and accurate clocks with typical orbital velocities $v/c \sim 10^{-3}$, can be seen as Nature's gift to relativists (Lorimer 2005). They have been excellent laboratories for precision tests of general relativity in gravitational fields considerably stronger than those prevailing in our Solar System. Current observations of several binary pulsars are perfectly consistent with GR predictions, as calculated through first post-Newtonian order. Observations of the first binary pulsar to be discovered, PSR B1913+16, also provided the first astrophysical evidence for gravitational radiation (earning the Nobel Prize for the binary's discoverers, Hulse and Taylor). Loss of energy due to gravitational-wave (radiation reaction) emission causes the binary's orbit to slowly shrink; $\dot{P}$ (an $O(\varepsilon^{2.5})$ effect) agrees with that predicted by GR to within 0.2%, which is within the error bars (Weisberg & Taylor 2004). The double pulsar system, PSR J0737-3039 A and B, discovered three years ago, should in the future provide even better tests of GR, for several reasons: it is the most highly relativistic of the known pulsar binaries; its distance and acceleration (relative to us) are much smaller; and, since both neutron stars are pulsars, it was possible to determine the mass ratio almost immediately from Newtonian-level dynamics, rather than having to infer it from relativistic effects. The last has made possible several additional GR tests that were not available previously (Kramer, *et al.* 2006). The orbital period derivative has already been measured (and is consistent with GR at the 1.4% level), and second-order post-Newtonian effects are expected to be measurable within several years (Kramer *et al.* 2006). (Why is radiation reaction – an $O(\varepsilon^{2.5})$ effect – more measurable than the $O(\varepsilon^{2})$ post-Newtonian effects? Because radiation reaction drains energy from the system and so causes inspiral, its effect on the orbital phase grows quadratically with time. By contrast, the first- and second-order post-Newtonian equations are conservative, and so their effect on the orbit grows only linearly in time. For observation times T of order $P/\varepsilon^{-0.5}$, the non-conservative $O(\varepsilon^{2.5})$ effect is more measurable than the second-order post-Newtonian corrections.)

LISA observations of coalescing massive black hole (MBH) binaries, or of stellar-mass compact objects spiraling into massive black holes, will allow us to confront GR with precision measurements in a strong-field/high-velocity regime not accessed by Solar System test or binary pulsar measurements. LISA will observe physics taking place just outside the event horizon, where typical velocities are $v/c \sim 1$. The merger of comparable-mass MBH binaries at cosmological distances produces an enormously powerful burst of gravitational radiation, which LISA will be able to measure with amplitude signal-to-noise as high as several thousand. In the months prior to merger, LISA will detect the gravitational waveform due to the binary's inspiral and from that inspiral waveform, the masses and spins of the two MBHs can be determined to high accuracy. Given these physical parameters, numerical relativity will be able to predict the exact shape of the burst waveform, and this can be compared directly to the observed burst – providing an ideal test of the theory. Stellar-mass compact objects spiraling into MBHs will provide a qualitatively different sort of test, but an equally exquisite one. The compact object

travels on a near-geodesic of the spacetime of the MBH, and as it spirals in, it effectively maps out the spacetime surrounding the MBH. For these extreme-mass-ratio inspirals (EMRIs), LISA will typically observe of order 10^5 cycles of inspiral waveform, all of which are emitted as the compact object spirals from 10 horizon radii down to a few horizon radii. Encoded in these waves is an extremely high precision map of the MBH's spacetime metric. Better opportunities than these for confronting GR with actual strong-field observations could hardly be hoped for. (One caveat, however, is that LISA observations of black hole binaries cannot discriminate between general relativity and scalar-tensor theories of gravity. The reason is that black holes do not support scalar fields; *i.e.*, they have no scalar "hair". Even after LISA flies, the best limits on scalar-tensor theories will come from Solar System and binary pulsar measurements; see Esposito-Farese 2004)



Did Einstein have the last word on gravity?

At the dawn of the 20^{th} century, Newton's theory of gravity was astonishingly successful. It provided a compelling and beautiful explanation of gravitational effects throughout the known cosmos. Newtonian gravity successfully predicted the existence of a previously unknown planet in the solar system. The theory passed every known experimental test, except one. Precision measurements of the precession of the perihelion of Mercury's orbit about the Sun revealed a small discrepancy of 43 seconds of arc per century. Newtonian gravity was unable to account for this anomalous precession, which was seen only in the orbital motion of the planet closest to the Sun – the planet where the Sun's gravity is strongest. GRs first triumph was to naturally account for this anomalous 43 seconds of arc per century.

At the dawn of the 21^{st} century, Einstein's theory of gravity is astonishingly successful. It also provides a compelling and beautiful explanation of gravitational effects through the cosmos as we know it today. GR successfully predicted phenomena such as gravitational lensing, black holes, and gravitational waves, and provides a natural framework for the expansion of the Universe. GR has passed every experimental test to date. But there is no well established quantum theory of gravity, and gravity is not yet unified with the other fundamental fields.

LISA provides unparalleled opportunities for making precision measurements in the regime of very strong and dynamical gravitational fields. Will such measurements unveil any flaws in the otherwise solid and successful edifice of GR? Even on macroscopic scales Newton did not have the last word on gravity.... did Einstein?

Now, this strong-field regime will quite likely be observed by ground-based gravitational-wave detectors several years before LISA flies (*e.g.*, the Advanced LIGO detectors should come online $\sim$ 2014 and LIGO is expected by that point to have observed BH mergers where the components are of roughly comparable mass. However, even the brightest BH mergers that LIGO will likely observe will still have amplitude signal-to-noise ratio ~100 times smaller than the brightest MBH mergers that LISA will observe. The precision with which LISA can measure the merger and ringdown waveforms will correspondingly be ~ 100 times better than for ground-based detectors. Similarly for extreme mass ratio inspirals: while the ground-based detectors may detect binaries with mass ratios $\sim 10^{-2}$ (*e.g.*, a neutron star spiraling into a 100 $M_\odot$ BH), in observations lasting $\sim 10^2 - 10^3$ cycles, the precision with which the spacetime can be mapped in such cases is at least two orders of magnitude worse than what is achievable with LISA's EMRI sources. Thus LISA will test our understanding of gravity in the most extreme conditions of strong and dynamical fields, and with a precision that is two orders of magnitude better than attainable from the ground.

GR has been extraordinarily fruitful in correctly predicting new physics, including the gravitational bending of light (or gravitational lensing), the gravitational redshift, black holes and gravitational waves. GR also provided the overall framework for modern cosmology, including the expansion of the Universe. Even if GR is fully correct (on lengthscales of astrophysical interest), LISA may reveal more new physics from strong-field GR. The famous singularity theorems of Penrose and Hawking assert that sufficiently compact objects must collapse, resulting in some spacetime singularity, but it is only a conjecture that the singularity is generically clothed by a black hole's event horizon. Might LISA reveal naked singularities or some other object formed of strongly warped spacetime? Could some central objects in galactic nuclei represent some other form of matter, such as massive boson or soliton stars? Since our understanding today of the nonlinear, strong gravity regime of GR is quite limited, LISA's "tests of GR" could reveal new objects that are unexpected, but perfectly consistent with GR.

The inspiral, merger, and ringdown of MBH binaries

LISA's strongest sources are expected to be coalescing MBH binaries where the components have roughly comparable masses, $0.1 \lesssim M_2/M_1 < 1$. The coalescence waveforms will be visible by eye in the data stream, standing up well above the noise, as illustrated in Figure 4-1.

As depicted in Figure 4-2, the coalescence can be described in three stages: inspiral, merger, and ringdown (Flanagan & Hughes 1998), all of which will typically be observable by LISA. The inspiral stage is a relatively slow, adiabatic process in which the BHs spiral together on quasi-circular orbits. The BHs have wide enough separations that they can be treated as point particles within the PN approximation; consequently, this stage can be computed analytically, with high-order PN expansions. The inspiral is followed by the dynamical

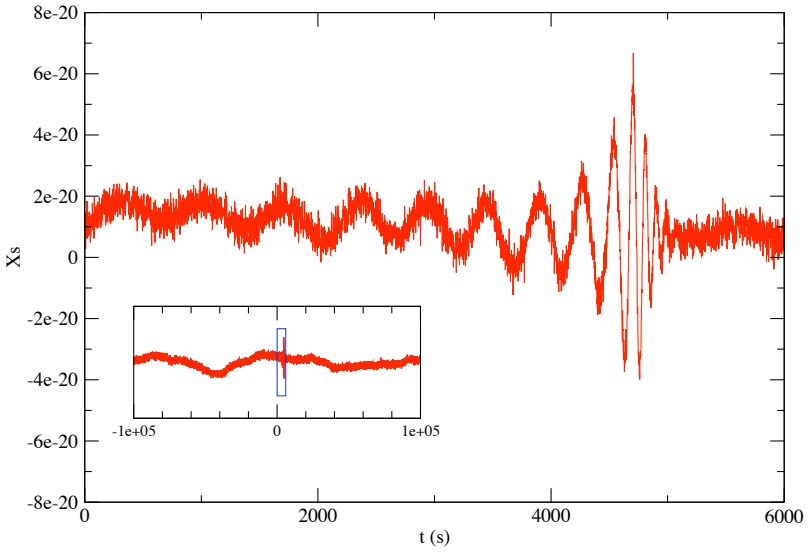


Figure 4-1 Gravitational wave signal for the final few orbits, plunge, merger and ringdown of an MBH-MBH binary. Here both MBHs have mass $10^5 M_\odot$ and are not spinning, the binary is at z=15, and is seen face-on. The signal is the sum of the gravitational waveform and simulated LISA noise. Note that even at z=15, the waveform stands up well above the noise and is visible in fine detail. The inset shows a longer stretch of data, containing the merger waveform. The large-amplitude, low-frequency "wiggles" are due to LISA's acceleration noise, which rises at lower frequencies.

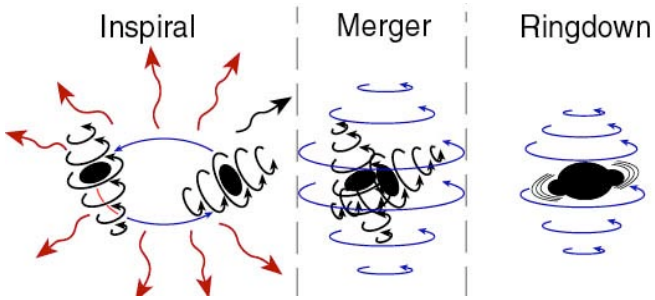

Figure 4-2 Schematic drawing of the three stages of the final coalescence of a comparable mass black hole binary, with spinning holes.

merger, in which the BHs leave their quasi-circular orbits and plunge together, forming a highly distorted remnant BH. Here, the BH velocities approach $v/c \sim 1$, the PN approximation breaks down, and the system can only be analyzed using numerical relativity simulations of the full Einstein equations. The distorted remnant settles into a stationary Kerr BH as it "rings down" by emitting gravitational radiation. While numerical relativity is required to tell us the initial state of the distorted BH, the evolution of that distortion — its "ringing down"— can be interpreted in terms of BH perturbation theory. At the end of the ringdown the final black hole is left in a quiescent state, with no residual structure besides its Kerr geometry. Its spacetime metric is then determined fully by its mass and spin, as required by the BH "no-hair" theorem.

For equal-mass MBH binaries with total mass in the range $3 \times 10^5 < M(1+z) < 3 \times 10^7 M_\odot$ where z is the cosmological redshift, the three stages all have comparable signal-to-noise; *i.e.*, within an order of magnitude of each other (see Figure 6 of Flanagan & Hughes 1998). From a typical LISA observation of the inspiral part of the signal, it should be possible to determine the physical parameters of the binary to extremely high accuracy. Using these parameters, numerical relativity should be able to predict precisely the merger and ringdown waves. The merger and ringdown waveforms will typically stand out well above the noise (by a factor $\sim 10^2 - 10^3$ after the noise has been band-passed to remove the large noise contribution from very low- and high-frequencies), so an extremely clean comparison will be possible between the observed waveforms and the predictions of general relativity.

We will now discuss the three stages of binary coalescence in greater detail, taking them in turn.

The inspiral stage: inferring the binary's masses and spins

With orbital velocities typically in the range $v/c \sim 1$, most of the inspiral stage can be well described using high-order post-Newtonian equations. The inspiral waveform is a chirp: a sinusoid that increases in frequency and amplitude as the BHs spiral together. The part of the inspiral stage that is observable to LISA lasts of order months to years. (More precisely, when the gravitational-wave frequency sweeps past 10^{-4} Hz, the time remaining until merger is

approximately $1.7 \times 10^8 s(0.25/\eta)[M(1+z)/2\times 10^5 M_\odot]^{-5/3}$ where $M \equiv M_1 + M_2$ is the total mass of the binary and $\eta \equiv M_1 M_2/M^2$ is the symmetric mass ratio. LISA will observe the last $10^4 - 10^5$ GW cycles from the inspiral. Since the inspiral signal is quite well understood theoretically, matched filtering can be used to dig these inspiral waveforms out of the noise, starting more than a year before the final merger, when the waves do not yet stick up above the noise as in Figure 4-1. And because the inspiral waveforms are strong, long-lived, and well-understood, it should be possible from the inspiral alone to determine the system parameters to amazingly high accuracy. Both masses should be determined to within fractional error $\sim 10^{-3}$, and their spins should be measured to within ~ 0.1 - 1% (Lang & Hughes 2006).

These are the size of random errors due to instrumental noise and confusion noise from white-dwarf (WD) binaries. Although waveforms available today are completely adequate for detection of waves, there will be some systematic errors in measured parameters due to the fact that the inspiral "template" waveforms, necessary for parameter estimation, will not be perfectly known theoretically. Highly accurate numerical solutions for tens of thousands of orbits are well beyond our current abilities, and will likely remain so for some time. However, great advances have been made in computing the inspiral to high order in post-Newtonian theory. For non-spinning bodies on nearly circular orbits, the post-Newtonian dynamics have been completely solved up through order $O(\varepsilon^{3.5})$ and the radiation reaction effects have been solved up through $O(\varepsilon^6)$: three-and-a-half orders beyond the order where radiation reaction effects first enters (Nissanke & Blanchet 2005). The influence of BH spin on the waveform phase has already been calculated to 2.5 orders beyond the lowest-order radiation reaction terms (Blanchet, Buonanno & Faye 2006). And for binaries with very small mass ratio, the post-Newtonian expansion is known to still much higher order. Additionally, it should also be possible to use numerical solutions to the late stages of inspiral to check and refine proposed methods for accelerating the convergence of PN expansion, such as Pade approximants. Therefore it seems very likely that well before LISA flies, theorists will be able to reduce to a very low level any systematic parameter estimation errors due to inaccurate theoretical inspiral waveforms.

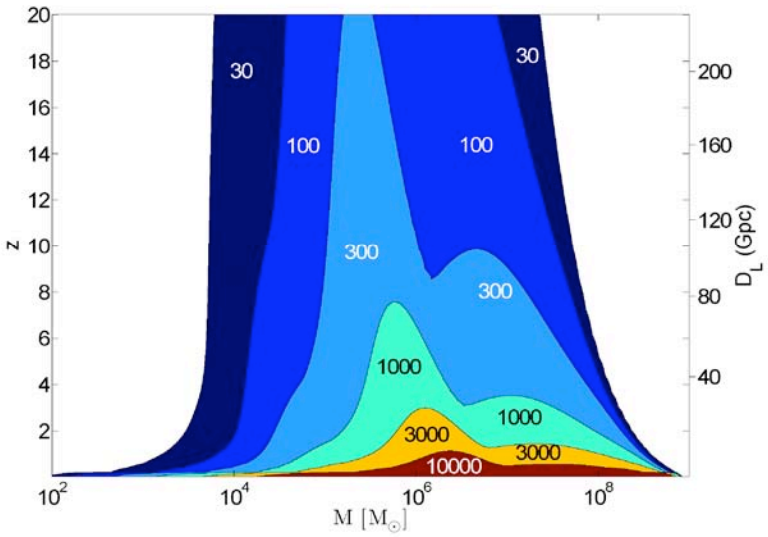

Figure 4-3 Plot of total signal-to-noise for all three stages of merger, for equal-mass binaries, as a function their total mass and redshift.

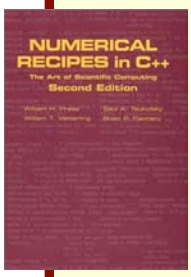
The merger stage: Spectacular bursts

The inspiral is followed by a dynamical merger that produces a burst of gravitational waves. This is a brief event, comprising only a few cycles if the holes spin slowly but more if fast, and lasting $\sim$ 1 hr $M/(10^6 M_\odot)$. However, it is fantastically energetic: during merger the gravitational-wave luminosity is $L_{GW} \sim 10^{23} L_\odot$, in that time producing more power than all the stars in the observable Universe. The final merger of MBH-MBH binaries occurs in the very strong-field, highly non-linear and highly dynamical regime of GR and is the strongest gravitational wave source that LISA is clearly predicted to see. LISA will be able to see the merger of two $10^4 M_\odot$ BHs out to redshift $z \sim 20$, and for mergers of $\sim 10^6 M_\odot$ BHs at $z \sim 1$ the LISA signal-to-noise will be in the thousands; see Figure 4-3. As mentioned above, LISA observations of the inspiral should give the masses and spins of the MBH components to $\sim$0.1%. With these in hand, numerical relativity will make a very specific prediction for the merger and ringdown radiation from the system. Comparison with the waveform that LISA actually observes will allow us to confront the predictions of GR with an ultra-high precision measurement in the fully nonlinear and dynamical regime of strong gravity.

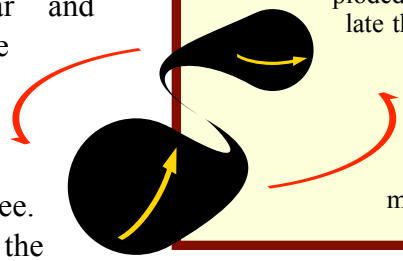


Numerical Relativity: Meeting the Theory Challenge

Recent dramatic advances in numerical techniques for simulating BH mergers and computing their waveforms have boosted opportunities to confronting GR with LISA observations. The importance – and difficulty – of calculating the gravitational waveforms from black hole mergers had been recognized by the AANM, Q2C, and Gravitational Physics decadal reports as a major theory challenge in this field. In the words of the Q2C report (page 118):

"Nearly as difficult as building these (gravitational wave) observatories, however, is the task of computing the gravitational waveforms that are expected when two black holes merge. This is a major challenge in computational general relativity and one that will stretch computational hardware and software to the limits. However, a bonus is that the waveforms will be quite unique to general relativity, and if they are reproduced observationally, scientists will have performed a highly sensitive test of gravity in the strong-field regime."

Numerical relativists have attempted to calculate gravitational waveforms from black hole mergers for over 30 years. The first full orbit of an equal mass, non-spinning black hole binary was finally achieved in late 2003. Roughly 1½ years later the field exploded, as several groups developed the means to simulate the final few orbits, plunge, merger and ringdown using dramatically different methodologies and achieving the same resulting gravitational waveforms. The first simulations with non-equal masses, and with spins, followed quickly. Numerical relativity is currently in an era of much activity and rapid progress, on a broad front.



To carry out this test, we must be able to compute the burst from merger and ringdown by solving Einstein's equations numerically. Such numerical simulations should start with the final few orbits of the black holes and then proceed into their plunge and merger, signaled by the formation of a single horizon, and continue through the ringdown of the remnant black hole. This has proved to be a very difficult undertaking, with attempts going back more than 30 years. Until 2005, the simulation codes were beset with many difficulties, including instabilities that caused the codes to crash before the evolution reached even one orbital period. Fortunately, a

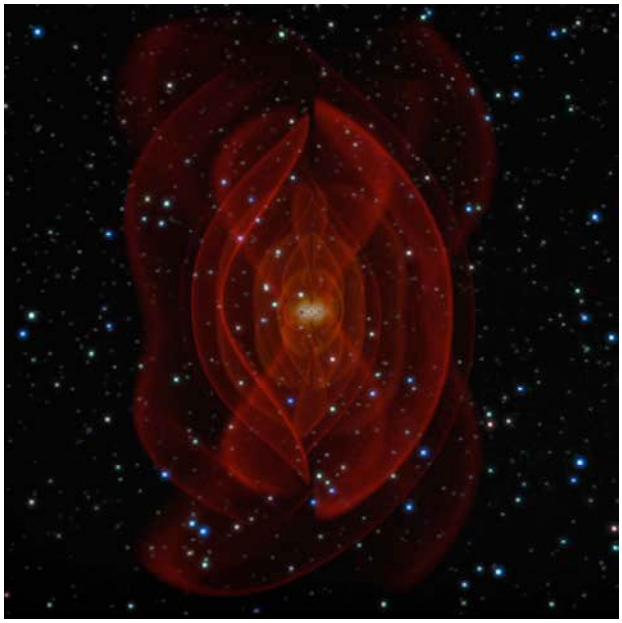


Figure 4-4 Gravitational waves from a numerical simulation of a binary black hole merger. The black holes are still separated in this frame and the gravitational waves are shown as the reddish contours.

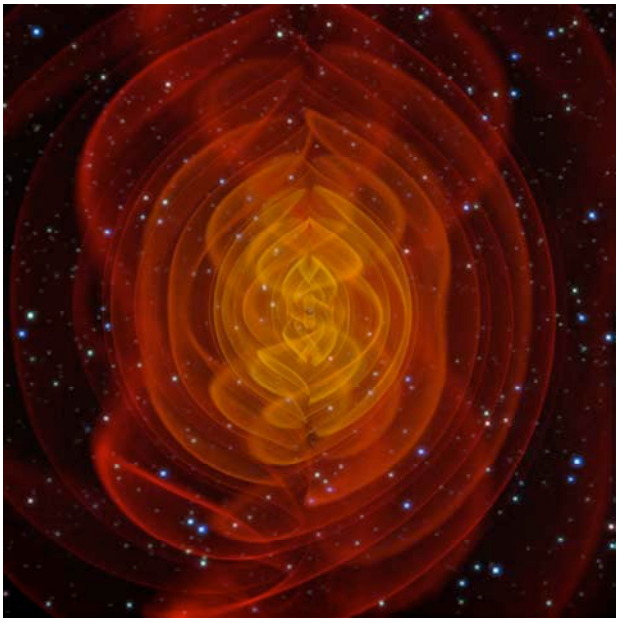

Figure 4-5 Here the black holes have merged and the resulting gravitational waves have increased in intensity, shown by the yellow and orange contours.

series of remarkable breakthroughs has occurred recently; see sidebar. With the development of new methods for evolving black holes on numerical grids, several groups can now evolve black hole binaries for several orbits and then through plunge, merger, and ringdown. So far, three groups have computed gravitational waveforms from the merger of two equal-mass, non-spinning BHs, and they all get the same simple shape shown in Figure 4-1 (Baker, Campanelli & Pretorius 2006). In addition, there is consensus that the merger of two equal-mass Schwarzschild BHs produces a final remnant BH with spin $J \sim 0.7GM/c$. Figures 4-4 and 4-5 are visualizations of the merger and emitted waves; Figure 4-1 is the waveform with superposed LISA noise.

Simulations of binaries in which the black holes have equal masses and spins, and non-equal masses but no spins, have also been carried out. Numerical relativity is now in an era of rapid progress, and it seems reasonable to expect that BH mergers with unequal masses and generic spins will be amenable to numerical solution well before LISA flies. In short, recent theoretical breakthroughs in numerical relativity expand the science that LISA can do, making LISA especially timely.

The ringdown stage: BH spectroscopy

Though numerical relativity waveforms from colliding holes naturally include the ringdown waves, those waves are well understood analytically. GR predicts are that every "excited" black

hole settles down to a stationary state, characterized entirely by its mass, spin and angular momentum[3], through the emission of gravitational radiation. These ringdown waves consist of a superposed set of BH quasi-normal modes (QNMs), waves with exponentially damped sinusoidal time dependence, plus a far weaker "tail" that decreases as (1/time)[6]. The modes are strongly damped as the mode energy is radiated away to infinity, so the final ringdown stage will be brief, lasting a few cycles

The quasinormal modes (QNMs) of Kerr black holes can be solved for using perturbation theory. That is, the spacetime metric is written as the Kerr metric plus a small perturbation, and Einstein's equations are expanded to first-order in that perturbation. The solutions can be decomposed into a sum of eigenmodes with complex eigenfrequencies. It was discovered in the 1970s that the partial differential equations for the eigenmodes/frequencies of Kerr BHs can be fully separated (*i.e.*, reduced to ordinary differential equations), so they are known to essentially arbitrary accuracy. While there are a countable infinity of these modes (corresponding to the angular order and overtone of the perturbation from the stationary state), the lowest order modes are the most readily excited and the most weakly damped; in practice only a few modes are likely to be observed. The frequencies and damping times of these ringdown QNMs are completely determined by the mass and angular momentum of the final, merged MBH.

We note that if two different QNMs are detected in a ringdown, then the ringdown radiation itself provides a test of strong-field GR and the hypothesis that the central massive objects in galactic nuclei are really Kerr BHs. The reason is that from two modes one measures four parameters (the frequencies and damping times of both modes), which must all be consistent with SAME mass and spin values (Dreyer 2003). Thus, in the same way that we can identify chemical elements through their spectroscopic fingerprint, so we can uniquely identify a BH (*i.e.*, determine its mass and spin) from the spectrum of its ringdown radiation. On the other hand, if the observed radiation arises from a different source (*e.g.*, a boson star), or if general relativity does not correctly describe gravity in the extremes of strong fields and dynamical spacetimes, the spectrum would very likely be inconsistent with that predicted by general relativity for black holes.

Extreme-Mass-Ratio Inspirals: Precision Probes of Kerr Spacetime

Introduction

Observational evidence for the existence of MBHs at the centers of galaxies is currently based on modeling the gravitational potentials of these objects using the motions of stars and gas, and comparing the results with those expected if the central object were a black hole. The best case today comes from stellar motions near the center of our galaxy, which reveal the presence of a compact dark object of mass $M \sim 4 \times 10^6 M_\odot$; stellar orbits show the central mass to be point-

[3] And electric charge, though for astrophysical black holes the charge has a negligible effect on the spacetime structure.

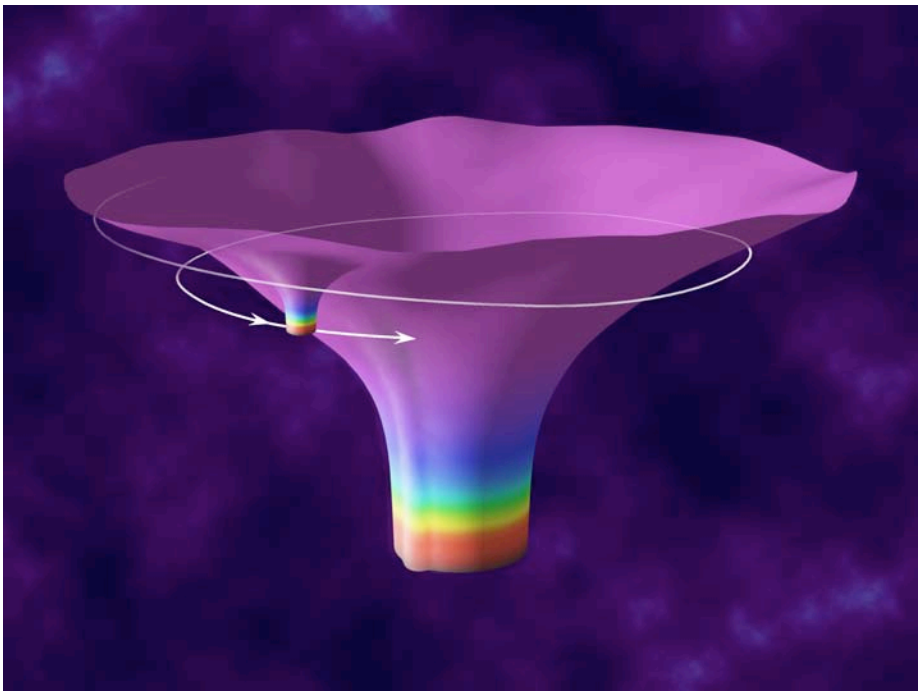

Figure 4-6 Embedding diagram of an EMRI, with the smaller black hole orbiting in the spacetime of the larger black hole. The colors depict the slowing of time (the "lapse" function) as one nears the horizons and the shape depicts the geometry of space in the orbital plane.

like down to a scale of $\sim$ 100 AU. LISA will map the structure of MBH spacetimes on length scales $\sim 10^4$ times smaller - the size of the horizon.

An inspiraling binary with one body much less massive than the other is referred to as an extreme-mass-ratio inspiral (EMRI). In the LISA context, the larger body is a $\sim 10^5 - 10^7 M_\odot$ MBH and the smaller one a stellar-mass compact object (white dwarf, neutron star, or stellar-mass BH) or perhaps an intermediate-mass BH, with mass $\sim 10^3 M_\odot$. Thus LISA EMRIs will have mass ratios $10^{-2} \lesssim m_2/m_1 \lesssim 10^{-7}$. While white dwarfs, neutron stars and BHs should all reach the event horizon of a MBH before being tidally shredded, the best current estimates are that inspirals of $\sim 10\ M_\odot$ BHs will dominate the LISA detection rate (both because mass segregation concentrates them more strongly near the MBH, and because, being more massive, they produce a stronger signal and so can be seen to greater distance). Therefore in this section we concentrate on the $\sim\ 10\ M_\odot$ BH case, shown in Figure 4-6, (but with the small hole enlarged in size for easy visualization).

Even the closest EMRI will yield a signal too weak to be immediately visible above the LISA noise, so matched filtering will be necessary to dig EMRI signals out of that noise. Fortunately, the matched filtering signal-to-noise scales like the square root of the number of observed GW cycles, and LISA will observe each EMRI for a timescale of order years, or equivalently for of order 10^5 cycles, so the matched filtering signal-to-noise will be a factor $\sim$ 300 higher than the instantaneous signal-to-noise. Unfortunately the number of independent year-long templates is so vast that straightforward matched-filtering, using a grid of templates densely covering the entire parameter space, will not be feasible computationally, and one will likely have to resort to filtering that is suboptimal (compared to straightforward Wiener filtering), but more computationally efficient. The best current estimate is that EMRIs with (total, matched-filtering) signal-to-noise > 30-35 will be detectable with such methods (Gair *et al.* 2004). Then a

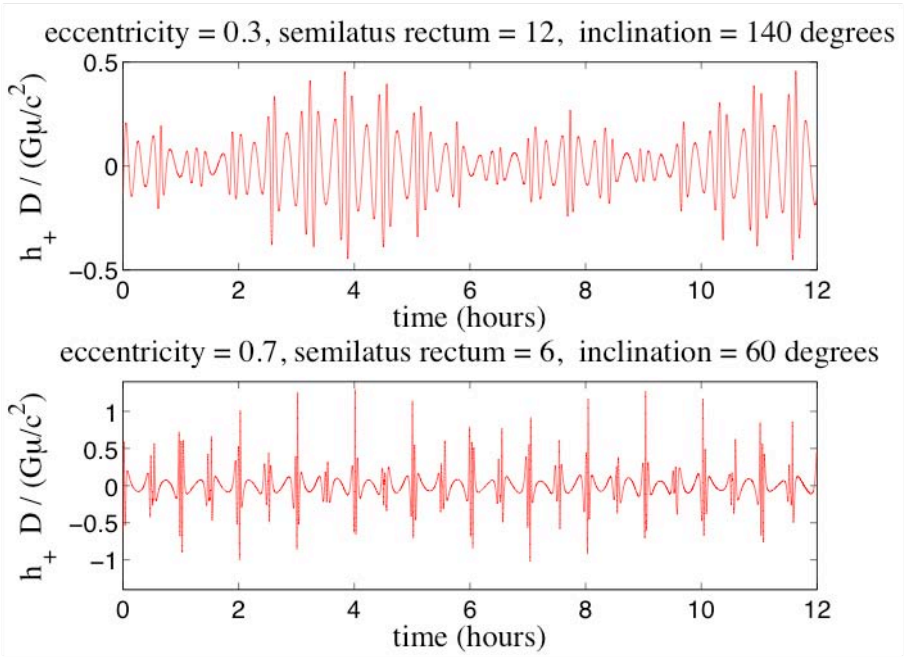

Figure 4-7 Segments of generic EMRI waveforms (Drasco & Hughes 2006); These are the plus-polarized waves produced by a test mass μ orbiting a $10^6 M_\odot$ black hole that is spinning at 90% of the maximal rate allowed by general relativity, a distance D from the observer. The two panels correspond to different configurations of the test mass' orbit, characterized by the shown parameters. The top panel assumes a slightly eccentric and inclined retrograde orbit modestly far from the horizon. The bottom panel assumes a highly eccentric and inclined prograde orbit much closer to the horizon. The amplitude modulation visible in the top panel is mostly due to Lense-Thirring precession of the orbital plane. The bottom panel's more eccentric orbit produces sharp spikes at each pericenter passage.

$10\,M_\odot$ BH spiraling into an MBH will be observable by LISA out to $z\sim1$. Given the current best estimate for the rate of BH inspirals in the Milky Way ($\sim 2.5\times10^{-7}$/yr; Hopman 2006), and extrapolating this rate to the rest of the Universe, leads to a LISA detection rate of ~ 50 - 100/yr, with the strongest sources having (matched-filtering) signal-to-noise > 100 (Gair *et al.* 2004).

The EMRIs are expected to be very clean astrophysical systems (except perhaps in the few percent of galaxies containing active galactic nuclei, where interactions with the accretion disk could possibly affect the dynamics). Over timescales of order a day, the orbits of the smaller body are essentially geodesics in the spacetime of the MBH. On longer timescales, the loss of energy and angular momentum due to gravitational-wave emission causes the smaller body to spiral in; *i.e.*, the geodesic's "constants" of integration change slowly over time. For LISAs observation time (of order years), the orbits are highly relativistic (radius < 10 Schwarzchild radii) and display extreme forms of perihelion precession and precession of the orbital plane due to dragging of inertial frames by the holes spin. Figure 4-7 shows two sample waveforms, corresponding to short stretches of time.

To correctly model the orbit over timescales longer than ~1 day, one must include gravitational radiation reaction, which causes the small body to lose energy and angular momentum. The natural approach to this problem is to take advantage of the tiny mass ratio m_2/m_1 and use perturbation theory; *i.e.,* treat the small body as producing a metric perturbation on the spacetime of the MBH. It is simplest to model the small body as a point particle, so one can ignore its internal structure [as was justified by the work of Mino *et al.* (1997)], but the cost of this simplification is that the perturbed metric diverges at the location of the particle, and so

the radiation reaction force must be regularized. A general (and quite beautiful) regularization prescription was given independently by Mino *et al.* (1997) and Quinn & Wald (1997), but implementing their prescription numerically has been a challenge. How to do so is at once a fascinating question in pure general relativity and a practical requirement for deriving the maximum science possible from LISA. It is therefore a very attractive problem for a relativist to work on, and a highly talented community of ~ 25 relativists is now heavily engaged in this subfield. Recently, Mino (2005) has suggested a relatively simple and practical solution to this problem, based on calculating the average effect of radiation reaction over many orbits rather than the instantaneous self-force. It is not yet clear whether Mino's proposal will yield waveforms that are sufficiently accurate for LISA's purposes, but, if not, there is also a well-developed alternative: Barack & Ori (2003) have developed a mode-sum numerical procedure for regularizing the self-force, and its effectiveness has been demonstrated for circular orbits in Schwarzschild, where the results can be checked using simpler methods (Barack & Lousto 2005). Therefore it seems very likely that theorists will provide extremely accurate EMRI template waveforms well before LISA flies.

Given the very large number of EMRI GW cycles that accumulate over a year of LISA observations (~ 100,000), a fit of the observed gravitational waves to theoretically calculated templates will be very sensitive to small changes in the templates physical parameters. As mentioned above, this sensitivity makes the search computationally challenging, but it allows extremely accurate determination of the source's parameters, once an EMRI signal is identified. For example, (assuming that GR is correct and the central massive object is a Kerr BH), LISA should be able to determine the mass and spin of the MBH to fractional accuracy $\sim 10^{-5} - 10^{-3}$ (Barack & Cutler 2004).

EMRI tests of the Kerr-ness of the central massive object in galactic nuclei

This level of precision suggests that we can do more — use the EMRIs as a highly precise observational test of the "Kerr-ness" of the central massive object. That is, if we do NOT assume that the larger object is a black hole, we can use gravitational waves from an EMRI to map the spacetime of that object. The spacetime outside a stationary axisymmetric object is fully determined by mass moments M_l and current multipole moments S_l. The mass moments tell us about the distribution of mass and energy in the source; they are analogous to electric charge moments in classical electricity and magnetism. The current multipole moments about the *motions* of mass and energy; they are analogous to magnetic moments. Since these moments fully characterize the spacetime, the orbits of the smaller object, and the gravitational waves it emits, are therefore determined by the spacetime multipolar structure. By observing these gravitational waves with LISA we can characterize the spacetime of the central object.

Indeed, Ryan (1995) showed that for inspiraling trajectories that are slightly eccentric and slightly non-equatorial, *in principle* all the multipole moments are redundantly encoded in the emitted gravitational waves, through the time-evolution of the orbit's three fundamental frequencies. Basically, these are the fundamental frequencies associated with the r, θ, and ϕ motions

(Drasco & Hughes 2004), or, equivalently, the radial frequency and the two precession frequencies. Extracting the moments from EMRI waves is analogous to geodesy, in which the distribution of the earth's mass is determined by studying the orbits of satellites. Black hole geodesy – also known as bothrodesy – is very powerful because Kerr black holes have a very special multipolar structure. A Kerr black hole with mass M and spin parameter a (in units with G=c=1) has multipole moments given by $M_l + iS_l = M(ia)^l$. Thus, $M_0 = M$, $S_l = aM$, $M_2 = -a^2 M$, and similarly for all other multipole moments; they are all completely determined by the first two moments, the black hole mass and spin. This is nothing more than the "no hair" theorem for black holes: a black hole's properties are entirely determined by its mass and spin.

How accurately can M_2 be extracted from an observed EMRI signal, independently of M and S_l? It was recently estimated that M_2 could be measured to within $\Delta M_2 \sim 10^{-2} - 10^{-4} M^3$ (Barack & Cutler, in preparation), along with $\Delta M/M$ and $\Delta S_l/M^2$ to $10^{-5} - 10^{-3}$. Thus the standard picture for the central massive object — a Kerr BH described by GR — makes a definite prediction regarding M_2, which can be checked to very high precision using EMRI data. Any inconsistency with the Kerr relation could signal a failure of GR, or the discover of a new type of compact object, or some surpisingly strong perturbation from other material or object.

Other tests of the Kerr-ness of the central massive object have also been proposed. Kesden *et al.* (2005) have argued persuasively that one can use EMRI waves to distinguish definitively between a central MBH and a boson star. In the BH case the GW signal "shuts off" shortly after the inspiraling body reaches the last stable orbit (and then plunges through the event horizon), while for a massive boson star, the signal gets prolonged, and its frequency derivative changes sign, as the body enters the boson star and spirals toward its center.

The above tests take the standard model of the central object (a Kerr BH described by GR) and either 1) compare it with a different model (*e.g.*, a boson star) or 2) embed that model in a larger one with extra free parameters (*e.g.*, Kerr, but with arbitrary quadrupole moment), and ask whether the best fit to the data is consistent with Kerr values for the extra parameters. These are all essentially comparison tests. There seems to be no unique or optimum way of constructing such tests —basically because today there is no compelling alternative to general relativity to compare against it. Nevertheless, tests of this sort would be very useful in either cementing confidence in the standard picture, or homing in on discrepancies.

But precisely because there is no compelling alternative to GR today, it is important to also consider other ways of "confronting GR" with EMRI data, which do not involve comparison with (perhaps somewhat *ad hoc*) alternatives. For instance, one could break an observed EMRI signal into, say, four consecutive pieces (each piece with signal-to-noise $\sim 100/\sqrt{4} = 50$), and estimate the binary's physical parameters from each piece separately. It is clear that very precise estimates of both BH masses and the MBH spin could be obtained from each segment, and all four segments must yield the same parameters, within the error bars. It is clear that inter-segment comparison would yield a quite precise test of the null hypothesis that the central massive object is indeed a Kerr BH. Other tests of a similar nature could easily be formulated.

Bounding the mass of the graviton

From LISA observations, it should be possible to improve significantly on the current Solar System bound on the graviton mass: $m_g < 4 \times 10^{-22}$ eV. Two different methods for bounding have been proposed. The first method is based on LISA observations of WD binaries. A large fraction of the gravitationally strongest WD binaries will be eclipsing, so optical observations will tell us the instant when, as seen from Earth, one body is (almost) directly behind the other. This is also the instant, when the (square of) the gravitational-wave strain field goes through a minimum, assuming that the gravitons and photons propagate at the same speed. However if gravitons and photons travel at different speeds, due to a non-zero graviton mass m_g, there will be a phase delay between the optical and gravitational signals. By bounding this phase delay, one bounds m_g. A single binary should be sufficient to set a limit of $m_g < 10^{-22}$ eV. With N such sources, the bound should decrease like $N^{-1/2}$, and N should be order 100, so a bound of $m_g < 10^{-23}$ eV could be achieved this way (Cooray & Seto 2004). (Note the bound from any binary is independent of its distance, D; doubling D would double the delay for any m_g but the error bar on the phase delay also doubles, since the signal-to-noise is halved.)

The second method is based on measuring the phase evolution of MBH inspiral signals. This phase evolution is predicted rather precisely by high-order post-Newtonian calculations. However if $m_g > 0$, the higher-frequency gravitational waves emitted late in the inspiral travel faster than the lower-frequency waves emitted earlier, and to some extent "catch up" with them. Since MBH inspirals are much stronger GW emitters than WD binaries, this leads to a correspondingly stronger bound: $m_g < 10^{-25}$ eV (Berti, Cardoso & Will 2006).

LISA Science Objectives and Investigations relevant to this section

(see Appendix 1)

5. Confront General Relativity with observations

5.1. Detect gravitational waves directly and measure their properties precisely.

5.2. Test whether the central massive objects in galactic nuclei are the black holes of general relativity.

5.3. Make precision tests of dynamical strong-field gravity in massive black hole binaries.

5. Precision Cosmometry and Cosmology

Precision cosmometry is defined as the art of making precision measurements of the world or the Universe. The measurement of distance forms the foundation for much of astronomy and cosmology. An example is the Hubble constant which has had a history of refinement spanning decades. LISA has the potential to make fundamental contributions to precision cosmometry with its ability to provide gravitationally calibrated distances to sources with a 3% accuracy or better.

Using precision cosmometry for cosmology

LISA measurements of waveforms from black hole binary merger inspirals yield gravitationally calibrated, absolute distances to high redshift. The individual raw absolute precision for a single event ranges from typically about 0.2% to 0.4% at a redshift $z = 1$ to 1% to 3% at $z \approx 3$ to 5. The absolute physical calibration, high per-event precision, and large redshift range all represent new and unique capabilities. A redshift-distance relation with this approach requires identification of the host galaxy to obtain a redshift independently, and additional errors are added by weak lensing noise at high z. Even a small number of events at $z < 1$ may allow LISA to measure the Hubble constant to about better than 1% accuracy, and together with events at higher redshifts may probe global curvature and cosmic dark energy with a precision comparable with other methods. The technique complements other methods; their combination provides unique information about the new physics of dark energy, and new tests of concordance cosmology.

Precision cosmology characterizes the structure and behavior of the Universe as a whole: its global curvature, its expansion with time, and the behavior of perturbations. The global curvature of space is a relic of the earliest observable moments of inflation and carries information about the initial conditions of the Universe; cosmic expansion history tests models of the new physics of dark energy; and cosmological perturbations test the dynamical predictions of general relativity on the largest scales. More than simply mapping our Universe, precision cosmology explores in detail the behavior of space, time, matter and energy at the opposite extremes to black holes: the lowest density, the largest scales, and the earliest times.

For the most powerful tests we seek not only high precision, but also a variety of different cosmometric techniques that measure global spacetime in different ways (see "Cosmology Primer" box). Precision measurements of cosmic microwave background (CMB) anisotropies (from COBE, balloon- and ground-based experiments, WMAP [Spergel *et al.* 2006], and in the future, Planck) set the highest standard of quality: CMB now reliably determines certain combinations of cosmological parameters with precision at a level of a few percent. Combining other types of measurements with the CMB data breaks degeneracies in fundamental quantities, increases reliability by controlling systematic errors, probes recent expansion where dark energy dominates, and allows deeper questions to be asked: for example, whether dark energy varies with time or reflects a pathology in the theory of gravity on large scales (rather than a new form of energy).

Key science questions

- What is the nature of dark energy?
- What is the global geometry of the Universe?
- What is the Hubble constant?
- Can redshifts be determined from electromagnetic observations by identifying the host galaxies of black hole merger events.

A cosmology primer

Precision cosmology aims to measure the global properties of our spacetime: the geometry (and statistical fluctuations) of the temporally evoloving, nearly spatially uniform 4-dimensional manifold that best represents all of the Universe that we can see. This geometry contains information about the curvature of 3-space, thought to be a relic of how the Universe began, and about the character of the average mass-energy content of the Universe over time.

Abundant evidence indicates that the Universe on the largest scales is nearly homogeneous and isotropic: on a large scale average, it is statistically the same everywhere and in all directions. Such a smooth, symmetric universe can be visualized as a uniform 3D space (which may have a uniform positive, flat, or negative spatial scalar curvature k/a^2, as specified by a curvature parameter k=1,0,-1), that uniformly changes size with time according to a cosmic scale factor $a(t)$. Referred to the present, the size is inversely proportional to a dimensionless ratio (1+z) where z is called the redshift. Points "at rest" in this space appear to recede at a speed cz proportional to their distance with physical rate of recession per unit separation given by the Hubble parameter $H(t) = \dot{a}/a$.

Einstein's equations relate the evolution of a to the mass-energy density and curvature:

$$\left(\frac{\dot{a}}{a}\right)^2 \equiv H^2 = \frac{8\pi G}{3}\sum_i \rho_i - \frac{kc^2}{a^2}$$

where the mass-energy is divided here into components i with density, ρ_i. As the Universe expands, the matter and energy spread out. Furthermore, if a component has a significant pressure (momentum flux) p_i, the work done during the expansion changes its internal energy. Local energy conservation gives:

$$\dot{\rho}_i = -3H(1+w_i)\rho_i,$$

where $w_i \equiv p_i/\rho_i c^2$ is the equation of state parameter for each component. For discrete components with constant w_i, the evolution of the scale factor can be written

$$H(a)^2 = H_0^2 \sum_i \Omega_i \left(\frac{a_0}{a}\right)^{3(1+w_i)}$$

where H_0 denotes the present-day Hubble constant, and the Ω_i represent the present-day densities of mass-energy components in units of the so-called critical density,

$$\rho_c = (3/8\pi G)H_0^2.$$

The history of the expansion of the Universe reflects both its geometry and composition. The sum includes a term Ω_k with w_k=-1/3 representing the dynamical effect of spatial curvature, components describing radiation (with w_k=1/3), and nonrelativistic (baryonic and cold dark) matter (with w_m=0). Of particular interest is the value of w_{DE} (or more generally, $w_{DE}(t)$) which reflects the physical character of mysterious cosmic dark energy. Current data suggest that the Universe is dominated by dark energy ($\Omega_{DE} \sim 0.74$), and w_{DE} is constrained at about the ten percent level by relative supernova distances (Astier *et al.* 2006), w_{DE} = -1.023 ± 0.090(random) ± 0.054(systematic). Einstein's cosmological constant Λ, corresponding to the gravitation of a uniform physical vacuum, has w_Λ=-1, with no t dependence. Precise data are capable of discovering whether the dark energy is consistent with an Einstein Λ or other models of $w_{DE}(t)$, estimating the other parameters including Ω_k, and testing whether general relativity is an accurate description of global behavior. Some techniques (such as relative distance distances from Type Ia supernovae or other standard candles, or gravitational lenses with time delays) measure the global spacetime metric directly via photon propagation. Others (such as weak gravitational lensing by intergalactic dark matter perturbations, or surveys of high redshift galaxy clusters) also measure the response of the smooth metric to mass density perturbations via the growth of structure. A few techniques offer absolute physical calibration of distances; these include Sunyaev-Zeldovich mapping of plasma in galaxy clusters, and, more precisely, mapping of the galaxy correlations imprinted by acoustic oscillations of baryons in the baryon/radiation plasma before recombination. The most precise data at present, the anisotropy spectrum of the microwave background, constrains most directly the behavior of the plasma/dark matter system at high redshift, as well as global light propagation and is most powerful when combined with one or more other techniques that probe the nearby Universe.

LISA will use gravitational wave propagation to obtain absolute, gravitationally calibrated luminosity distances, a combination of attributes not shared by any other technique. Even a small number of absolute distances measures H_0, a measurement of central importance. LISA/BHB constraints are similar to the absolute calibration provided by Baryon Acoustic Oscillation technique, but provide a pure-physics calibration not reliant on cosmological models; by combining these two techniques, new constraints can be placed on "dark radiation" such as new types of relativistic particles.

Improved precision in measurements of other quantities, such as absolute and relative distances, growth of structure and fluctuation power spectrum have thus emerged as a top priority of cosmological research. Over the next decade several large programs are being carried forward with this goal (NRC Committee on the Physics of the Universe 2003, Albrecht *et al.* 2006). Each of the proposed techniques has complementary strengths, weaknesses, sources of systematic errors and physical and astronomical assumptions, and thus it is prudent to pursue all of them.

Unique features of black hole binary distances compared with other techniques

LISA's distance measurements to black hole binary (BHB) mergers will independently and precisely measure absolute distances in an entirely new way. Among all the techniques used for cosmological measurement, BHB is unique in several ways, being:

- Physically calibrated assuming only general relativity (no astronomical assumptions about system configuration or environment);
- Absolutely calibrated (a true physical distance in laboratory units based only on gravity — not a distance ratio to an astronomically defined reference);
- Of very high intrinsic precision (ranging from 0.2% to 3% for a single event at $1 < z < 5$); and
- Useful over a very wide range of redshift (detectable BHB

A special challenge is calibration of the large-scale cosmos to absolute (ultimately, laboratory) standards of length or time. Such measurements allow globally-measured quantities (such as CMB angles and galaxy redshifts) to be connected to locally-measured quantities, such as the temperature of the cosmic microwave background, cosmic chronometers, and element abundances. Traditionally this absolute calibration employs a cosmic distance ladder, using direct geometrical parallax measurements of nearby stars to calibrate indirect measures for larger distances, in a series of steps extending to cosmological scales. Other absolute calibrators are now becoming competitive but present major challenges in systematic reliability and precision, and require a variety of assumptions — again, requiring multiple approaches for a robust result (see box on “Absolute Distance Calibration”).

LISA will add a unique and complementary new tool: absolutely calibrated distances determined by measuring the waves generated by massive binary black hole inspiral. Previous sections provide detailed discussion of these waves; for our purpose here, the main point to note is that measurement of these inspiral waves makes it possible to directly determine the luminosity distance to a source with a relative precision that can be as good as 0.1%. The main weakness of this tool relative to other techniques is the still-uncertain number and redshift distribution of events that can provide useful distances, as discussed below. For several applications, the need to identify a host galaxy and corresponding redshift may limit the applicability of this technique. On the other hand the intrinsic precision may be higher than any other technique, possibly in some respects even better than the CMB, and it brings an absolute physical calibration based on gravity alone, unlike any other technique. Even with a small number of events, the unique features of black hole binary inspirals — their reliable absolute calibration, inherent precision, and large range — introduce a new capability that promises to make all other precision measurements more robust and informative.

Absolute cosmometry with black hole binaries

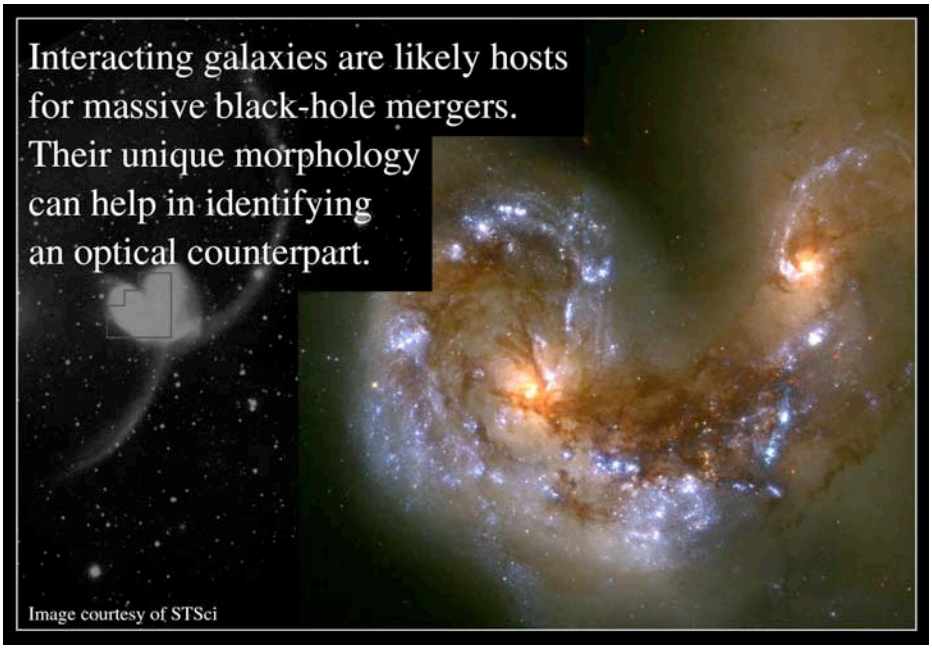
The principle of estimating distances from measured waveforms is elegantly simple (Schutz 1986): the chirping time τ of an inspiral/merger event, together with its orbital frequency ω and strain h, gives an absolute luminosity distance $D \approx c/\omega^2 \tau h$, with a numerical factor depending on details of the configuration that are precisely determined by the measured waveform. (As explained in previous sections, roughly speaking, the directly measured redshifted chirp mass tells the redshifted final absolute Schwarzschild radius, and the ratio of that length to the luminosity distance is the metric strain, h.)

LISA is synergistic with deep multiband imaging, synoptic monitoring, and deep multiobject spectroscopy. LISA data and electromagnetic data will rely on each other and will be used iteratively to create a more powerful probe than either on its own, both of precision cosmology and of the behavior of galactic stars and gas surrounding massive black holes. LISA waveforms provide a final level of precision better than any other technique but require supporting electromagnetic data to get there.

However, as discussed in detail in Section 2, *LISA Mission Overview*, LISA measurements cannot independently determine the redshift of a source. In gravitational wave measurements, the source's intrinsic frequency and chirp time are always measured in combination with cosmic redshift: $\omega = \omega_{int}/(1+z)$, $\tau = (1+z)\tau_{int}$. The redshift is always degenerate with the source's intrinsic parameters, and cannot be determined from the GW data alone. An independent measurement of redshift is therefore needed. This may be accomplished by getting the optical redshift to the host galaxy, for instance by identifying an electromagnetic radiation counterpart to the event.

If a cosmological model is assumed, then a redshift can be inferred self-consistently by requiring agreement between the estimated distance and that predicted from the cosmology. Thus to the extent that cosmological parameters are roughly known, only a certain narrow range of redshift is allowed for the host. Once a host is identified, the precise direction allows a still more precise estimate of distance from LISA. Thus LISA data will be used iteratively and synergistically with electromagnetic data where these are available, to achieve maximal precision.

Identification of the host galaxy to a merger event can occur in many different ways. For an unusually nearby ($z < 1$) event with large black hole mass and signal-to-noise ratio, the LISA error box in angle and redshift might contain fewer than a thousand candidate galaxies, and the host might be easily identified from large scale optical morphology (such as tidal tails) as the site of a recent merger event. More typically, the error box contains of order ten thousand galaxies, and the merger event may not be associated with a major visible disruption; in many cases the redshift is also very high, making optical identification difficult. On the other hand, models suggest that the same merger that creates a black hole binary often sends interstellar gas raining into the new galaxy nucleus, and the same gas that helps the two holes dissipate energy and momentum as they sink towards each other also forms a bright infrared nuclear starburst. For



large binary mass ratios, and total binary masses at the upper end of the range of expected LISA BHB events (more than about $10^6 M_\odot$), the starburst is expected to still be active when the merger event occurs (Dotti *et al.* 2006). Such starbursts will be visible to very high redshift with JWST, and observations in the infrared penetrate deeply even into highly obscured nuclei.

An even more distinctive signature to identify the host galaxy may come from responses of the material near the black holes' horizons to the merger event, which can lead to observable time-variable X-ray/UV emission from the galactic nucleus, modulated by the evolution of the potential as the inspiral progresses. (In the case of obscured nuclei, the time variations may appear in reprocessed infrared emission.) For most LISA-observable holes (less than a few million $M_\odot$), gas accretion disks are evacuated during the merger process but then reestablish emission within a few years, causing an "afterglow" — a newly observable X-ray source (Milosavljevic & Phinney 2005). For higher mass holes, the interaction of accretion discs as the holes approach each other can lead to observable, variable X-ray precursors to the merger event (Dotti *et al.* 2006). If the two holes have disks and/or black-hole-spin-powered jet emission, the disrupted disks and jets can show nonthermal signatures that may appear from radio to gamma rays. Recent evidence of low power AGN (presumably from low mass holes) suggest that such evidence may not be at all rare or unusual. Only a tiny fraction (much smaller than $\sim 10^{-10}$) of the variable gravitational energy of the system needs to appear as a variable electromagnetic signal to be clearly visible.

At redshifts significantly less than unity, the relevant inspiral events consist of a compact stellar mass or intermediate mass black hole (IMBH) captured by a massive black hole in a galactic nuclei. These events will be extremely large mass ratio inspirals (see section on EMRIs). The signal-to-noise ratio and per-event precision are not as high for these as for binaries of comparable mass, but are still possibly good enough (a few percent per event, possibly for hundreds of events) for precision measurement of H_0. Even if electromagnetic counterparts for EMRIs are not found, adequate redshift calibration for a large sample might be obtained statistically from galaxy surveys in the LISA error boxes.

Absolute Distance Calibration

One of the most important sources of error in constraining global parameters at present is the determination of the absolute cosmic distance scale at low redshift, the Hubble constant H_0. This is not well constrained by CMB measurements, which provide an absolute ruler at high redshift, the sound horizon size at recombination r_S=147.8 ± 2.6 Mpc. The CMB data confine models to a narrow degeneracy line, well approximated by Ω_k = -0.3040 + 0.4067 Ω_Λ (Spergel *et al.* 2006) but do not distinguish well between points along this line. A precise measure of absolute distance, even at low redshift, narrows the allowed region to a small interval on this line. With the HST Key Project estimates of H_0, WMAP yields Ω_k =-0.003 ± 0.015, with the error dominated by H_0.

The best distance ladder estimate, the HST Key Project value for the Hubble constant H_0 = 72 ± 8 km/s/Mpc (Freedman *et al.* 2001), still has an uncertainty of more than ten percent. The possibility of systematic errors in this value cannot be completely ruled out, as perhaps suggested by other different HST estimates (Sandage *et al.* 2006) [H_0 = 62.3 ± 1.3 (random) ± 5.0 (systematic) km/s/Mpc] and by recent evidence of a low value ≈ 61 km/s/Mpc from independent Cepheid calibration via eclipsing binaries (Bonanos *et al.* 2006). Other absolute calibration techniques include gravitational lens time delays, and Sunyaev-Zeldovich observations of hot gas in galaxy clusters. So far the systematic errors in these techniques have prevented reliable precision at better than the ten percent level.

A new promising technique now emerging uses very long baseline radio observations of proper motions of distant megamasers in disk galaxies; this method is essentially geometrical, with some assumptions about orbit configuration and motions. Currently the formal error from this method [H_0 = 74 ± 3 (random) ± 6 (systematic) km/s/Mpc based on one object still tied to Cepheids rather than distant Hubble flow (Macri *et al.* 2006)] is comparable to the Key Project error. As more objects are observed in the coming decade, the megamaser technique may achieve a precision at the few percent level at sufficiently large distances that Cepheids or other secondary calibrators will be unnecessary.

The Baryon Acoustic Oscillation (BAO) technique also provides an absolute calibration, based on the known physics of the dark matter/baryon-radiation plasma system around recombination. Currently it offers precision at the 4% level (Eisenstein *et al.* 2005), with prospects for improvement from a larger sample size. This calibration depends on precise understanding of the matter/radiation energy ratio, largely constrained by CMB.

LISA's calibration is based only on the physics of gravitational waves, without reference to cosmological contents, detailed properties of astronomical systems, such as history or environment, or even Standard Model physics. (All of the relevant parameters of the inspiralling black holes can be measured from the waveform and ultimately connect to laboratory measurements of Newton's G and speed of light c). For a single object, the main source of error is noise from gravitational lensing, which can change the measured h and therefore inferred distance by an amount that is unknown for each individual object. This effect is partially correctable using a statistical sample and in any case is small at $z < 1$.

By measuring the inspiral waves, particularly in the case where binaries are of comparable mass, LISA will pinpoint many events to better than a degree (in some cases, much better). LISA will also be able to predict the time of merger well in advance (often, hours to weeks), allowing searches for precursors and afterglows, as well as emission associated with the moment of the merger itself. In general, finding and studying electromagnetic signatures from an active inspiral/merger nucleus requires deep imaging over a wide (~ degree) field, in multiple wavebands. The time variable signatures require sampling on a timescale as long as intervals of years, down to a time resolution scale as short as the ~ 1000 second orbital period. Fortunately, such capability is being created in many bands, including large infrared arrays on large aperture telescopes, extremely capable optical systems such as LSST (which will image galaxies to $z > 1$, in a field 4 degrees across, in less than a minute), extremely wide angle radio interferometry

(being demonstrated in systems such as the Allen Telescope Array), and new capabilities in space from the infrared (JWST) to gamma rays (GLAST).

LISA electromagnetic counterpart sources may provide a rich field of study, with many identifiable hosts and counterparts. LISA sources have possible electromagnetic counterparts over a wide variety of wavebands and timescales: potentially, an exploratory bonanza providing access to new phenomena over a huge range of scales. On the other hand given our ignorance about the processes in galactic nuclei associated with massive black holes and their mergers, it is also possible that the observable electromagnetic signatures may be very rare, in which case precision cosmology with these sources will be impractical.

Another important source of uncertainty is the rate of events, as discussed in Section 3, "Black hole astrophysics". Standard galaxy formation theory suggests that the first black holes formed from the first massive stars, in the first baryonic collapses at redshifts of order 20. Subsequent hierarchical clustering of halos leads to mergers of holes on successively larger scales, eventually forming the population of nuclear massive black holes found today in galactic nuclei. Detailed models of this process (Sesana *et al.* 2004, Volonteri 2006) predict that LISA will see many dozens of massive black hole merger events per year, spread over a range of masses from 10^4 to 10^7 solar masses and a range of redshifts from 1 to 20. On the other hand a more conservative model for the formation of the massive black holes, based only on observed populations of massive black holes, and allowing them to grow as much as possible via accretion rather than mergers, can produce rates an order of magnitude smaller. The total rate and redshift distribution makes a big difference in LISA's capability for precision cosmology. Similarly, the rate of EMRIs is highly uncertain (covering a similar range of possible rates), because of required extrapolation to nuclear stellar populations in galaxies where we have very limited information at present.

The most important practical limit on precision of distance measurements at high redshift comes from gravitational lensing, which can magnify and brighten an object, or demagnify it relative to the mean for a given cosmology, and thus bias its inferred distance. Because high precision is the goal, even small-amplitude modulation by weak lensing is a concern. This effect must be controlled at high redshift by using a statistical sample, as is done for example with supernova distance indicators. The overall precision thus depends on the BHB redshift distribution and event rates.

Impact of LISA/BHB distances: Examples

Since the BHB technique yields independent and physically calibrated absolute distances it complements other techniques of precision cosmology, many of which yield relative distances only, and all of which use different assumptions with radically different systematic errors and biases from BHBs.

The potential contribution of BHB to precision cosmology has not yet been evaluated as thoroughly as other tools, and is subject to the above uncertainties, some of which will not be

resolved until LISA flies. Nevertheless it is useful to cite several benchmark examples of potential impact:

- In a homogeneous universe, the BHB technique with realistic LISA capabilities and source parameters yields absolute distances with a raw per-event precision from about 0.2% to 0.4% at $z = 1$, to about 1% to 2% $z = 3$ to $z = 5$ (Holz & Hughes 2005), depending on the source properties; in some cases, even 0.1% precision is possible, as shown in Figure 5 -1 (Lang & Hughes 2006).

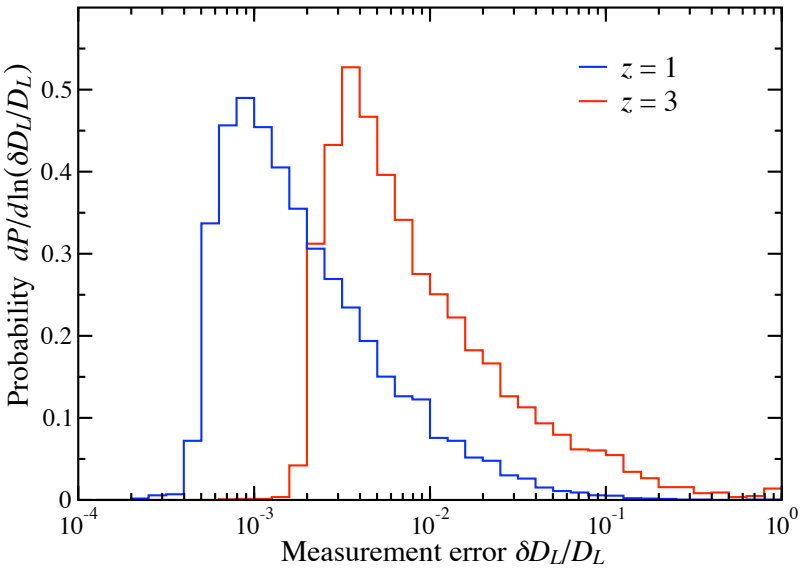


Figure 5-1: Simulated distribution of errors in BHB luminosity distances D_L at $z = 1$ (blue) and $z = 3$ (red), with black hole masses of 10^5 and $6 \times 10^5 M_\odot$, assuming that an electromagnetic counterpart allows precise sky position determination (Holz & Hughes 2005). Even at $z = 3$ most measurement errors are less than 2%.

- Since most lines of sight to $z < 1$ are nearly empty of dark matter, lensing errors are relatively small. A few massive inspiral events, or a large number of EMRI events, at redshift less than or of order unity may lead to a reliable measurement of the Hubble constant, H_0 to better than 1%, an order of magnitude improvement over current techniques. Absolute gravitational calibration adds unique information even if other techniques attain comparable formal precision with different assumptions.

- Calibration of the absolute distance scale, in combination with CMB measurements alone, and a definite scaling law for the dark energy *w(a)*, allows a determination of *w* with high precision (Hu 2005, Eisenstein & White 2004). With Planck quality CMB data alone, calibration of the Hubble constant at 2% precision achieves *w* accuracy of better than 3% (Olling 2007). Similarly, a one percent constraint on absolute distance, combined with the CMB data, yields $\sim 10^{-3}$ error on global curvature Ω_k (Knox 2006); in this respect the constraints are similar to those obtainable in the future from Baryon Acoustic Oscillations (Eisenstein *et al.* 2005). With both techniques (that is, LISA and BAO together), a new tight constraint can be derived on the density of any invisible relativistic species or "dark radiation" that affects the BAO calibration.

- LISA/BHB distances are also useful at moderate *z* (of order 2 to 3) if the BHB sample is large enough for fitting to a lensing amplification model. Even with conservative assumptions about lensing noise, a sample of 100 LISA/BHB events provides comparable precision to a sample of ≈ 3000 SNIa distances at comparable redshift (Dalal *et al.* 2006).

• The considerable number of events from higher redshift, out to $z \sim 20$, will provide measurements of black hole mass mergers as a function of distance and measurements of integrated weak lensing along multiple lines of sight to high redshift. The galaxy counterparts of these sources will be infrared galaxies, many of them in very early stages of assembly, and many of them potentially observable with JWST. LISA's observations will complement the revolutionary JWST views of early structure and galaxy formation, adding detailed information about the early growth of nuclear regions, massive black holes, and dark matter density fluctuations at high redshift.

LISA Science Objectives and Investigations relevant to this section (see Appendix 1)

6. Probe new physics and cosmology with gravitational waves

6.1. Study cosmic expansion history, geometry and dark energy using precise gravitationally calibrated distances and redshifts measured from electromagnetic counterparts or determined statistically.

6. Ultra-Compact Binaries

Summary

Close binary stars are double stars in which two compact objects such as white dwarfs and neutron stars, orbit each other in a short period. Binaries with orbital periods below a few hours emit gravitational radiation in the LISA band and are generally called ultra-compact binaries. They have relatively weak gravitational wave signals in comparison to massive black hole binaries, but are numerous in the Galaxy and even the Solar neighborhood. The prospects for LISA in this area of astrophysics are truly spectacular. Several thousand systems are expected to be detected individually, with their parameters determined to high precision, while the combined signals of the millions of compact binaries in the LISA band will form a well detectable background signal. This should be compared to less than 50 ultra-compact binaries known today. The shear number of detections will allow study of entire populations of binaries in such detail that not only the properties of this particular population can be determined, but through comparison with models, the formation of these binaries and thus many preceding phases in binary evolution can be strongly constrained. This has a strong bearing on our understanding of many high-energy phenomena in the Universe such as supernova explosions, gamma-ray bursts and X-ray sources as they share parts of the evolution history of the binaries detectable by LISA.

The number of sources in the LISA band also ensures that many of them can be detected at high signal-to-noise ratio (often larger than 100), allowing for detailed study of individual binaries. For many the

Key science questions

- Is general relativity the correct theory of gravitation?
- Is there a large population of ultra-compact binaries in the Galaxy?
- How did compact binaries form and what is the outcome of a common-envelope phase?
- What is the nature of the fundamental physical interactions in compact binaries?
- How are the compact binaries distributed in the Galaxy and what does that tell us about the formation and evolution of the Galaxy?

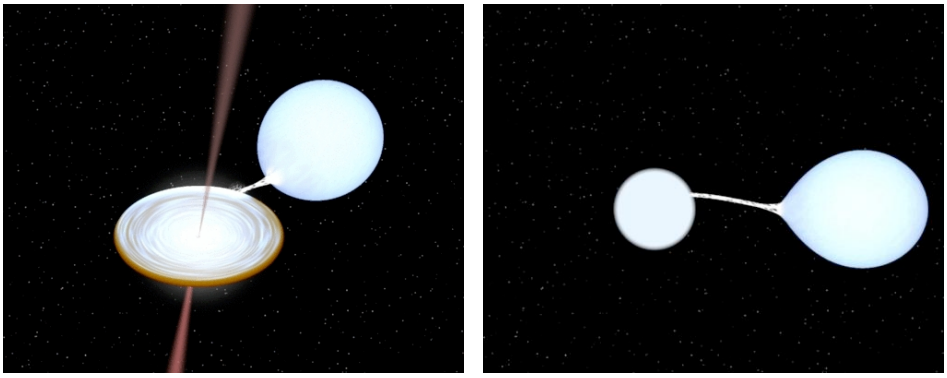

Figure 6-1: Impression of two types of ultra-compact binaries: (left) an ultra-compact X-ray binary in which a neutron star accretes from a compact companion; (right) an AM CVn binary in which a white dwarf accretes from a compact companion.

frequency and phase evolution can be studied. This will enable the study of the physics of tides and mass transfer in unprecedented detail. The extreme conditions of short orbital periods, strong gravitational fields and high mass-transfer rates are unique in astrophysics.

The LISA measurements will provide very different information compared to what can be deduced from electromagnetic detections. In particular LISA's capability to determine distances as well as the fact that the gravitational wave signals are unaffected by interstellar dust provide huge advantages over other detection techniques. Compared to GAIA, LISA will detect a quite different population, with most distance determinations right in the Galactic center — where most ultra-compact binaries are — rather than between the Sun and the Galactic center. The distance determinations will make it possible to map the distribution of many compact binaries in the Galaxy, providing a new method to study Galactic structure. On the other hand, many of the detectable binaries can be studied electromagnetically thus providing a strong complementarity if both techniques are combined. Dedicated complementary observing programs as well as public data releases will ensure simultaneous and follow-up electromagnetic observations.

The importance of electromagnetic observations

The LISA measurements will provide complementary information to what can be deduced from electromagnetic detections. In particular its capability to determine distances as well as the fact that the gravitational wave signals are unaffected by interstellar dust provide huge advantages over other detection techniques. On the other side, the positional accuracy of LISA is quite limited compared to electromagnetic detectors. This highlights the importance of coordinated gravitational wave and electromagnetic observations, a unique possibility when studying gravitational waves at low frequencies. Although the majority of the binaries discovered by LISA will not likely be detected with electromagnetic detectors due to the dust absorption, the shear number of expected gravitational wave detections will ensure that there are still many tens or hundreds for which it is possible to do complementary electromagnetic observations. This will yield not only their position in the sky — thus putting strong priors on the gravitational wave parameter estimation — but also provide additional information, ranging from temperature and age estimates if only broadband colors can be measured, to individual masses and even radii if the system is eclipsing or spectra can be taken.

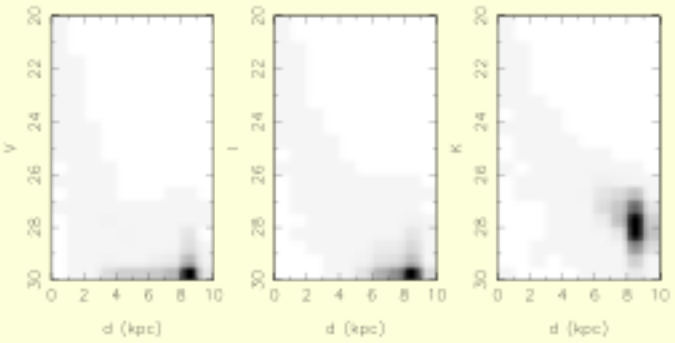

Figure 6-2: Optical and infrared magnitudes of the expected double white dwarf binaries detected by LISA.

A number of guaranteed detectable sources are known to date. Some of these can be used to verify instrument performance by looking for a gravitational signal at twice the orbital period and comparing the signal to expectations. In addition, once LISA has detected several nearby binaries and determined their sky position they can be observed optically thus providing an additional quantitative check on instrument sensitivity. Among the currently identified sources are the two most exotic but controversial binaries known, possibly with ultra-short orbital

Tutorial: Ultra-compact binaries

At the end of the 1960s, binary stars with periods of less than one hour were discovered, and astrophysicists recognized that the two stars are so close together that an ordinary star like the Sun could not fit in their orbits. The close proximity of the objects suggests that both components are remnants: white dwarfs, helium stars, neutron stars, or even black holes that form after stars exhaust their nuclear fuel. The components of ultra-compact binaries are stars that have evolved beyond hydrogen-core burning.

A useful distinction can be made between systems in which the two components are far apart (detached systems) and systems in which the components are so close together that mass is being transferred from one star to the other (interacting systems). Examples of detached systems are double neutron stars and double white dwarfs. Their existence in the LISA band is inferred from longer period systems that are known and are evolving towards shorter periods, such as the double pulsar PSR J0737 -3039 and the double white dwarf WD 0957-666.

Currently some 30 interacting ultra-compact binaries are known. They naturally divide in two classes, based on their observed characteristics (Figure 6-1). In ultra-compact X-ray binaries, gas falls onto a neutron star whose potential well is so deep that the gas heats up to millions of Kelvin and produces abundant X-rays. The second class comprises the AM CVn stars, so named because the first of them was a variable star discovered in the constellation Canes Venatici (hunting dogs). In AM CVn systems gas falls onto a white dwarf, which has a much shallower potential well than a neutron star. The gas is heated to only about 100 000 K, and most radiation is emitted at optical and UV wavelengths in the range of 100–600 nm. The number of known systems is increasing regularly due to new discoveries or period determinations of X-ray sources that turn out to be ultra-compact X-ray binaries.

periods. As LISA will really open a new window to the Universe, arguably the most exciting prospect for LISA is the detection of many additional completely unknown and highly exotic sources in the Galaxy.

LISA as a workhorse: thousands of new binaries

Ultra-compact binaries (see Tutorial Box: Ultra-compact binaries) will completely dominate the number of source detections by LISA. Current estimates suggest the number of resolved compact binaries that will be detected by LISA will be counted in thousands, if not ten-thousands. These systems will be dominated by the shortest period systems and most will have periods less than about 20 min (Figure 6-3). If we compare that with the fact that less than 50 ultra-compact binaries[4] are known today — less than a handful with periods shorter than 20 min — it is clear that the knowledge of this population will be revolutionized by LISA. As these systems are relatively short lived and faint, there is no hope to detect these system with any other means than via gravitational radiation. Their detection will allow us to test different models for the common-envelope phase: the dominant uncertainty in our understanding of binary evolution and many high-energy phenomena. The internal statistical accuracy delivered by the shear number of detected sources will ensure that the common-envelope phase will be put to the most critical test that can be expected in the midterm future of astrophysics.

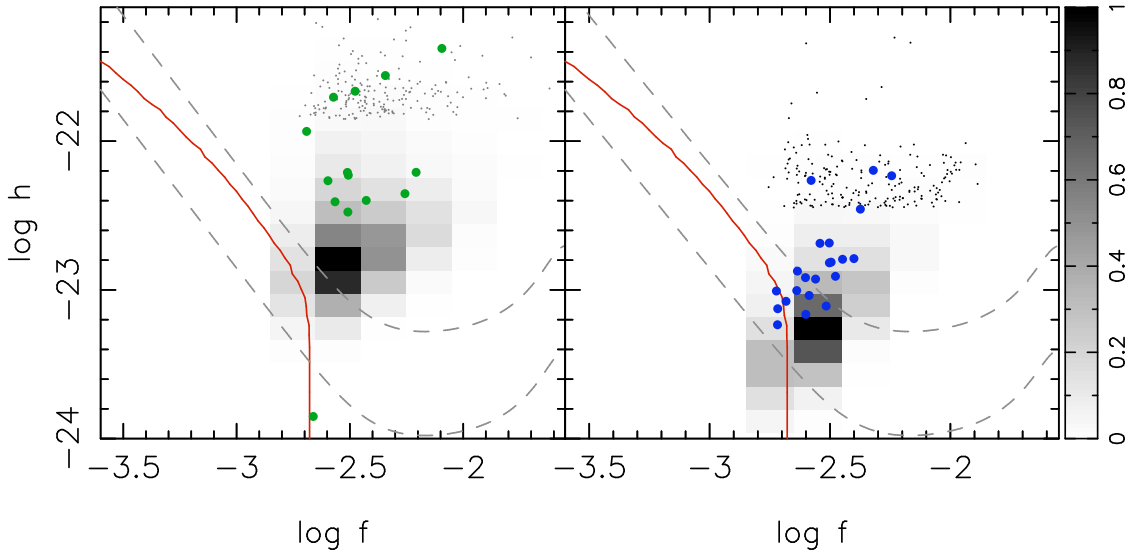

Figure 6-3: GWR wave amplitude *h* as function of the GWR frequency *f* (Hz) for the Galactic binaries that are expected to be detectable by LISA. The left panel shows the (10658) double white dwarf systems as the grey shade, with the 200 strongest sources as points, to increase their visibility. The right panel shows the (9831) resolved AM CVn systems that are expected, again showing the 200 strongest sources as points. Over plotted with the large symbols are the neutron star binaries in the left panel and the ultra-compact X-ray sources in the right panel. The average double white dwarf background is plotted as the solid line, while the dashed curves show the LISA sensitivity for a integration time of 1 year giving S/N of 1 and 5 respectively. Based on Nelemans *et al*. (2004).

Key question: the outcome of the common envelope phase

Less than half of the stars in the Universe are single, the majority being part of a binary, a triple or a higher order system. Of the binaries on the order of half are formed with a sufficiently small orbital separation that during the evolution of the components into giants or super giants the stars will interact. Especially for low-mass stars the majority of interactions are unstable and will lead to runaway mass transfer. Based on the observed short orbital periods of binaries that have passed this stage it is argued that somehow the companion of the giant ends up inside the giant's outer layers. During that common envelope phase, friction reduces the velocity of the companion, leading to orbital shrinkage and transfer of angular momentum from the orbit into the envelope of the giant. Along with angular momentum, orbital energy is deposited in the envelope, whose matter is then unbound from the giant's core, leading to a very compact binary consisting of the core of the giant and the original companion (Paczynski 1976).

Virtually all compact binaries and most of the systems giving rise to high-energy phenomena (such as X-ray binaries, relativistic binary pulsars and possibly gamma-ray bursts) have experienced at least one common-envelope phase. Given the importance of this phase in high-energy astrophysics our understanding of the physics and our ability to predict the outcome of

Tutorial: Evolution of a star

Based on the fundamental set of structure equations — balancing gravity with pressure and accounting for energy generation and transport — it has been possible to construct stellar models that compare very well to the observed stars in the local Universe. Stars first stay on the main sequence, when they are burning hydrogen in their high pressure and temperature cores just as our Sun is currently doing. The nuclear burning, however, cannot go on forever. In time, no hydrogen remains in the core where the nuclear burning takes place. Once the hydrogen is gone, the pressure in the core cannot be sustained; gravity wins the battle of forces, and so the core contracts. Meanwhile, the outer layers of the star expand, typically by an impressive factor of 10 to 100, and the star becomes a red giant. Stars less massive than about 8 times the mass of the Sun lose their outer layers into space due to a stellar wind. All that remains is a compact degenerate core, about the size of Earth but typically 300 000 times more massive, forever cooling and visible as a small, initially hot star called a white dwarf.

More massive stars will continue nuclear fusion and their core will be burnt into heavier and heavier elements until it is made of iron. But neither fusion nor fission can produce energy from iron, so the iron core has no way of counterbalancing gravity and it collapses. The extreme pressure forces the electrons and protons to combine into a degenerate gas of neutrons that, if the core is not too heavy, generates enough additional pressure to halt the contraction. The resulting neutron star has a radius of about 10 km and a mass of 3×10^{30} kg. If the core is massive enough, even the pressure of the degenerate neutrons cannot offset gravity, and the core collapses into a black hole. Neutron stars are formed from the cores of stars with masses between about 10 and 25 solar masses; black holes, as far as we know, are created from stars with masses greater than about 25 solar masses. During the formation of either a neutron star or a black hole, the outer layers of the star are blown into space in a violent explosion called a supernova.

the common-envelope phase are alarmingly poor. Theoretical progress to understand the phase from first physical principles is slow (*e.g.* Taam & Sandquist 2000) and observational tests have led to questioning of the applicability of the standard formalism described above. Comparison of the parameters of the thousands of binaries detected by LISA with model predictions will provide a direct test of the different proposed outcomes of the common-envelope phase and our understanding of the preceding binary evolution in general.

Formation of ultra-compact binaries in globular clusters

Of special interest are globular clusters, dense assemblies of up to a million stars that represent the oldest stellar populations in the Galaxy. The angular resolution that can be achieved with LISA is such that globular clusters can be resolved, so that the cluster sources can be distinguished from the Galactic disc sources (Figure 6-4). Globular clusters have a strong overabundance of bright X-ray sources probably due to dynamical interactions. In particular it seems that the number of ultra-compact X-ray binaries is severely enlarged compared to the other Galactic populations. It is not clear if ultra-compact binaries with white dwarf components are overproduced as well. LISA will directly test this by determining the number of ultra-compact binaries in globular clusters. This will provide unique information, since the details of how these interactions lead to the formation of ultra-compact X-ray binaries are poorly understood (Verbunt & Lewin 2006).

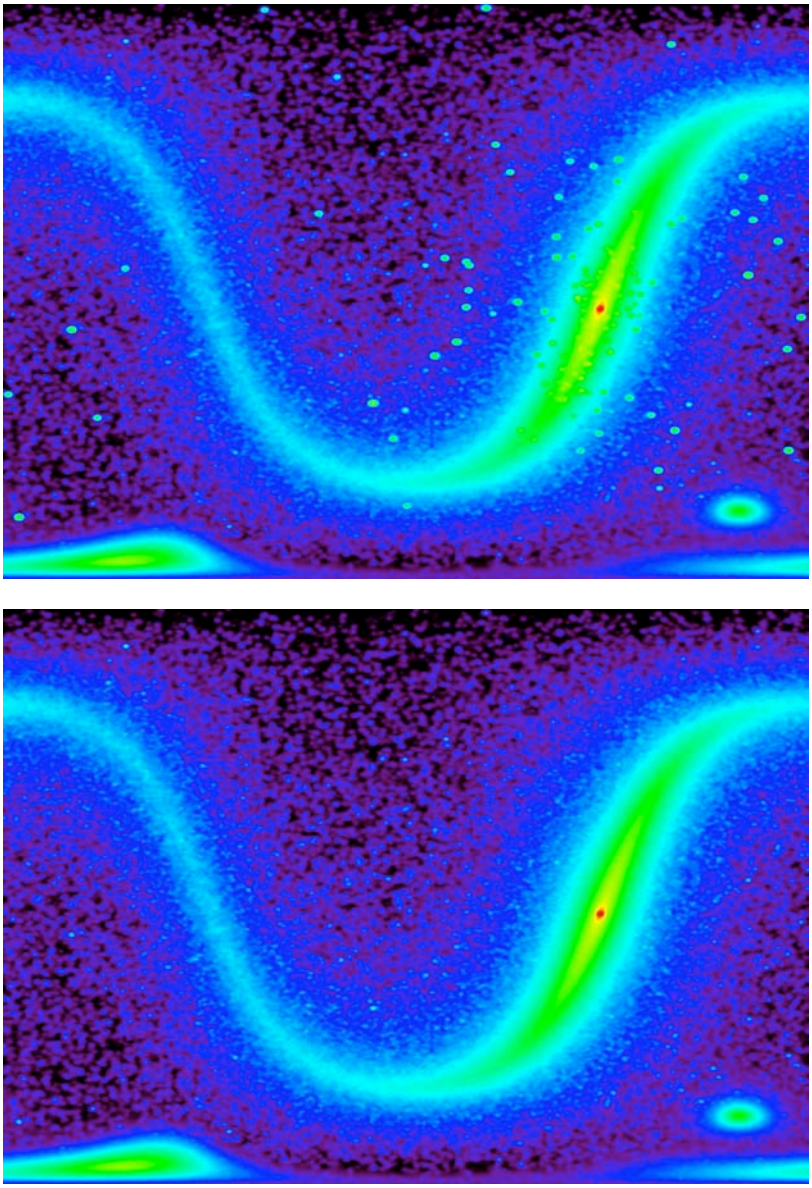

Figure 6-4: Sky brightness in GWR as seen through LISA eyes showing the Galactic disc and bulge, globular clusters, LMC and SMC. In the top plot the number of ultra-compact binaries in globular clusters is assumed to be enhanced compared to the field making the globular clusters stand out, while in the bottom plot the number is not enhanced.

The foreground of Galactic gravitational waves

At frequencies below a few mHz the number of sources in the Galaxy is so large that only a small percentage, the brightest (and closest) sources, will be individually detected. The vast majority will form an unresolved foreground signal in the detector. (We distinguish the Galactic "foreground" from the diffuse extragalactic "background".) This foreground is often described as an additional noise component which is misleading for two reasons. The first is that there is a lot of astrophysical information in the foreground. The overall level of the foreground is a measure of the total number of ultra-compact binaries, which is very valuable information given the current uncertainty levels in the normalization of the population models. The spectral shape of the foreground also contains information about the homogeneity of the sample, as simple models of a steady state with one type of binary predict a very distinct shape. In addition, due to the concentration of sources in the Galactic center the foreground is strongly modulated during the year, with periods in which the foreground is more than a factor 2 lower than during other periods (Figure 6-5). The cyclo-stationary character of the foreground allows for further tests of the population models and thus the uncertainties in binary evolution theory *e.g.* Edlund *et al.* (2005)

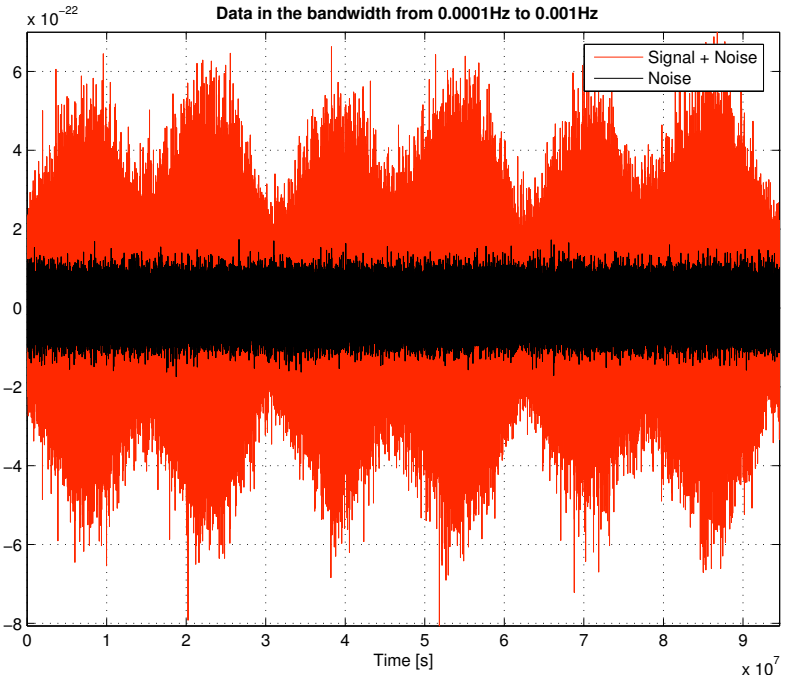

Figure 6-5: Level of the Galactic gravitational wave background as function of time, showing the yearly change. From Edlund *et al.* (2005)

The extragalactic ultra-compact binary background

The masses of white dwarfs and their minimal separation set a maximum to the signal strength of an individual binary, which puts the distance of individual binaries detectable by LISA to less than 100 kpc. This means the LMC and SMC are just within reach, but no individual ultra-compact binaries can be detected further away. However, the combined extragalactic signal — dominated by the signals from sources around redshift of 1 — is expected to be just around the limit of the sensitivity of LISA at a few mHz (Farmer & Phinney 2003). So if the resolved binaries in the Galaxy can be effectively removed, (non) detection of this extragalactic compact-binary background will provide insight in the cosmic star formation provided that the Galactic binaries have greatly reduced the uncertainties in the binary evolution that also hinder the extragalactic background predictions.

Verifying LISA and testing GR

The first and arguably most fundamental test that LISA will perform is direct measurement of gravitational radiation, although this might well have happened earlier using ground-based detectors. However, LISA is able to test a much simpler and cleaner system than the ground-based detectors by measuring the monochromatic signal of a detached binary. The brightest expected sources have signal-to-noise ratios larger than 100 and will allow detailed tests of the monochromatic and higher order terms. For the most compact high-frequency sources (above a few mHz) the first and second derivative of the frequency also will be measured. In addition, the most exciting possibility and expectation is the unexpected. LISA will likely discover objects and phenomena that are completely unknown and might shed new light on our understanding of the Universe.

Verification binaries

A subset of the known ultra-compact binaries have been recognized as ideal verification sources, as they should be detected in a few weeks to months and thus can be used to verify the performance of the instrument (Stroeer & Vecchio 2006). The reliability of the verification binaries has been improved recently by determinations of distances and systems parameters thus providing predictions of the expected signals with well defined error bars (Figure 6-6). Their expected monochromatic nature within the LISA mission time prevents astrophysical effects (see next section) hampering their detection.

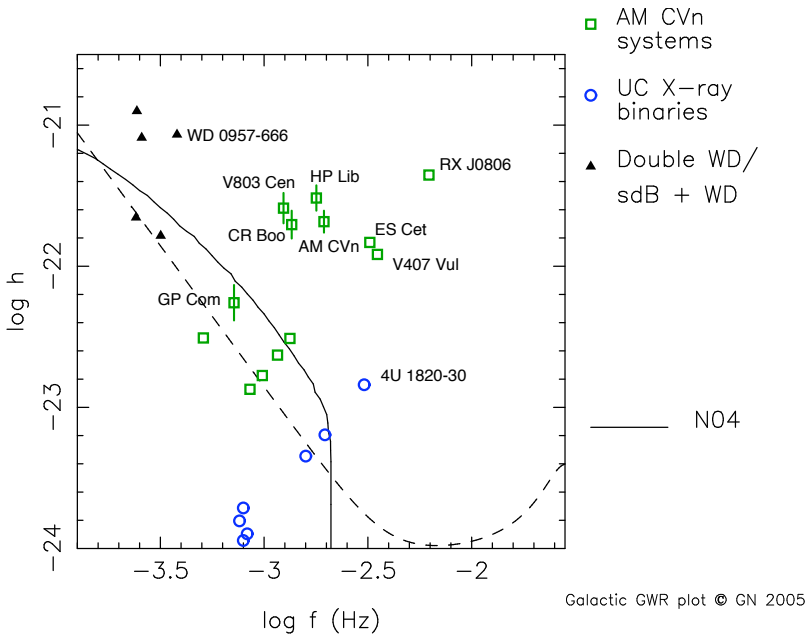

Figure 6-6: Gravitational wave strain versus frequency for the verification binaries. The instrument sensitivity and the average Galactic background are also plotted. Based on Roelofs *et al.* (2006)

The LISA measurements will immediately test the determination of the system parameters and, more importantly, will provide the definitive answers the debate about the nature of the two shortest period binaries RX J0806.3+1527 and V407 Vul. These have received special attention in the past few years because they show repeating signals with periods of 5.4 and 9.5 minutes. In some interpretations, those times are the remarkably small orbital periods of binaries in which two white dwarfs are separated by about a quarter of the Earth Moon distance. A good deal of debate and uncertainty attends the two systems, and several competing theories purport to explain them, ranging from a detached pair of magnetic white dwarfs in which their X-ray emission is produced by induction, to direct accretion models in which the observed periods are not orbital periods at all (see Nelemans 2006). No model is strongly favored, and we might have to wait until LISA is launched before the two objects are understood.

Outlook: expected developments in the next decade

There are a number of initiatives that will improve our knowledge of ultra-compact binaries in the next decade, before LISA will fly. One of the major contributions to the increase in the number of known AM CVn systems in the last years has been the Sloan Digital Sky Survey (SDSS), in which 6 new systems have been found. This number will certainly go up with the

ongoing extension of the SDSS to lower Galactic latitudes (the SEGUE survey) and the European Galactic Plane Surveys, two surveys that are particularly well designed for finding compact binaries. However, all SDSS systems have relatively long orbital periods (longer than about 30 minutes). Two surveys capable of finding AM CVn stars with periods less than 30 minutes are underway or will start soon: the Rapid Time Survey (RATS[5]) and OmegaWhite[6].

For the future there are initiatives to find more ultra-compact X-ray binaries both through the continued monitoring of the sky to search for X-ray transients with RXTE and other satellites, as well as through dedicated X-ray and optical surveys of the Galactic Bulge that are currently in development.

With these developments the number of verification sources available for LISA will be several tens allowing detailed tests of the performance of the instrument.

Studying the astrophysics of compact binaries using LISA

Although the effect of gravitational radiation on the orbit will dominate the evolution of the binaries detected by LISA, additional physical processes will cause strong deviations from the simple point mass approximation. The two most important interactions that occur are tides — when at least one of the stars in a binary system is not in co-rotation with the orbital motion or when the orbit is eccentric — and mass exchange. Because many binaries will be easily detected, these interactions do not hamper their detection, but instead will allow for tests of the physics underlying these deviations. Gravitational wave measurements will provide a completely complementary approach to many aspects of astrophysics because they are optimal for the study of short period systems in contrast to the current bias towards bright electromagnetic systems and events.

Physics of tidal interaction

LISA measurements of individual short period binaries will give a wealth of information on the physics of tides and mass transfer (stability). For detached systems with little or no interaction, the frequency evolution is well determined. The strain amplitude h, the frequency f and its derivatives are connected by:

$$h \propto M^{5/3} f^{2/3} d^{-1} \quad (1)$$

$$\dot{f} \propto M^{5/3} f^{11/3} \quad (2)$$

$$\ddot{f} = \frac{11}{3}\frac{\dot{f}}{f} \quad (3)$$

[5] http://www.mssl.ucl.ac.uk/~gtbr/rats.html

[6] http://www.astro.ru.nłomegawhite/

where M is the chirp mass and d is the distance. Thus measurement of h, f, $\dot{f}$ provides chirp mass and distance. Additional measurement of $\ddot{f}$ gives a direct test of the dominance of gravitational wave radiation in the frequency evolution (third equation). Tidal interaction between white dwarfs in detached systems before the onset of mass transfer will give rise to distinct deviations of the frequency evolution as compared to systems with no or little tidal interaction. The strength of the tidal interaction is virtually completely unknown, with estimates ranging over many orders of magnitude (Marsh *et al.* 2004). Knowledge of the strength of the tides is not only important for the understanding of the physics of tides in general and the physics of white dwarf interiors, but has important consequences for the tidal heating (and possibly observability) of LISA sources and the stability of mass transfer between white dwarfs (Racine *et al.* 2006).

Physics of mass-transfer stability

Detached ultra-compact binaries will evolve to shorter and shorter periods due to the angular momentum loss through gravitational wave radiation. At sufficiently short orbital period (a few minutes) one of the stars becomes larger than its Roche lobe — the equipotential surface that crosses the minimum of the potential between the two stars — and material "leaks" out of the potential well of one star onto the other star. Depending on the difference between the change of the radius of this star and the Roche lobe upon mass transfer, there may be positive or negative feedback, leading to either limited, stable mass transfer, or a runaway mass-transfer instability.

For double white dwarfs and white dwarf - neutron star binaries the stability of the ensuing mass transfer has important consequences, both for the number of expected mass-transferring LISA sources as well as a number of open astrophysical questions. The stable systems will form detectable interacting binaries (AM CVn systems or ultra-compact X-ray binaries). LISA will detect a number of double white dwarfs and AM CVn systems that are so close to the onset of mass transfer that the stability of the mass transfer can be tested directly by comparing the two numbers. In addition, LISA will detect several ultra-compact X-ray binaries at the very early stages of mass transfer, providing a test of the mass transfer stability in these systems as well.

For AM CVn systems the dominant uncertainty in the mass-transfer stability is again the tidal interaction between the two white dwarfs. Most likely the mass transfer will proceed via the direct impact configuration: due to the proximity of the two stars the mass transfer stream lands directly on the surface of the accreting white dwarf, rather than wrapping around the accreting stars, interacting with itself to form a flat accretion disk in the plane of the orbit (Webbink 1984). It turns out that the stability of the mass transfer depends critically on the tidal interaction between the two white dwarfs (Marsh *et al.* 2004). In absence of any tidal interaction there will be additional angular momentum loss from the orbit due to the transfer of angular momentum from the orbit to the accreting star which will consequently spin-up. This is different from the cases where the accretion is via a disc for which most of the angular momentum generally is stored in the disc and eventually via very efficient tidal interaction put back into the orbit.

However, efficient tidal coupling between the accreting star and the companion might return the angular momentum back to the orbit as well (Racine *et al.* 2006, d'Souza *et al.* 2006; see Figure 6-7), thus reducing the magnitude of the spin-up.

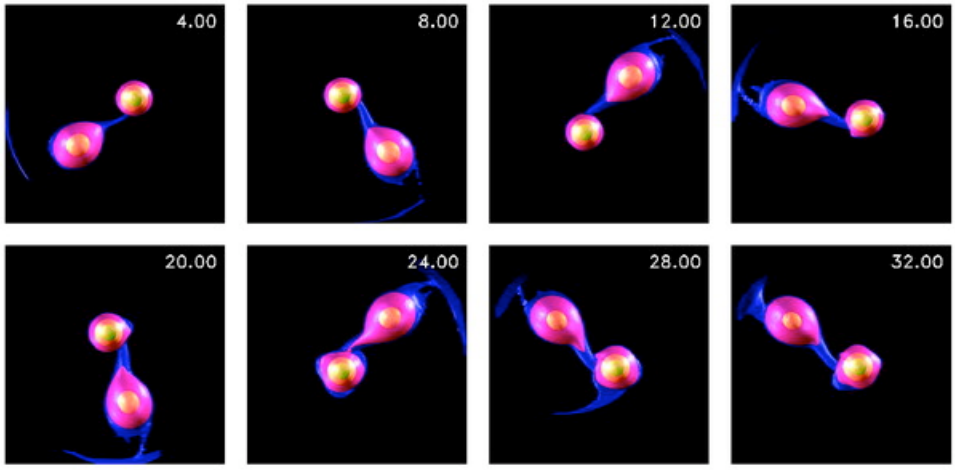

Figure 6-7: Numerical simulation of the stability of mass transfer in a binary with mass ratio 0.5, in which the mass transfer is stable (d'Souza *et al.* 2006).

The difference between efficient and inefficient tidal coupling is rather dramatic: the fraction of double white dwarfs estimated to survive the onset of mass transfer can drop from about 20 percent to 0.2 percent (Nelemans *et al.* 2001) depending on assumptions about the tidal coupling. This difference is very easily measurable with LISA.

For ultra-compact X-ray binaries, the stability issue is completely different. At the onset, the mass transfer is orders of magnitude above the Eddington limit for a neutron star (the mass transfer rate at which the potential energy liberated in the accretion can couple to the infalling gas to blow it away). For normal stars and white dwarfs this would likely lead to complete merger of the system, but the enormous amount of energy liberated when matter is falling into the very deep potential well of a neutron star allows matter to be dumped on it at rates up to a thousand times the Eddington limit. This allows the formation of ultra-compact X-ray binaries from white dwarf-neutron star pairs, if the white dwarf has a low mass (see Yungelson *et al.* 2002). LISA will unambiguously test this prediction, by detecting a several tens of ultra-compact X-ray binaries with periods between 5 and 20 minutes (Figure 6-3).

Double white dwarf mergers

The 80 to 99.8 percent of the double white dwarfs that experience run-away mass transfer and merger likely give rise to quite spectacular phenomena. Although it is not expected that LISA will be able to witness the actual merger of a double white dwarf it will certainly detect the shortest period binary known, expected at a period of about 3 minutes and give an extremely good estimate of their merger rate. Mergers of double white dwarfs have been proposed as progenitors of single subdwarf O and B stars, R Corona Borealis stars and maybe all massive white dwarfs. The merger of a sufficiently massive double white dwarf has been proposed as the trigger for type Ia supernova events, the standard candles that play an important role in our

understanding of the expansion of the Universe and the existence of dark energy. Alternatively, if the merger does not lead to an explosion a (rapidly spinning) neutron star will be formed. This is one possible way to form isolated millisecond radio pulsars as well as magnetars, which have been proposed as sites for short gamma-ray bursts *e.g.* Levan *et al.* (2006). LISA will be able to put strong constraints on these hypotheses. By measuring (chirp) masses and coalescence times LISA will directly determine the merger rate for double white dwarfs with different masses which can then be compared with the rates and population of their possible descendants determined by other means.

Neutron star and black hole binaries

In addition to the thousands of white dwarf binaries, several tens of neutron star binaries will be detected by LISA, if the current observational and theoretical estimates of the formation rate of neutron star binaries turn out to be reliable (*e.g.* Nelemans *et al.* 2001). For all these populations, the sample will be complete at the shortest periods as the systems can be seen throughout the Galaxy and thus the sample will be independent of selection effects such as those present in radio pulsar surveys which currently hamper our knowledge about this population in the Galaxy. In addition, by the time LISA will fly, Advanced LIGO will likely have detected a number of double neutron star mergers from far away galaxies, so these measurements together will test our ability to extrapolate our population models from our own galaxy to the rest of the Universe.

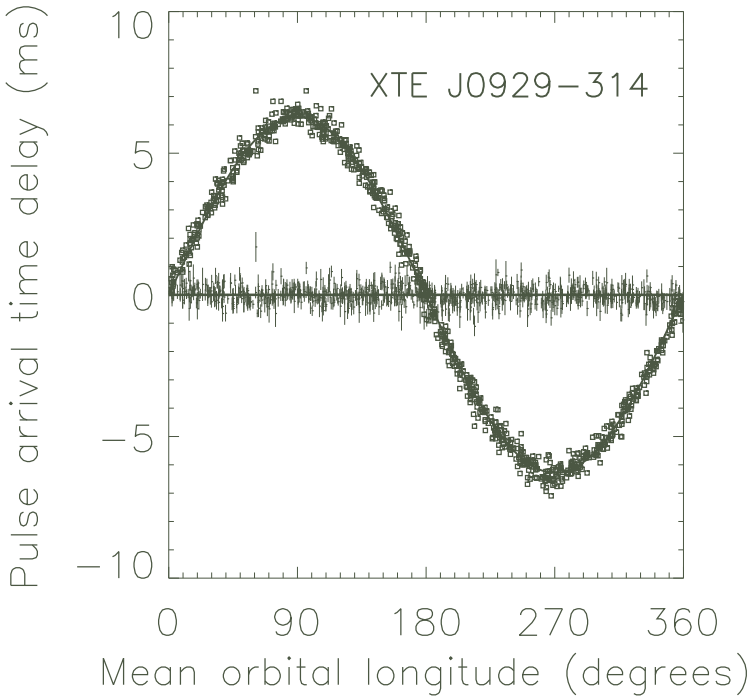

Figure 6-8: Imprint of the 40 min orbital period on the arrival times of the X-ray pulsations in the ultra-compact X-ray binary XTE J0929-314. From Galloway *et al.* (2002)

Another opportunity for LISA to test a long-standing hypothesis concerning neutron stars is provided as LISA will not be biased towards detecting transient systems that suddenly show up as bright X-ray sources. A very special situation might arise in the

millisecond X-ray pulsars in ultra-compact X-ray binaries. In recent years, observations of X-ray pulsations from many ultra-compact X-ray binaries have enabled astrophysicists to determine the rotation rate of the neutron star using the NASA mission RXTE (Figure 6-8). As had been expected on theoretical grounds, the neutron stars are spinning rapidly several hundred times per second due to the angular momentum gained from infalling matter. The measurements give credence to the idea that rapidly spinning neutron stars observed as millisecond radio pulsars are descendants of accreting neutron stars in binary systems (*e.g.* Bhattacharya & van den Heuvel 1991). However, scientists have yet to establish the exact role of ultra-compact binaries in the formation of these pulsars. The distribution of spin periods discovered in X-ray binaries suggests additional neutron star angular momentum loss on top of the plasma physics interaction between the accretion and magnetic field of the spinning neutron stars (Chakrabarty *et al*. 2003). One exciting possibility is that this additional angular momentum loss is due to strong gravitational wave emission (Bildstein 1998). In that case ultra-compact X-ray binaries might be the only sources that could be studied simultaneously with LISA and Advanced LIGO, with LISA detecting the orbital period and LIGO detecting the neutron star period.

If they exist in sufficient quantities, LISA will easily pick up black hole binaries in the Galaxy. There is a lot of uncertainty about the number of ultra-compact stellar mass binary black holes in the Galaxy *e.g.* Belczynski *et al*. (2002) but if they exist they will show up in the LISA band and indeed this is the only way such systems may ever be detected.

New studies of galactic structure with LISA

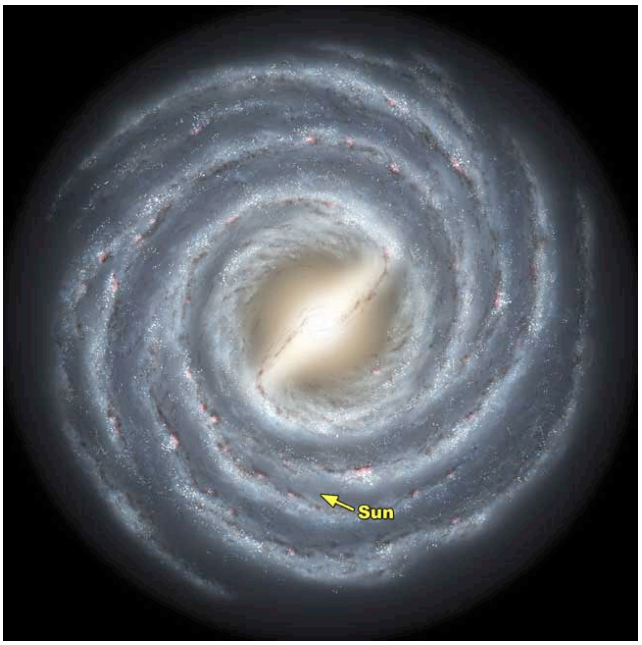
One of the major advantages of LISA is that it will determine distances for more than 100 compact binaries by measuring their $\dot{f}$ (Equation 2). The exact ability of LISA to determine distances depends critically on the mission lifetime, as larger life times lead to more accurate $\dot{f}$ measurements.

The directional dependence of the Galactic background as well as the directional accuracy for the resolved systems allow for a statistical assessment of the contributions of the different Galactic components such as the Galactic bulge (with its bar), the thin and thick disc and especially the Galactic halo.

Galactic halo

The halo sources will of course be distributed completely differently from the other Galactic components. The LISA directional sensitivity will immediately pick up any strong halo population. The halo population might be enhanced compared to the disc as the formation and evolution of binaries in the halo may have been quite different. Such old and metal poor population can locally only be studied in globular clusters, where the formation and evolution of

binaries is generally completely altered by dynamical effects. There is currently a very interesting suggestion. Two of the 18 known AM CVn systems seem to be most consistent with belonging to the halo. They have very low metal abundances and anomalous velocities. If true this implies a very large number of AM CVn stars in the halo, maybe as many as in the rest of the Galaxy. LISA would certainly pick up the short period systems in this population.



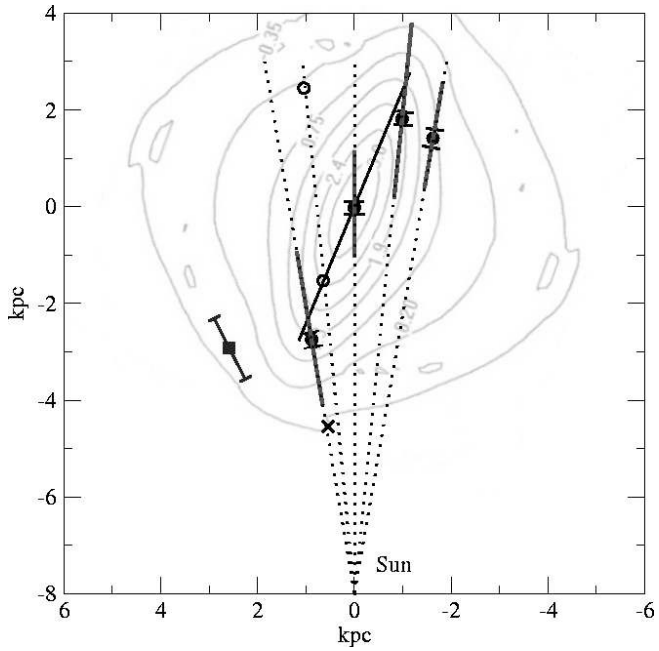


Figure 6-9: Different models for the Galactic bar: above the Spitzer GLIMPSE model, below the model of Bizants and Gerhardt with measured distances to red clump stars (from Babusiaux & Gilmore 2006). Note the difference in the angle of the bar.

Galactic center and bar

The Galactic center is one of the most interesting areas of the Galaxy, with a central super-massive black hole surrounded by a dense assembly of stars with intriguing properties. Dynamical effects, in particular mass segregation, will lead to many interactions close to the central black hole so that wide binaries will become tighter or will be disrupted (for a review see Alexander 2005). This likely leads to an increase in the number of ultra-compact binaries as well as the possibility of extreme mass-ratio inspirals (see other sections in this volume). However, current observational techniques, fundamental observational limits due to the extreme faintness of these sources as well as severe limitations to theoretical calculations of these processes result in a virtual absence of any constraints on these populations and this will likely remain the situation until LISA will fly.

Another major question about the central region of the Galaxy is the size and orientation of a bar (see Hadamache *et al.* 2006, Gerhard 2002, also Figure 6-9). Because the ultra-compact binaries are expected to closely follow the mass distribution in the Galaxy, direct

measurement of distances and directions to hundreds of ultra-compact binaries in the Bulge will put a constraint on the bar, independent of the interpretation of star counts.

Galactic disc scale height

The level and shape of the double white dwarf background will provide information on the scale height of the ultra-compact binary population (Benacquista & Holley-Bockelmann 2006) in the disc of the Galaxy. For many of the resolved sources the LISA measurements will also provide an estimate of the orbital inclination which for the first time will give hints on the dynamics of the formation of binaries from interstellar clouds because in a statistical way the angular momentum vectors of the binaries can be compared to the overall angular momentum of the Galaxy.

LISA Science Objectives and Investigations relevant to this section

(see Appendix 1)

4. Survey compact stellar-mass binaries and study the structure of the Galaxy

4.1. Elucidate the formation and evolution of Galactic stellar-mass binaries; constrain the diffuse extragalactic foreground.

4.2. Determine the spatial distribution of stellar mass binaries in the Milky Way and environs.

4.3. Improve our understanding of white dwarfs, their masses, and their interactions in binaries and enable combined gravitational and electromagnetic observations.

7. New Physics and the Early Universe

Signatures of motions in the early Universe

LISA can detect a broad band stochastic background caused by a first-order phase transition with critical temperature from about 100 GeV to 1000 TeV. Proposed phase transitions include electroweak or supersymmetry breaking, dynamically active submillimeter extra dimensions, and some types of inflationary reheating. LISA may also detect a background, and possibly bursts, from otherwise unobservable cosmic superstrings.

Gravitational waves penetrate all of cosmic history, and LISA explores scales, epochs, and new physical effects not accessible in any other way (Figure 7-1). A detectable gravitational wave background in the LISA band is predicted by a number of new physical ideas for early cosmological evolution (Maggiore 2000, Hogan 2006a). Two important mechanisms for generating stochastic backgrounds are relativistic phase transitions and cosmic strings:

- Many types of new physics predict first-order phase transitions leading to bulk motions from cataclysmic bubble nucleation, cavitation, collisions, and turbulence (Figure 7-2). The cosmic expansion rate at a temperature of about 1TeV, corresponding to an apparent horizon size of about $c/H = ca/\dot{a} \approx 1$ mm at that time, is redshifted now to a frequency

$$f_0 = \dot{a}(t) \approx 10^{-4}\text{Hz}\,[H(t) \times 1\text{mm}/c]^{1/2} \approx 10^{-4}\text{Hz}\,(T/1\text{TeV})\,.$$

Thus, LISA's frequency band of about 0.1 to 100 millihertz today corresponds to the horizon at and beyond the Terascale frontier of fundamental physics. This allows LISA to probe bulk motions at times about 3×10^{-18} to 3×10^{-10} seconds after the Big Bang, a period not directly accessible with any other technique. Taking a typical broad spectrum into account, LISA has the sensitivity to detect cosmological backgrounds caused by new phase transitions from 0.1 to 1000 TeV, if more than a modest fraction $\approx 10^{-7}$ of the energy density is converted to gravitational radiation in LISA's band (Figure 7-3).

- Fundamental string theory, the subject of intense theoretical study as a unified framework for all particles and forces of nature, also predicts the possibility of new fundamental objects called cosmic superstrings, stretched to astronomical size by the cosmic expansion, that lose energy principally through gravitational radiation with a very broad and uniquely identifiable

Key science questions

- Is there a first-order phase transition at or beyond TeV energies?
- Are there extra dimensions at the submillimeter scale?
- Do stable superstrings exist, and can they be blown up to form cosmic strings?
- What was the quantum state of the Universe at or before the Big Bang?
- How did inflation end?
- Were there violent events in the early Universe that left no relic trace in conventional particles and fields?

spectrum. LISA will be our most sensitive probe for these objects by many orders of magnitude and so offers the possibility of detecting direct evidence of fundamental strings.

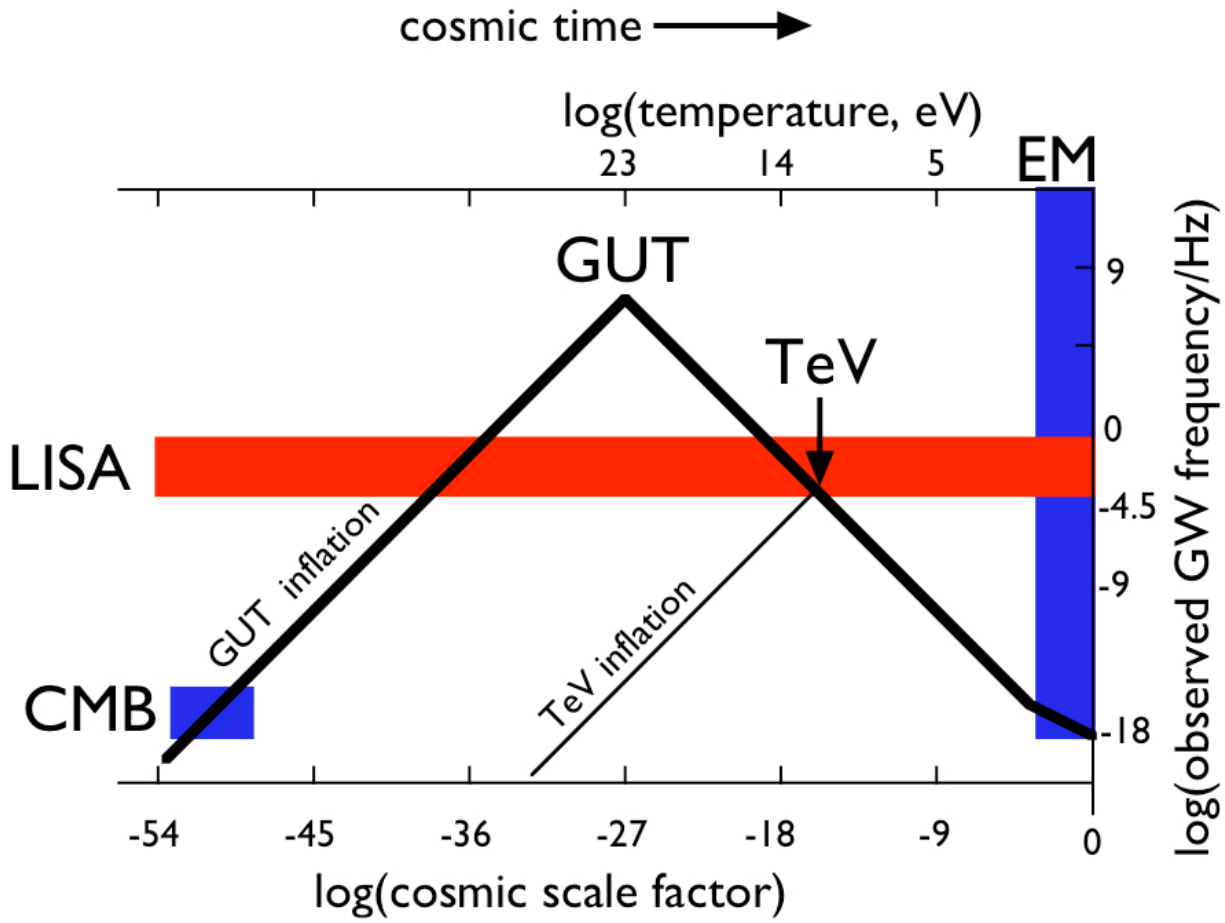

Figure 7-1: The history of mass motions the Universe, in units that show the unique penetration power and discovery potential of gravitational waves in cosmology. The observed (redshifted) frequency of wave-generating motions is shown as a function of cosmic scale factor *a*, with the present epoch at the right. The red bar shows the range of cosmic history accessed by LISA. Blue regions are accessible to electromagnetic (EM) observations; the bar to the right shows the Universe since recombination (some sources are also seen by LISA, where the two bars overlap), and the box at lower left shows the relic fluctuations imprinted in the CMB at inflation. The heavy solid line shows the redshifted Hubble rate or horizon scale, for a standard Grand Unified Theory (GUT) inflationary cosmology; the peak represents the epoch of reheating. Regions above this line correspond to motions smaller (*i.e.*, at higher frequencies) than the apparent horizon. LISA probes all processes within the the horizon up to about 1000 TeV, as well as a regime of cosmic inflation different from CMB observations.

First-Order Cosmological Phase Transitions: Bulk Motion from Bubble Nucleation, Cavitation, Collisions, Turbulence

Abundant evidence suggests that the physical vacuum was not always in its current state, but once had a significantly higher free energy. This idea is fundamental and general: it underlies symmetry breaking in theories such as the Standard Model and its supersymmetric extensions, and cosmological models including almost all versions of inflation. Common to all these schemes is the feature that a cold, nearly uniform free energy contained in the original ("false") vacuum is liberated in a phase transition to a final (or "true") vacuum, and eventually converted into thermal energy of radiation and hot plasma.

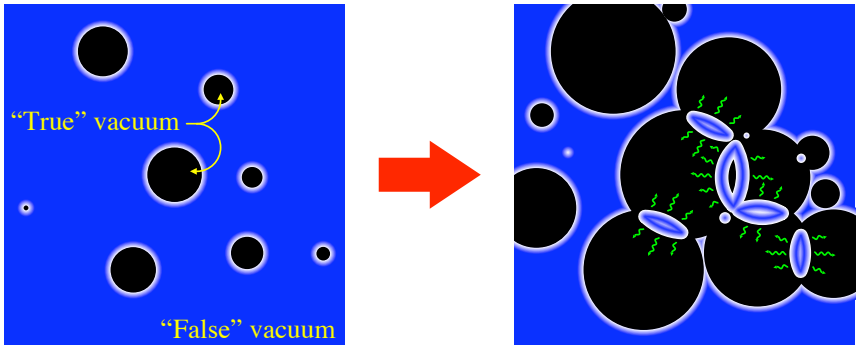

Figure 7-2: First-order phase transition between a "false" and a "true" vacuum. When expanding bubbles of the new phase collide, the latent heat of the old phase is converted into relativistic matter flows, which can produce gravitational radiation.

In many theories the conversion between vacuum states corresponds to a first-order phase transition. In an expanding universe this leads to a cataclysmic process. After supercooling below the critical temperature for the transition, a thermal or quantum jump across an energy barrier leads to the formation of bubbles of the new phase at widely separated nucleation sites. The bubbles rapidly expand and collide (Figure 7-2). The internal energy is thus converted to organized flows of mass-energy, whose bulk kinetic energy eventually dissipates via turbulence and finally thermalizes. The initial bubble collision and subsequent turbulent cascade lead to relativistic flows and acceleration of matter that radiate gravitational waves on a scale not far below the horizon scale (Witten 1984, Hogan 1986, Kosowsky *et al.* 2002, Dolgov *et al.* 2002).

Dynamics of Warped Submillimeter Extra Dimensions

A "theory of everything" based on quantum superstrings requires many, as yet invisible extra dimensions for mathematical consistency. The sizes of the dimensions, their shapes, and how they are stabilized are unknown. If they exist, gravity can penetrate into them so they must be small or highly "warped" — with sizes or radii of curvature below the submillimeter scale limits set by direct laboratory tests of the gravitational inverse-square law. (The scales probed by Standard Model particles and fields are much smaller than this, but fields other than gravity might be confined to a 3-dimensional subspace or "brane" living in a larger dimensional space.)

LISA, the LHC and the electroweak phase transition

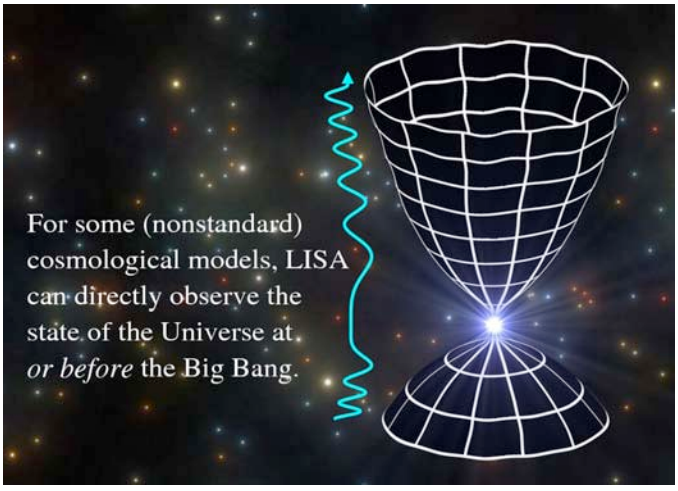
A moderately strong first order TeV-scale electroweak phase transition leads to the production of a detectable background of gravitational waves through bubble collisions and turbulence (Hogan 1986, Grojean & Servant 2006). In the Standard Model and its minimal supersymmetric extension, the phase transition associated with electroweak symmetry breaking by a Higgs field is now expected to be second order. However, other extensions of the Standard Model predict a first order phase transition, and electroweak baryogenesis generally requires it. In the next few years CERN's Large Hadron Collider will probe details of the Higgs sector and the nature of phase transitions in the Terascale region.

Since the Hubble length at the Terascale is about a millimeter, the current threshold where possible new effects of extra dimensions might appear happens to be about the same in the laboratory gravity, particle/field, and cosmological realms: that is, at present, laboratory gravity experiments, accelerator physics, and LISA cosmology converge on the same new regime in very different ways. It is even possible that new properties of gravity on this scale are related to cosmic dark energy (whose energy density is about $(0.1\text{mm})^{-4}$ in particle units).

The dynamics associated with the stabilization of extra dimensions at a certain size or warp radius might introduce a source of free internal energy released coherently on a "mesoscopic" (submillimeter to nanometer) scale, leading to a detectable background (Hogan 2000, Randall & Servant 2006). If the extra dimensions are much smaller than the Hubble length when the stabilization occurs, the behavior of the extra dimensions is nearly equivalent to scalar field behavior as viewed in conventional 3-dimensional space, with effects similar to the phase transitions just discussed (Figure 7-3). Brane condensation also introduces a new kind of mechanism for generating gravitational waves: motion and curvature of our Standard Model brane in the extra dimensions. LISA's high frequency limit at 1000 TeV corresponds to direct probes of extra dimensions as small as 10^{-6} mm.

Terascale Inflationary Reheating

Inflation represents an extraordinarily coherent behavior of an energetic scalar field that is nearly uniform across the observable Universe. After inflation, the internal potential energy of this field is converted into a thermal mix of relativistic particles, in a process known as "reheating". The reheating temperature might be as cool as 1 TeV, especially in some braneworld models where the Planck scale is itself not far above the Terascale.



There is no reason to assume a quiet,

orderly reheating process; the decay of the inflaton energy may be violently unstable. In many scenarios, the conversion begins with macroscopically coherent but inhomogeneous motions that eventually cascade to microscopic scales. Quantum coherent processes such as "preheating" transform the energy into coherent classical motions which, like the phase transitions discussed above, generate backgrounds of the order of 10^{-3} of the thermal plasma density (Felder & Kofman 2006, Easther & Lim 2006). As with those transitions, the characteristic frequency of the background matches the LISA band if the final reheating occurred at 0.1 to 1000 TeV.

Exotic Inflationary Quantum Vacuum Fluctuations

The amplification of quantum vacuum fluctuations during inflation leads to a background of primordial gravitational waves. An optimistic estimate of this background in the case of conventional inflation limits these to less than about 10^{-10} of the cosmic microwave background energy density, far below LISA's sensitivity; in many inflation models it is much less (Chongchitnan & Efstathiou 2006). However, some unconventional versions of inflation, particularly pre-Big-Bang or bouncing brane scenarios, predict possibly detectable backgrounds in the LISA band (see for example Buonanno 2003, Buonanno *et al.* 1997). Although some key parameters remain unknown, which limits the predictive power of these models, they are significantly constrained by gravitational wave backgrounds.

Backgrounds and Bursts from Cosmic Strings

String theory is the leading candidate for a theory unifying all of physics: both the quantum fields of the Standard Model, and the spacetime dynamics of general relativity. Many versions of string theory predict the cosmological formation of cosmic superstrings (Polchinski 2005): quasi-stable strings that form after inflation and are stretched to enormous length by the cosmic expansion. In equivalent field-theory language, cosmic strings arise from certain types of phase transitions, and stable relics of the high-energy phase persist in the form of one-dimensional strings that resemble flux tubes or trapped vortex lines.

Observational evidence for string theory

The discovery of an identifiable superstring background (and possibly, but less likely, superstring bursts) would be the first direct evidence that all particles and fields are indeed actually made of strings, and would help shape the rich mathematical insights of string theory into a model of the real world.

The primordial network of strings spawns isolated, oscillating loops that ultimately radiate almost all of their energy into gravitational waves. Their gravitational waves are mainly governed by a dimensionless parameter $G\mu/c^4$, where μ is the energy per unit length, or tension, in the string. Current limits on gravitational wave backgrounds from pulsar timing already

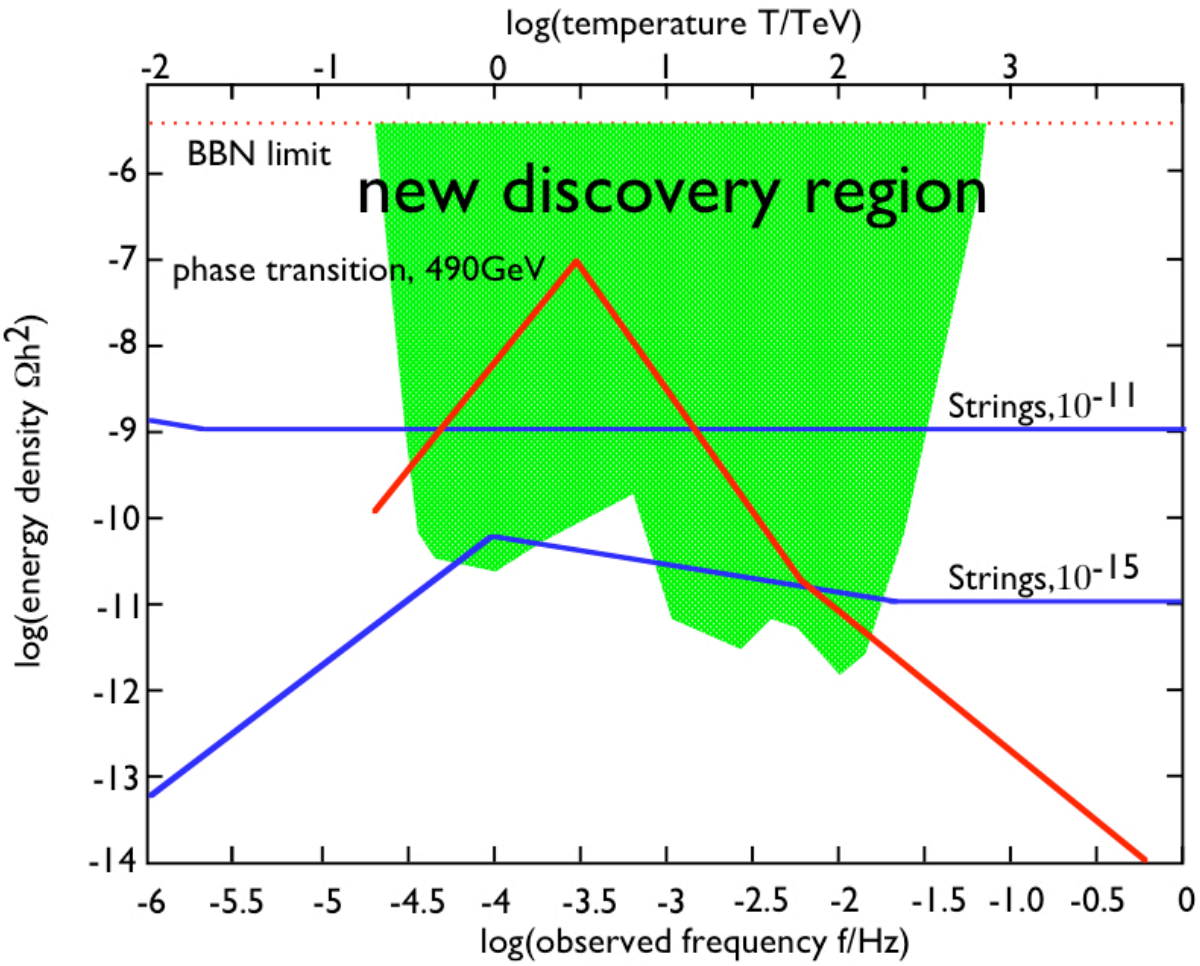


Figure 7-3: Gravitational wave background broad-band energy density is shown in units of the critical density for $h_0 = 1$. The new discovery region shown for LISA assumes a broad band limit using Sagnac calibration to distinguish instrument noise from isotropic gravitational wave backgrounds (Hogan & Bender 2001, updated with optimistic estimate for confusion from unresolved extragalactic binaries from Farmer & Phinney 2003). LISA's sensitivity extends about seven orders of magnitude below the energy density of thermal radiation, and six orders of magnitude below current limits from Big Bang Nucleosynthesis. The background spectrum from cosmic superstrings (Hogan 2006b) is shown for two values of string tension, $G\mu/c^4 = 10^{-11}$ and 10^{-15}. A model spectrum is shown from a first order phase transition of warped extra dimensions (Randall & Servant 2006), which is typical of strongly first order transition spectra; the spectrum moves to the right in the case of a higher transition critical temperature, down and right for a smaller nucleation scale or a smaller latent heat. Top axis is labeled by the temperature where the horizon size maps to the corresponding observed frequency.

suggest that if cosmic strings exist, they must be so light that they have no observable effects except from their gravitational radiation.

Figure 7-3 includes predicted stochastic background spectra (Hogan 2006b) from strings for two values of $G\mu/c^4$ spanning a range of scenarios motivated by brane world inflation. (These estimates are plotted for a "large loop" scenario where newly formed loops are about 0.1 of the horizon size.) The spectrum from cosmic strings is distinguishably different from that of phase

transitions or any other predicted source: it has nearly constant energy per logarithmic frequency interval over many decades at high frequencies, including the range where LISA is likely to observe it, and falls off at low frequencies since large string loops are rare and radiate slowly. LISA's sensitivity to $G\mu/c^4$ is many orders of magnitude deeper than the best possible future sensitivity from pulsar timing (which works at nanohertz frequencies, where light strings radiate very weakly and are buried in confusion noise).

If the strings are not too much lighter than $G\mu/c^4 \approx 10^{-10}$, occasional distinctive bursts might be seen from loops that happen to beam gravitational waves in our direction from "cusp catastrophes", where a momentary event produces a sharply-bent bit of string moving at nearly the speed of light (Damour & Vilenkin 2005, Siemens *et al.* 2006). These rare events, if they are intense enough to stand out above the background, are recognizable from their universal waveform, which derives just from the geometry of the cusps. Although individual burst events, if detected, give the clearest signature of a string source, the first detectable sign of a superstring loop population is likely their integrated stochastic background as shown in Figure 7-3 (Hogan 2006b).

LISA Science Objectives and Investigations relevant to this section

(see Appendix 1)

6. Probe new physics and cosmology with gravitational waves

6.2. Measure the or set bounds on the spectrum of cosmological GW backgrounds.

6.3. Search for burst events from cosmic string cusps.

8. LISA and the Key Questions of Astronomy and Physics

LISA addresses forcefully and directly many of the research priorities and big questions raised by recent astronomy and physics decadal and community reports such *Astronomy and Astrophysics in the New Millennium*, and *Connecting Quarks with the Cosmos*. It might not be an exaggeration to say that LISA will completely transform much of physics and astronomy. Since LISA will study the universe in an entirely new way, its discoveries are also likely to expand the scope of both sciences significantly and reshape the questions of the future.

LISA science addresses a very broad cross-section of some of the most important and exciting science priorities identified by major national and international reviews and studies. For instance, the roadmap for the NASA Beyond Einstein program identified five major science objectives and thirteen research focus areas (NASA SEU 2002). LISA, as a Great Observatory in the Beyond Einstein program, addresses all five science objectives, with particularly strong emphasis on four of the five. Furthermore, LISA addresses eight of the thirteen identified research focus areas, many in a way that is unique and impossible to accomplish using conventional space- and ground-based observatories. The Beyond Einstein objectives and focus areas for which LISA has

Beyond Einstein science objectives addressed by LISA

Science Objective 1: Find out what powered the Big Bang

Research Focus Area 1. Search for gravitational waves from inflation and phase transitions in the Big Bang.

Research Focus Area 2. Determine the size, shape, and energy content of the Universe.

Science Objective 2: Observe how black holes manipulate space, time, and matter

Research Focus Area 3. Perform a census of black holes throughout the Universe.

Research Focus Area 4. Determine how black holes are formed and how they evolve.

Research Focus Area 5. Test Einstein's theory of gravity and map space-time near the event horizons of black holes and throughout the Universe.

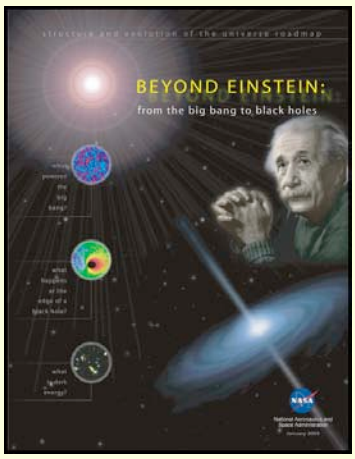
Research Focus Area 6. Observe stars and gas plunging into black holes.

Science Objective 3: Identify the mysterious dark energy pulling the Universe apart.

Research Focus Area 7. Determine the cosmic evolution of the dark energy pulling the Universe apart.

Science Objective 5: Understand the development of structure in the Universe.

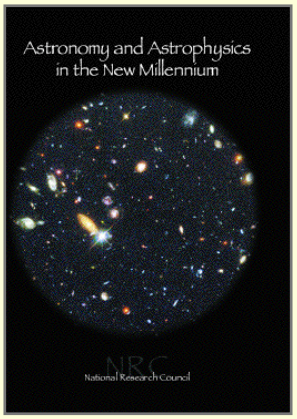
Research Focus Area 12: Discover how the interplay of baryons, dark matter, and gravity shapes galaxies and systems of galaxies.

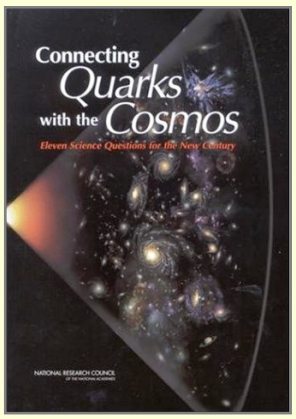


particularly powerful capabilities are given in the accompanying box.

In the US, LISA has been endorsed as a high priority mission in several influential reports. In particular, National Research Council (NRC) has issued several reports emphasizing the opportunities for exciting new science using gravitational waves. In 1999 the NRC report,

Major science questions of the AANM and Q2C reports addressed in unique ways by LISA

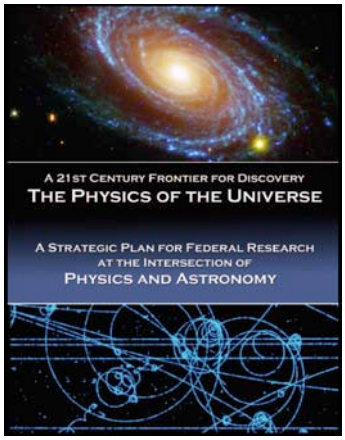




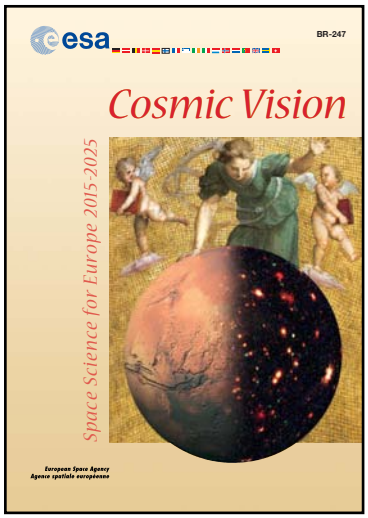
Report	Major Science Question	Relevant LISA Science
AANM & Q2C	How did the universe begin, evolve into today's structures, what is its destiny?	Gravitational waves are the only radiation that can be used to study the earliest beginnings of the Universe
AANM	How do galaxies form and evolve?	Massive black holes and mergers play a fundamental role in galaxy evolution
AANM	How do stars form and evolve?	Ultra-compact binaries represent the extreme endpoints of stellar binary evolution
Q2C	Did Einstein have the last word on gravity?	Black hole mergers allow precision tests of dynamic and static strong field gravity
Q2C	What is the nature of Dark Energy?	Precision distance estimates using black hole binaries offer a potentially powerful capability
Q2C	Are there additional spacetime dimensions?	Gravity is one of our best probes of the existence of extra dimensions

Gravitational Physics: Exploring the Structure of Space and Time (NRC 1999), described 12 science opportunities, several of which require LISA observations to be realized. A short time later, the 2000 NRC Decadal Survey, *Astronomy and Astrophysics in the new Millennium* (AANM: NRC 2001), stated that "LISA is unique among the recommended new initiatives in

that it is designed to detect the gravitational radiation predicted by Einstein's theory of general relativity. The direct measurement of gravitational radiation from astrophysical sources will open a new window onto the universe and enable investigations of the physics of strong gravitational fields." Likewise, the 2003 NRC report *Connecting Quarks with the Cosmos* (Q2C: NRC 2003) endorsed LISA and characterized LISA as having "great potential to address questions that lie at the boundary between physics and astronomy". The science in the AANM and Q2C reports was summarized in a set of 16 fundamental questions, 5 from the AANM report and 11 in the Q2C report. Many of these very important questions are addressed in a new and unique way by LISA science, as indicated in the accompanying box.



Following the AANM, Beyond Einstein, and Q2C reports, the National Science and Technology Council (NSTC) issued a major report, A 21st Century Frontier of Discovery: *The Physics of the Universe - A Strategic Plan for Federal Research at the Intersection of Physics and Astronomy*. This report endorsed the Beyond Einstein program as a key component of the strategy for federal research investment in physics and astronomy and stated that the execution of the LISA mission is "necessary to open up this powerful new window on the universe and create the new field of gravitational wave astronomy." Most recently, the NRC undertook a *Review of Progress in Astronomy and Astrophysics Toward the Decadal Vision*, issuing a letter report (NRC 2005). This report reviewed post-AANM astronomical discoveries and highlighted in particular progress in three broad areas: the universe and the nature of matter and energy, our place in the cosmos, and the formation and evolution of black holes. LISA is recognized as a facility-class mission, together with Con-X, that will "provide a broad and flexible science return across all of astrophysics, as have HST, CGRO, Chandra and Spitzer before them."



In Europe, LISA and LISA Pathfinder are integral components of ESA's Cosmic Vision Scientific Programme announced in 2005 (ESA 2005). The ESA space science program has traditionally been organized in long-term strategic plans. The Horizon 2000 plan was brought forward in 1985, followed by Horizon 2000 Plus in 1995. All of the missions in these programs have been realized subsequently, showing a remarkable stability in strategic planning. LISA first appeared in Horizon 2000 Plus, as a Cornerstone mission in Fundamental Physics. The other Cornerstone missions in this program are Herschel and Gaia in Astronomy and Bepi Colombo in Solar System Science, all to be launched soon, to follow Rosetta, which is flying already. LISA has subsequently been reconfirmed and it is now taken for granted in the Cosmic Vision Programme: "Despite some delays and descoping owing to budgetary constraints, the promises of Horizon 2000 will be broadly fulfilled when the astronomical missions Herschel and Planck set off into space in 2007. The second step in this

decadal series is Horizon 2000 Plus, including highly promising missions such as Gaia, BepiColombo, JWST, LISA and Solar Orbiter. Another challenge is LISA (Laser Interferometer Space Antenna), a joint ESA/NASA project which, by searching for gravitational waves, will open a new window on the Universe. On LISA Pathfinder (2011), ESA will test European and American contributions to the amazing technology required for this project."

1. ESA Cosmic Vision science objectives

2. ***Science Question 1: What are the conditions for planet formation and the emergence of life?***
   3. Research Topic 1.1. From gas and dust to stars and planets.
   4. Research Topic 1.2. From exo-planets to biomarkers.
   5. Research Topic 1.3. Life and habitability in the solar system.
6. ***Science Question 2: How does the solar system work?***
   7. Research Topic 2.1. From the sun to the edge of the solar system.
   8. Research Topic 2.2. The giant planets and their environments.
   9. Research Topic 2.3. Asteroids and other small bodies.
10. ***Science Question 3: What are the fundamental physical laws of the universe?***
    11. Research Topic 3.1. Explore the limits of contemporary physics.
    12. Research Topic 3.2. The gravitational wave Universe.
    13. Research Topic 3.3. Matter under extreme conditions.
14. ***Science Question 4: How did the Universe originate and what is it made of?***
    15. Research Topic 4.1. The early Universe.
    16. Research Topic 4.2. The Universe taking shape.
    17. Research Topic 4.3. The evolving violent Universe.
    18.

Cosmic Vision is constructed around four general Science Questions with three research topics each. While LISA as a Cornerstone mission in Fundamental Physics clearly belongs to Research Topic 3.2, it addresses all Research Topics in both Science Question 3 and Science Question 4.

Several of the ESA member states have roadmaps that make statements on space science and LISA in particular. In the German "Denkschrift Astronomie" (Deutsche Forschungsgemeinshaft 2003), LISA is a Golden Bullet and rated top priority. In the UK, LISA and LISA Pathfinder are contained in the Particle Physics and Astronomy Research Council (PPARC) Strategic Plan and have just been confirmed in the 2006 Delivery Plan (PPARC 2006). In the European Community's ApPEC Astroparticle Physics in Europe Roadmap (ApPEC 2006), active support for LISA is also foreseen as a top priority.

Appendix 1: LISA science objectives and scientific investigations

1. Understand the formation of massive black holes

1.1. Search for a population of seed black holes at early epochs.

1.2. Search for remnants of the first (Pop III) stars through observation of intermediate-mass black hole captures, both at formation and at later epochs.

2. Trace the growth and merger history of massive black holes and their host galaxies

2.1. Determine the relative importance of different black hole growth mechanisms as a function of redshift.

2.2. Determine the merger history of 10^4 to 3×10^5 $M_\odot$ black holes before the era of the earliest known quasars ($z \sim 6$).

2.3. Determine the merger history of 3×10^5 to 10^7 $M_\odot$ black holes at later epochs ($z < 6$).

2.4. Determine the masses and spins of low-z massive black holes (MBH) using observations of extreme mass ratio inspiral (EMRI) events ($z \lesssim 1$).

2.5. Enable the search for electromagnetic counterparts to MBH mergers in order to determine the host galaxy.

3. Explore stellar populations and dynamics in galactic nuclei

3.1. Characterize the immediate environment of MBH in $z \lesssim 1$ galactic nuclei from EMRI capture signals.

3.2. Study intermediate-mass black holes from their capture signals.

3.3. Improve our understanding of stars and gas in the vicinity of extragalactic black holes using coordinated gravitational and electromagnetic observations.

4. Survey compact stellar-mass binaries and study the structure of the Galaxy

4.1. Elucidate the formation and evolution of Galactic stellar-mass binaries; constrain the diffuse extragalactic foreground.

4.2. Determine the spatial distribution of stellar mass binaries in the Milky Way and environs.

4.3. Improve our understanding of white dwarfs, their masses, and their interactions in binaries and enable combined gravitational and electromagnetic observations.

5. **Confront General Relativity with observations**

5.1. Detect gravitational waves directly and measure their properties precisely.

5.2. Test whether the central massive objects in galactic nuclei are the black holes of general relativity.

5.3. Make precision tests of dynamical strong-field gravity in MBH binaries.

6. Probe new physics and cosmology with gravitational waves

6.1. Study cosmic expansion history, geometry and dark energy using precise gravitationally calibrated distances in cases and redshifts measured from electromagnetic counterparts or determined statistically.

6.2. Measure or set bounds on the spectrum of cosmological GW backgrounds.

6.3. Search for burst events from cosmic string cusps.

7. Search for unforeseen sources of gravitational waves

Abstract. We present an approach to experimentally evaluate gravity gradient noise, a potentially limiting noise source in advanced interferometric gravitational wave (GW) detectors. In addition, the method can be used to provide sub-percent calibration in phase and amplitude of modern interferometric GW detectors. Knowledge of calibration to such certainties shall enhance the scientific output of the instruments in case of an eventual detection of GWs. The method relies on a rotating symmetrical two-body mass, a Dynamic gravity Field Generator (DFG). The placement of the DFG in the proximity of one of the interferometer's suspended test masses generates a change in the local gravitational field detectable with current interferometric GW detectors.

1. Introduction

Dynamic gravity fields generated by rotating masses have been used previously in several experimental tests; however, their exploitation in conjunction with interferometric gravitational detectors has not been addressed until now. Forward and Miller [1] in 1967 developed a gravity field generator that allowed them to calibrate an orbiter sensor capable of measuring the lunar mass distribution. A similar technique was used by Weber *et al.* [2, 3] to calibrate a GW bar detector, where a volume of matter was acoustically stressed at 1660 Hz and the resulting noise excess in the detector was found to be consistent with theory. At the University of Tokyo, in the 1980s, a series of experiments were conducted to test the law of gravitation up to a distance of 10 m [4, 5, 6, 7, 8]. In these studies, the coupling between the dynamic field, generated by a rotating mass, and the quadrupole moment of a mechanical oscillator antenna was measured confirming the gravitational law within experimental uncertainties [7, 8]. In the 1990s, the gravitational wave group at the University of Rome developed and carried out experiments [9, 10] on the cryogenic GW bar detector, EXPLORER, at CERN. A device, with quadrupole moment of $\mathcal{M}_2 = 6.65 \times 10^{-2}$ kg m^2 and rotating in the frequency range of $450 - 470$ Hz, was developed to calibrate the antenna and was also used to confirm existing upper limits to Yukawa-like gravitational potential violations at laboratory scale.

The increased sensitivity and bandwidth of modern interferometric gravitational wave detectors warrants a new investigation into and opens exciting new possibilities for application of advanced gravity field generators in GW research. Presently interferometric gravitational wave detectors are reaching their design sensitivity enabling us to probe for gravitational radiation from sources well beyond the Local Group of galaxies. The response of these detectors to GW radiation is usually evaluated by direct injection of possible waveforms with known amplitude via magnetic actuators, also used for active control of the test masses' (essentially the interferometer mirrors) displacement. In addition, displacement in the test mass position can be induced by local gravity fields produced by a Dynamic gravity Field Generator (DFG). A DFG is essentially a symmetric rotating object with a significant quadrupole moment. When it is placed in the proximity of one of the interferometer mirrors, the induced change due to the device's quadrupole moment can be measured by the GW detectors such as the Laser Interferometer Gravitational Wave Observatory (LIGO) [11, 12], the VIRGO experiment [13], the 300 m Laser Interferometer Gravitational Wave Antenna (TAMA300) [14] and the GEO600 interferometer [15]. Future detectors, such as Advanced LIGO (AdLIGO) [16], offer higher sensitivity.

Several authors (see for example [17, 18, 19]) pointed out that gravity gradient (or Newtonian) noise, generated by density fluctuations in the Earth and the atmosphere, can be a potentially limiting noise source in advanced interferometric GW detectors. Motion of massive bodies (e.g. due to human activity) in the vicinity of the interferometer test masses also alters the local gravitational field, mainly at low

frequencies [20, 21, 17]. Gravity gradient noise manifests itself as an induced motion of the interferometer mirrors due to the fluctuation of the local gravity field. The DFGs described here can be used to modulate the local gravitational field around the test mass (TM) at a precise frequency and phase on a well-controlled manner and thereby directly validate/evaluate the expected noise generation and coupling mechanisms to complex structures.

In addition, DFGs have the potential to provide sub-percent amplitude and phase calibration of interferometric GW detectors. In the case of LIGO currently there are two calibration methods in use. The first one uses the interferometer TM's coil-magnet actuator to calibrate the gravitational wave channel (see for example [22] and [23]) while the second method uses the radiation pressure exerted on the TM by an independent laser source (see for example [24], [25], [26] and recently [27]). A DFG provides an alternative and independent sub-percent calibration, significantly improving the current accuracy of several percents (see e.g. [28]).

In this work we describe a hypothetical two-body DFG coupled to an ideal interferometric gravitational wave detector. The induced displacement on the suspended TM is dominated by the quadrupole moment of the DFG mass distribution in the case of a symmetric device. Any undesired system asymmetry will contribute to the dipole moment and can be measured and accounted for directly. We asses the application of such devices for the calibration of interferometric GW detectors as well their possible usage in gravity gradient noise studies that will eventually limit the performance of long baseline detectors at low frequencies.

Additionally, two DFGs in a null experiment setup can be used to explore violations to Newton's $1/r^2$ law well beyond the current limits. We investigated this possibility in detail for the LIGO, Advanced LIGO and Virgo detectors via numerical simulations. This is the subject of a separate publication. [29]

2. Newtonian field dynamics from a two-mass DFG

In analytical derivations, throughout this paper we will treat the suspended interferometer TM and the masses of the two-body DFG as point masses for simplicity. First we calculate the acceleration, along the laser beam axis, the mass is subjected to from a DFG configuration shown in fig.(1). Masses m_1 and m_2 are separated by a distance r_1 and r_2, respectively, from the center of rotation and are rotating at a frequency of $f_0 = \omega_0/(2\pi)$. The center of mass of mirror M and the DFG's center of rotation are separated by a distance d, where $d > r_{1,2}$.

Assuming that the distance between the DFG's i-th mass and the mirror is $h_{\rm i}$, the Newtonian potential at the mirror's center of mass is

$$V^{\rm c} = \sum_{i=1}^{2} V_{\rm i}^{\rm c} = -GM \sum_{i=1}^{2} \frac{m_{\rm i}}{h_{\rm i}}. \tag{1}$$

Introducing the variables $R_1 = r_1/d$, and $R_2 = -r_2/d$, $h_{\rm i}$, being a function of time can

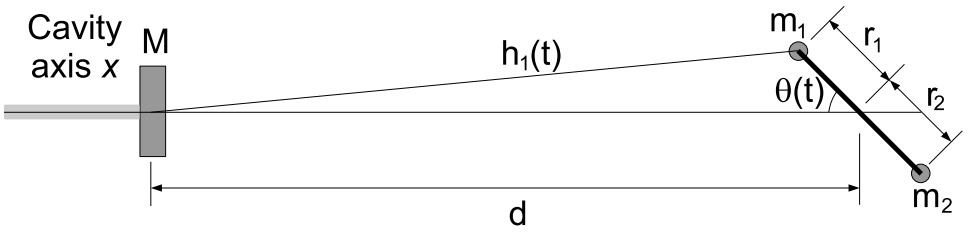

Figure 1. Schematic of an ideal symmetric two-mass DFG. The system consists of two masses, m_1 and m_2, separated by a distance of r_1 and r_2 from the center of rotation. The center of rotation is placed a distance d away from the mirror's center of mass. The system rotates at a frequency of $f_0 = \omega_0/(2\pi)$ where $\theta(t) = \omega_0 t$. The x axis denotes the interferometer's optical axis and only accelerations along this axis are considered.

be written as

$$h_{\rm i}(t) = d\,\sqrt{1 + R_{\rm i}^2 - 2R_{\rm i}\cos\theta(t)} \tag{2}$$

where $\theta(t) = \omega_0 t$ (see fig.(1)). The magnitude of the TM's induced acceleration along the laser beam axis is

$$a^{\rm c} = \frac{1}{M}\left|\frac{\partial V^{\rm c}}{\partial d}\right| = \frac{G}{d^2}\sum_{i=1}^{2} m_{\rm i} B_{\rm i}(R_{\rm i},\theta). \tag{3}$$

Here $B_{\rm i}(R_{\rm i},\theta)$ is a geometrical factor

$$B_{\rm i}(R_{\rm i},\theta) = \frac{1 - R_{\rm i}\cos\theta}{(1 - 2R_{\rm i}\cos\theta + R_{\rm i}^2)^{3/2}}. \tag{4}$$

For the case of a much smaller lever arm $r_{\rm i}$ than the distance d ($R_{\rm i} \ll 1$) we can expand $V^{\rm c}$ thereby expressing the induced acceleration $a^{\rm c}$ in terms of the n-th multipole moment $\mathcal{M}_{\rm n}$ of the DFG's mass distribution

$$a^{\rm c} = \frac{G}{d^2}\sum_{n=0}^{\infty}\frac{n+1}{d^n}\cdot\mathcal{M}_{\rm n}\cdot P_{\rm n}(\cos\theta) \tag{5}$$

where

$$\mathcal{M}_{\rm n} = m_1 r_1^n + (-1)^n m_2 r_2^n \tag{6}$$

and $P_{\rm n}(\cos\theta)$ is the Legendre polynomial of n-th order.

We remark that the DFG's dipole moment, as well as the higher-order odd moments, contribute only to the odd harmonic terms, whereas the quadrupole moment and the higher-order even terms, contribute only to the even harmonic terms. In the case of an ideally symmetric DFG, all odd moments vanish and the induced displacement is dominated by the quadrupole moment $\mathcal{M}_2$ at twice the rotation frequency.

2.1. Induced Displacement from the Newtonian Potential

The suspended TM can be considered as a free body for frequencies well above the eigenfrequencies of the suspension which typically lie around 1 Hz [30]. Neglecting the

time-independent term, double integrating eq.(5) with respect to time and considering only the dominant terms in the first few harmonics, the TM's displacement along the laser beam axis, x, can be written as

$$x(t) \simeq \frac{G}{(d\ \omega_0)^2} \times \left[2 \cdot \frac{\mathcal{M}_1}{d} \cdot \cos\omega_0 t + \frac{9}{16} \cdot \frac{\mathcal{M}_2}{d^2} \cdot \cos 2\omega_0 t + \frac{5}{18} \cdot \frac{\mathcal{M}_3}{d^3} \cdot \cos 3\omega_0 t \right] \tag{7}$$

In the case of a symmetric two-mass DFG, the dipole and the octopole contribution vanishes and the quadrupole moment $\mathcal{M}_2$ dominates. For initial LIGO throughout the paper we will consider the case of $m_1 = m_2 = 1.5$ kg, $r_1 = r_2 = 0.25$ m (equivalent to a quadrupole moment of $\mathcal{M}_2 = 0.1875$ kg m^2), with a rotation frequency of $f_0 = \omega_0/(2\pi) = 51$ Hz and a distance of $d = 2.5$ m. The resulting RMS displacement change $x_{\rm rms}$ at twice the rotation frequency is 1.24×10^{-18} m and scales according to

$$x_{\rm rms} \simeq 1.24 \times 10^{-18}\ {\rm m} \times \left(\frac{\mathcal{M}_2}{0.1875\ {\rm kg\ m^2}} \right) \times \left(\frac{51\ {\rm Hz}}{f_0} \right)^2 \times \left(\frac{2.5\ {\rm m}}{d} \right)^4 \tag{8}$$

Fig.(2) shows the design sensitivities for initial LIGO, AdLIGO and VIRGO also including LIGO's nominal displacement sensitivity for the beginning of the fifth science run [31] (S5) (data taking began in November 2005 and it is scheduled to collect one year of integrated data). The LIGO detectors' displacement sensitivity at 102 Hz is $\sim 2 \times 10^{-19}$ m$/\sqrt{\rm Hz}$ (see gray curve in fig.(2)).

The signal-to-noise ratio (SNR), defined as the ratio of the RMS signal to the displacement noise spectrum density integrated for a time T, gives a measure of how much a given stimulus is above background. For the above mentioned device, in the case of LIGO during S5 at 102 Hz (that is twice the above mentioned rotation frequency), and for an integration time of 1 s, we obtain an SNR of 6. In general terms, for an arbitrary noise floor $\tilde{n}$, and integration time T, the SNR scales as

$$SNR \simeq 6 \times \left(\frac{2 \times 10^{-19}\ {\rm m}/\sqrt{\rm Hz}}{\tilde{n}} \right) \times \left(\frac{T}{1\ {\rm s}} \right)^{1/2} \times \left(\frac{x_{\rm rms}}{1.24 \times 10^{-18}\ {\rm m}} \right) \tag{9}$$

where $x_{\rm rms}$ is shown in eq.(8). At the present sensitivity level of LIGO it is possible to sense such a dynamically changing gravity field from the DFG in question using a relatively small integration time.

Fig.(3) shows the SNR for different detectors as a function of twice the rotational frequency with an integration time of half an hour. Using once again the example cited above (DFG of quadrupole moment $\mathcal{M}_2 = 0.1875$ kg m^2), the top portion of the figure shows that for rotational frequencies ranging between 10 Hz and 500 Hz a distance of 2.5 m can be used for the initial LIGO detectors.

The center part of fig.(3) shows the SNR for the VIRGO detector. Due to the detector's sensitivity at low frequencies, low rotational frequencies, as low as ~ 10 Hz,

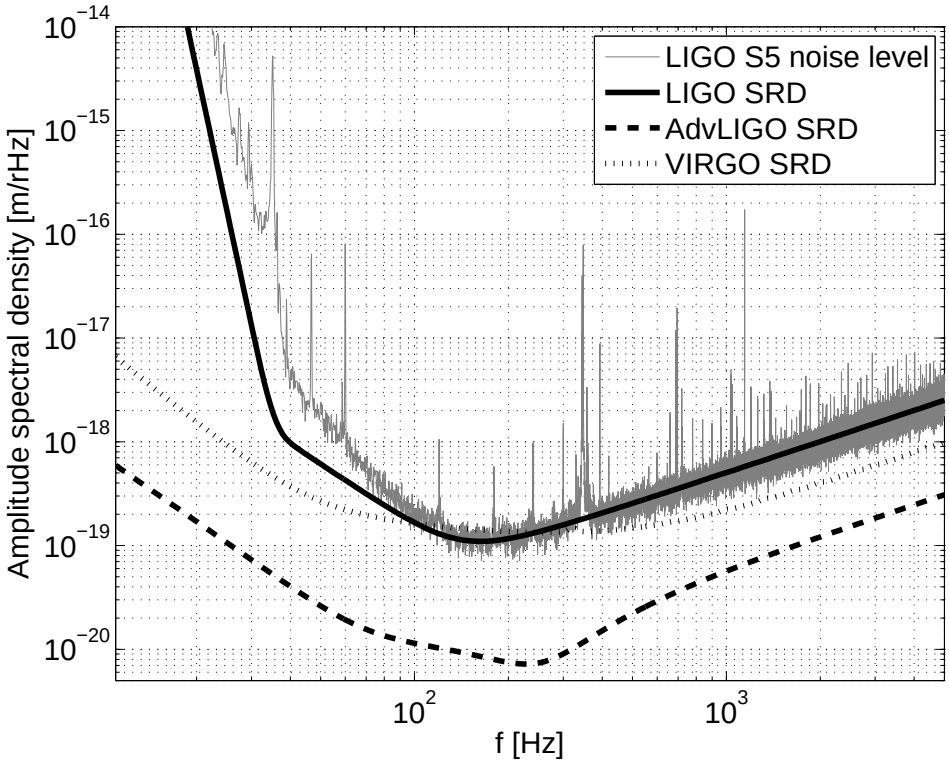

Figure 2. The nominal displacement sensitivity of LIGO (gray trace) at the beginning of the fifth science run (S5) together with its design curve (black); the design sensitivity (SRD) for Advanced LIGO (dashed) and the European VIRGO detector (dotted) are also shown.

could be used. The bottom portion of fig.(3) shows the response from the Advanced LIGO interferometer.

We would like to point out, that the choice of the rotational frequency as well as the DFG placement affects the level of spurious couplings. This is addressed in the sections to come.

2.2. A hypothetical DFG design

In fig.(4) we show a hypothetical DFG design based on the parameters discussed in this section. It consists of an Aircraft Grade (6Al/6V/2Sn) Titanium disc 60 cm in diameter and 10 cm in height. The disc has two cylindrical slots, 50 cm apart, which can hold different materials. The choice of materials was motivated by the desire to maximize density difference and strength while still keeping the material cost within the bounds of reason. We use Tungsten cylinders, 3.6 cm in diameter, as an example in the following sections. Practical details, such as the expansion and stress factors of the DFG under prolonged operating conditions must be modeled and simulated by finite element analysis methods, then subsequently measured and taken into account. These studies are beyond the scope of this paper.

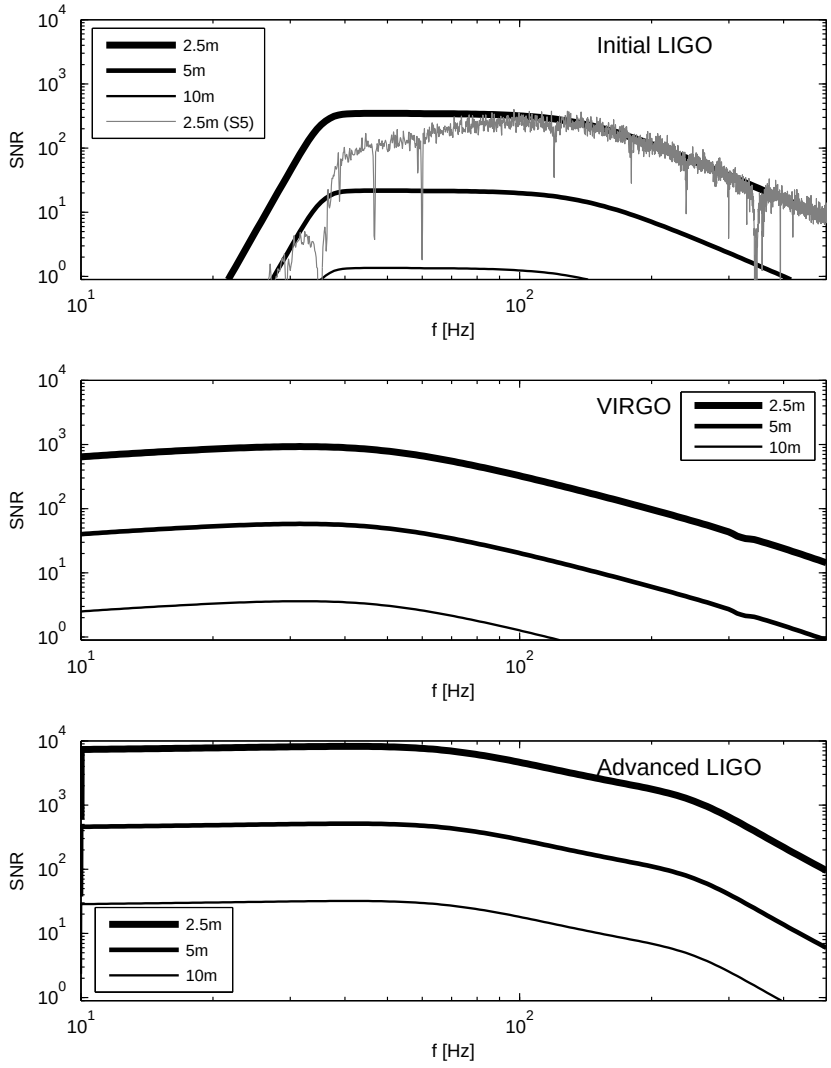

Figure 3. The Signal-to-Noise Ratio due to a DFG of quadrupole moment $\mathcal{M}_2 = 0.1875$ kg m^2 and 1/2 hour of integration time. Top: initial LIGO with the DFG positioned 2.5, 5 and 10m away from the TM; Middle: VIRGO for positions of 2.5, 5, and 10m; Bottom: Advanced LIGO with distances to the TM of 2.5, 5 and 10m.

2.3. Gravity Gradient Noise Studies with DFGs

A DFG in the proximity of the test mass of the interferometer can be used to experimentally investigate and model the coupling between the varying gravity field and the complex suspension system of the test mass in many fundamental configurations. The artificial gravity gradient field generated by a DFG not only couples to the test mass but also into all stages of the multistage suspension system and gives rise to possible second order effects. By varying the placement and rotation frequency of the

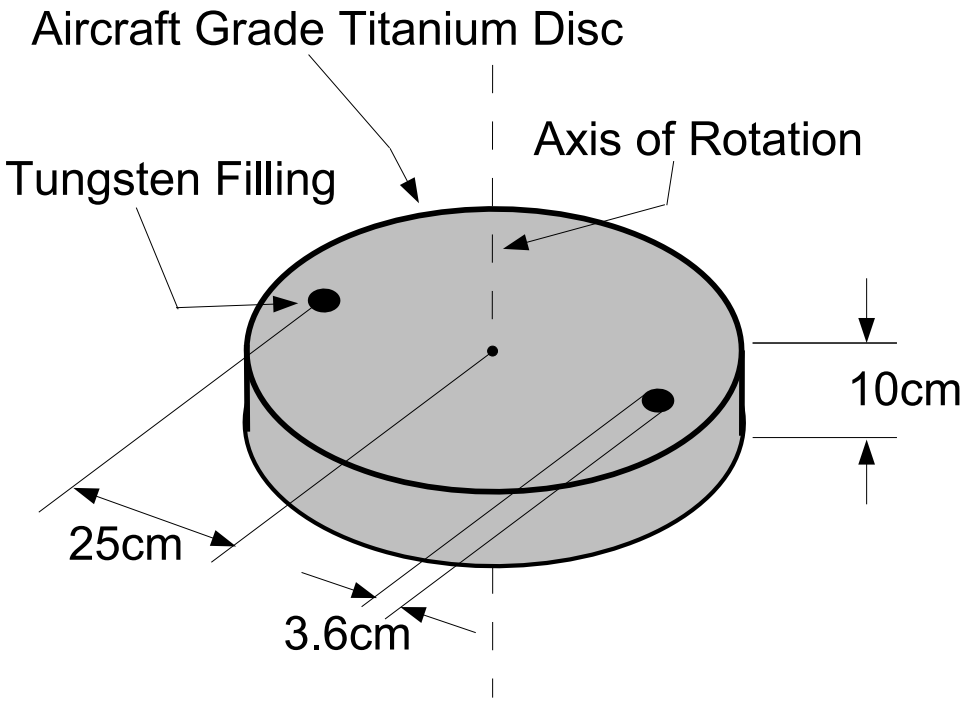

Figure 4. Sketch of a hypothetical DFG. The DFG consists of an Aircraft Grade (6Al/6V/2Sn) Titanium disc 50 cm in diameter and 10 cm in height. It holds two Tungsten cylinders at 20 cm from the rotation axis. The radius of the Tungsten cylinders is 1.8 cm.

DFG, this artificial gravity field can simulate conceivable gravity gradient noise sources specific to the local environment of the interferometric detector in question. With a DFG the dependence of the TM's displacement on the orientation of the gravity gradient noise source can be mapped: the DFG can be installed at different distances from the TM in the axis of the laser beam as well as placed off-axis and out of the plane of the interferometer. This is especially important since gravity gradient noise couples to the system from each direction on different ways thus potentially introduces problems into the detection chain via hard to track second order effects and possible nonlinear couplings. Additional advantage of artificially generated dynamic gravity gradients is that the frequency dependence of the interferometer's response to Newtonian noise sources could be mapped out in detail, which is especially important for the low frequency region. The results might eventually be used in generating approaches for mitigating the effect of local gravity gradients in future detectors at low frequencies besides providing accurate information about the nature of this noise source.

2.4. Calibration of an Interferometric GW Detector using a DFG

In this section we address the level of precision we must achieve when using the DFG as a calibration tool. While the present calibration accuracy of 2-10% in amplitude and phase [28] (depending on frequency range) might seem adequate for upper limit

and event rate studies, it will be important to know the calibration of the detector to a higher accuracy when the collaborations enter the "detection era". In the context of a detected signal via a global network of interferometric GW detectors, where the waveform is recoverable, amplitude and phase calibration known to a higher precision shall be beneficial. Coherent network methods will perform better, pointing accuracy will increase, source distance information can be recovered and used with a higher accuracy. With an increase in calibration certainty the precision of waveform and polarization recovery is expected to improve, which in turn allows for better scientific output.

With the DFG method, the achievable calibration accuracy would be limited by the uncertainty in the gravitational constant, G, at the subpercent level. To estimate the calibration uncertainty we first consider the TM displacement $x_{\rm rms}$ induced by the DFG due to its quadrupole moment $\mathcal{M}_2$ is given in eq.(8). In statistical terms (assuming a large number of DFGs identical within practical tolerances), the relative uncertainties in the measurement of the gravitational constant ($\delta G/G$), in the mass ($\delta m/m$), arm length ($\delta r/r$), rotation frequency ($\delta f_0/f_0$) and distance from the TM center of mass ($\delta d/d$) add in quadrature leading to a relative uncertainty on the induced displacement ($\delta x/x$) and is approximately described by

$$\left(\frac{\delta x}{x}\right)^2 \simeq \left(\frac{\delta G}{G}\right)^2 + \left(\frac{\delta m}{m}\right)^2 + 4\left(\frac{\delta r}{r}\right)^2 + \\ + 4\left(\frac{\delta f_0}{f_0}\right)^2 + 16\left(\frac{\delta d}{d}\right)^2 \tag{10}$$

Our goal is to achieve sub-percent precision in amplitude calibration, therefore we need to keep the relative uncertainties of every DFG parameter well below $\simeq 0.1\%$.

The currently accepted value of the gravitational constant, G, is $((6.6742\pm0.0010)\times 10^{-11}\mathrm{m}^3\mathrm{kg}^{-1}\mathrm{s}^{-2})$. This means, that there is a $\simeq 0.015\%$ contribution to the relative uncertainty on the induced displacement just by taking into consideration the precision of previous G measurements. G contributes as the leading term in limiting the precision of amplitude calibration if the uncertainties related to manufacturing and/or measurement of the other parameters contributing to each of the other four terms in equation (10) is below 0.015%. Thus we require

$$\begin{aligned} \frac{\delta m}{m} &\leq 1.5\times 10^{-4} \\ \frac{\delta r}{r} &\leq 7.5\times 10^{-5} \\ \frac{\delta f_0}{f_0} &\leq 7.5\times 10^{-5} \\ \frac{\delta d}{d} &\leq 3.75\times 10^{-5} \end{aligned} \tag{11}$$

These levels of uncertainties adding up in quadrature yield 0.035% uncertainty in ($\delta x/x$), more than adequate for a sub-percent amplitude calibration.

Considering the DFG described in sec.(2.1), with $m_1 = m_2 = 1.5$ kg, $r_1 = r_2 = 0.25$ m, rotation frequency of $f_0 = 51$ Hz and distance from the TM of $d = 2.5$ m, the required uncertainties in (11) translate to

$$\begin{aligned} \delta m &= 2.25 \times 10^{-4} kg \\ \delta r &= 1.9 \times 10^{-5} m \\ \delta f_0 &= 3.8 \times 10^{-3} Hz \\ \delta d &= 9.4 \times 10^{-5} m \end{aligned} \tag{12}$$

Most off the shelf balances can be used to measure the DFG masses, while the ultimate precision of mass determination, δm, is ~ 50 μg [32] with a state of the art mass comparator. Uncertainties on δr are determined by machining precision and can be kept within ~ 1 μm [33].

The uncertainty in the rotational frequency f_0 can be addressed by using a precision optical encoder to provide pulses which can be used to phase lock the DFG to an atomic clock or GPS. In this case, the uncertainty is limited by the encoder itself or the servo system. For a rotation period of $1/f_0 = 20$ ms and an off-the-shelf 16-bit optical encoder providing a square pulse train at 3.2 MHz ($\simeq 300$ ns/pulse), the relative position of the square wave rising edge with respect to the atomic clock signal can be determined within $\delta t \simeq 10$ ns. This allows for a high precision of $\delta f_0/f_0 \sim 10^{-6}$.

Distance d could change somewhat over time when a DFG is used as a calibration device. The thermal variations in the TM and DFG housings are kept within fractions of a degree and should not play a significant role. The tidal-compensation system, a servo-mechanism acting on the position of the TM to compensate for earth-moon and earth-sun tidal effects, displaces the TM locally with peak to peak excursions of the order of ~ 300 μm (see [34] and [35]). This kind of excursion can be taken into account during the calibration.

Distance d can be directly measured via laser based range finding (i.e. Light Detection and Ranging, LIDAR) technologies, which can provide better than $\delta d \simeq 1$ μm uncertainty in lab environments [36].

When direct distance measurement between the TM and the DFG is not possible, an alternative method for finding d can be adopted. The $2\omega_0$ component can be measured as a function of d by varying the DFG's position by a well known amount and using a χ^2 minimization procedure to estimate the effective distance d. For simplicity, let the distance vary linearly

$$d(t) = d_0 + v\ t \tag{13}$$

where v is the DFG's pivot velocity along the beam axis. Following eq.(8), the uncalibrated interferometer response R_{IFO} to the DFG's stimulus can be described as

$$R_{IFO} = \frac{K}{(d_0 + v\ t)^4} \tag{14}$$

where K and d_0 are free parameters. A linear sweep of the pivot's position would provide an estimate of d_0 while any residual would provide information on any $d(t)$ component that could potentially be significant. The uncertainty in d_0 will be statistical in nature and eventually will be limited to the systematic uncertainty of the other parameters, such as the dipole moment and the rotation frequency. In this case

$$\frac{\delta d}{d} \sim \frac{\delta r}{r} \sim 10^{-5} \tag{15}$$

There are also other uncertainties that need to be addressed for realistic measurements, most of them are second order in nature. For example, an accurate alignment of the DFG is necessary: the effective arm length $\tilde{r}$ is altered if the plane of rotation of the DFG is not aligned with the plane of the interferometer. Restricting this change to 19 μm (same as the uncertainty in r) restrains the leveling of the DFG to 0.7°, which is achievable with commercial optical positioning methods.

Placing the DFG out of line with the Fabry-Perot arm introduces another second-order source of error. This error creates a distance $\tilde{d}$ which differs from d. Requiring their relative change $(\tilde{d} - d)/d$ to be of the order of 10^{-5} sets an alignment requirement to the cavity with an order of 1 cm, which is easily achievable with optical positioning.

The phase of the rotating DFG can be measured by phase locking the DFG to an atomic clock or GPS. The phase uncertainty (in the first order) is therefore due to $\delta t/t$. Taking the previously mentioned $\delta f_0/f_0 \sim 10^{-6}$ value as a basis, the precision of phase calibration can even be better than $\simeq 0.01\%$.

The quoted accuracy of calibration for the LIGO detector for recent science runs [28] is at the 6-10% level and valid for a broad range of frequencies and for the entire length of the science run. The inherent accuracy of the calibration method itself is at the order of 1-2% [37]. Using DFG as calibration tool this can be pushed down to the subpercent level for amplitude calibration and an even better accuracy can be achieved for phase calibration.

To take full advantage of this proposed calibration method for interferometric GW detectors, we envision a DFG positioned at around 2-3 m from each end mirror of the two arms of the interferometer. The rotation frequencies can be chosen such that subpercent level calibration could be provided for the most sensitive region of the detector response. The employment of two separate DFGs, rotating at slightly different frequencies, would allow the calibration of the two interferometer arms separately in a spectrally similar region. Additionally, with longer integration times higher order harmonics become detectable, thus the device can be used for calibration of interferometer response of frequency regions at points separated by the DFG's rotation frequency.

3. Mitigation of Spurious Couplings from the DFG's Motor

In interferometric GW detectors, using DFGs as a calibration tool means that the new device will be put in close proximity (e.g. 2.5 meters) of the test mass for a prolonged period of time, while the GW detector itself is in a continuous data taking mode. Thus,

it is necessary that spurious coupling of the DFG to the suspended mirror be negligible, as detailed in this chapter. The only acceptable effect on the GW data should be the fine and easily filterable lines at the multiples of the rotational frequency of the DFG. Of most concern is the electro-magnetic coupling via the motor driving the system, the acoustic coupling via the local interferometer optical sensors and the seismic vibrations induced by an unbalanced DFG.

3.1. Electro-Magnetic Coupling

There are two ways the motor's electro-magnetic field could couple to the test mass. One coupling is the interaction of the motor's electro-magnetic (EM) field with the interferometer electronics residing next to the DFG. The other way is through the coupling of the DFG's EM field with the coil-magnet system needed to drive the TM in position.

With the proper Electromagnetic Interference (EMI) shielding in place and using DC permanent magnet servo motors the parasitic emission can be mitigated. The DFG could be equipped with a non-integer gear ratio to completely separate the EM harmonics from the Newtonian signal since the induced displacement appears at harmonics of the rotation frequency of the DFG and not of the motor.

It is also possible to completely eliminate the mechanical coupling via an Eddy Current Motor, which also simplifies the DFG, balancing and bearing design.

3.2. Acoustic coupling

For the LIGO interferometers, acoustic signals near the detector could potentially couple directly to the gravitational wave channel. A possible coupling mechanism could consist of an acoustic stimulus exciting the beam position on an optical sensor. If the sensor in question is used to feedback on TM positions, the acoustic excitation finds its way into the detector. This effect is mitigated by installing the DFG in its own vacuum envelope.

3.3. Seismic coupling

The most obvious concern is the TM coupling through the ground. For an ideally symmetric DFG, as described in earlier sections, the dipole moment vanishes and so does its contribution to the Newtonian field. Any asymmetry in the system creates a non-null dipole moment at the rotation frequency, introducing ground vibration. In this section we use a simple model to estimate this cross-coupling for the initial LIGO case.

For an asymmetric DFG, the device's center of rotation will be subjected to a sinusoidal force F' at the rotation frequency ω_0 whose RMS value along the beam axis can be written as

$$F'_{\rm rms} = \frac{1}{\sqrt{2}}\,\omega_0^2\,\mathcal{M}_1 \tag{16}$$

where $\mathcal{M}_1$ is the dipole moment of the DFG. The displacement $\delta x_{\rm react}$ of the reaction mass due to the asymmetry, to first order approximation, is

$$\delta x_{\rm react} = \frac{m\, r}{\sqrt{2}\, M_{\rm react}}\ (\epsilon_r + \epsilon_m) \tag{17}$$

where $\epsilon_r = \delta r/r$ and $\epsilon_m = \delta m/m$. The TM displacement can then be expressed as

$$\delta x_{\rm rms} = \delta x_{\rm react}\ {\rm R(f)} \tag{18}$$

where R(f) is the attenuation factor provided by LIGO's seismic isolation stage and suspension.

To estimate the motion of the cement slab beneath both the DFG and the TM we select achievable uncertainty requirements of 11. For a plausible reaction mass $M_{\rm react}$ of 100 tons (assuming a concrete slab $10m \times 10m \times 0.5m$) its mass displacement is

$$\delta x_{\rm react} = 6 \times 10^{-10}{\rm m} \tag{19}$$

LIGO's stack[38] reduces this displacement down by a factor of $\sim 10^6$ at 51 Hz while the suspension stage [30] brings it down by an another factor of $\sim (51\ {\rm Hz}/0.74\ {\rm Hz})^2 = 4500$. This results in a TM displacement of

$$\delta x_{\rm rms} = 1.3 \times 10^{-19} m \tag{20}$$

which is below the noise floor of LIGO and is a negligible spurious coupling.

The above estimated effect of seismic coupling can be further reduced by attaching the rotating DFG to a light slab with very small reaction mass $M_{\rm react}$. The seismic signal of a high-precision seismometer coupled to the slab, resulting from system asymmetries, can be substantially reduced by iterative adjustment of the balancing of the DFG. Attaching this balanced DFG to a heavy slab with higher $M_{\rm react}$ will reduce $\delta x_{\rm react}$ to be well below the ambient seismic field. The reduction factor is given by the ratio of the reaction mass of the light slab to the reaction mass of the heavy slab. This can lead to a TM RMS displacement even orders of magnitude smaller than as given in eq.(20).

4. Safety

Significant kinetic energy (i.e. tens of kJs) is stored in the DFG once it rotates and crucial safety considerations must be addressed. There are two major points of failure management to be concerned with. (a.) The vacuum chamber of the DFGs must be made strong enough to withstand the damage of an accidentally disintegrating disk. This is the standard solution for high speed gyroscopes. (b.) For added security, the gap between the inner wall of the vacuum chamber and the outer edge of the rotating disk must be kept relatively *small*. In the event of an incident where the DFG's material starts to yield or its angular acceleration is uncontrolled the disk will expand radially touching the sidewall and slowly stop, preempting a catastrophic failure. These conditions can be met using Finite Element Analysis (FEA) aided design, in-house destructive testing of sacrificial parts and relying only on X-ray rated base materials.

5. Conclusion

These initial feasibility studies of simple DFGs indicate that they are capable of dynamically changing the local gravitational field by an amount detectable by current interferometric gravitational wave detectors.

The DFGs can be designed, manufactured, tuned and characterized to be symmetric and safe enough to eliminate concerns about vibrations and spurious couplings, once positioned in the proximity of one of the suspended TMs.

The generated gravity gradient signal is proportional to the DFG's quadrupole moment with its signature appearing at twice the rotation frequency. At the present detector sensitivity level of LIGO, systematic uncertainties due to the DFGs can be well below the 0.1% level in amplitude with insignificant timing uncertainties. This apparatus provides a detector-independent calibration technique that can significantly surpass the achievable precision of other existing calibration methods.

The DFG also offers a unique and distinctive way to generate a differential arm length displacement for gravitational wave detectors. Apart from calibration objectives, it could also be used to validate the expected noise generation and coupling mechanism of Newtonian noise, possibly a limiting factor in advanced gravitational wave detectors.

There are many details that need attention when designing and manufacturing a practical device. Finite element analysis of the DFGs and subsequent experimental studies are necessary to completely understand the stresses the DFG is subjected to. The DFGs will be enclosed in a separate vacuum chamber. A prototype design and test will be necessary to balance the disk and test vibration control. Other mostly practical problems, such as safety, can also be solved as was shown in past applications/experiments that have used rapidly rotating instruments.

Generation of High-Frequency Gravitational Waves (HFGW) by Means of an Array of Micro- and Nano-Devices

by
Robert M. L. Baker, Jr.†

ABSTRACT

The process by which High-Frequency Gravitational Waves (HFGW) are generated by means of the time rate of change of the acceleration of a mass or masses, termed a "jerk" or a "shake," is developed. Arrays of micro- and nano-devices, termed energizing and energizable elements, are utilized to generate a train of coherent gravitational waves. As the waves progress along the axis of such devices they are reinforced by the energizable elements, under the control of a computer logic system in order to be modulated for applications such as communication. Starting with a theoretical non-rotating, but ratcheting or jerking rim or ring, linear devices, such as a stack of ratcheting rims or rings, evolve. These devices emulate a rotating rim. But the changing centrifugal force vector of a rotating rim or ring, which is tangent to rim and represents a jerk, is replaced by the electromagnetically, reciprocally jerked energizable elements of a non-rotating rim that do not involve large g loads. Two specific devices are described to illustrate the concept: the first such device involves a barrel or stacks of concentric rims whose surface or edges are covered with an array of ultra-small micromagnets (energizable elements) surrounded by a sheath of ultra-small microcoils (energizing elements); it generates approximately 380 kW of HFGW. The second is much smaller, 18 mm in length, and through use of a superconducting lens delivers a flux of 6.3×10^{-7} watts per square meter at a 7 km distant receiver – about that of a handheld radio transceiver. Other HFGW generators utilizing nanowire lattices for a high-frequency nanomechanical resonators and parallel current-carrying plates are also investigated and the question of null GW generation for symmetrical systems is considered.

The problem, which all of the devices discussed in this paper solve, is to cause a system of masses, which could be mini-magnets, micro-devices, nano-devices, individual molecules, submicroscopic particles, or individual electrons (as in a superconductor), under computer logic control, to move in concert with a jerk in order to *build up* (generate) HFGW with either planar or cylindrical wave propagation. Such jerking masses produce a very long sequence of HFGW pulses having significant average power and ability to carry information without generating incapacitating heat, causing disruptive g loads, or producing overpowering EM radiation.

Nomenclature

A	area
a	semi-major axis of a two-body orbit
a	acceleration
B	magnetic flux density
c	speed of light or, alternatively, the electron mobility speed

$D_{\alpha\beta}$	quadrupole moment-of-inertia tensor
d	diameter or distance between conductors
E	energy
e	eccentricity of a two-body orbit
F	force per unit length
f	force
$\mathbf{f_{cf}}$	centrifugal-force vector
G	universal gravitational constant
h	strain in the space-time continuum , ? *l*/*l* caused by GW passage
I	moment of inertia
i	current
l	length
M	mean anomaly for a two-body orbit
m	mass of an object on orbit in characteristic units or of any object in kilograms
m	sum of the masses of a pair of binary stars or mass of a rod in kilograms
N	noise or index of GW refraction or number of pulses in an activation time interval
n	mean motion for a two-body orbit or number of objects or elements or number of rim or ring sections in a stack
n	number of coil turns or number of concentric rims or rings
P	the magnitude of the power of a gravitational-radiation source
p	parameter or semilatus rectum = $a(1-e^2)$
q	charge or periastron distance, a(1-e)
R	resistance or range
r	radial distance to an object on orbit; alternately, the effective radius of gyration
r	radius of a magnetic core, piston or barrel or stack of rims
S	GW flux
s	distance or displacement
t	time
t`	spinning-rod time
V	volume or speed
v	true anomaly of a two-body orbit
v	velocity or frequency
x	axis of orthogonal coordinate system
y	axis of orthogonal coordinate system
z	axis of rotation orthogonal to x and y axis
α	attenuation or diffraction angle
Δ	small increment
Δf_{cfx}	incremental x component of centrifugal force
Δf_{cfy}	incremental y component of centrifugal force
Δt	time increment
d	fraction of a linear-motor, GW generator's barrel radius that is an energizing-element sheath and/or energizable-element core
δl	thickness of a given rim or ring
δm	differential mass
δt	differential time or activation time interval
?	the central angle of a rotating rod
κ_{I3dot}	coefficient (constant or function) of the kernel in the d^3I/dt^3 formulation of the quadrupole
λ	wavelength
μ	$= m_1 + m_2$ = sum of masses on a two-body orbit in characteristic units
μ_0	permeability of free space
ν	frequency
σ	absorption cross section
τ	characteristic time; for heliocentric unit systems = 5.022×10^5 seconds
ω	angular rotational rate

b	current in adjacent wire
cf	centrifugal
d	diffraction
GW	gravitational wave
l	longitudinal
p	phase
r	radial
t	tangential
x	x component
y	y component

1. INTRODUCTION

The general concept of the devices discussed in this paper is to simulate scientifically acceptable generation of gravitational waves (GW) like those that are produced by energizable celestial systems such as rotating binary stars, star-black-hole collisions, star explosions, star collapse, binary black holes, spinning black holes, etc. through the use of smaller macro- and micro-, terrestrial or laboratory energizable systems. Such terrestrial systems generate well over 40 orders of magnitude more force intensity by virtue of their use of non-gravitational forces (nuclear or electromagnetic compared to gravitational) than a typical celestial system and well over 12 orders of magnitude greater frequency (THz or QHz {10^{15} Hertz; the term Quadrahertz, QHz, is preferred over Petahertz or PHz} and higher compared to kHz or very small fractions of a Hz) than a typical celestial system. Terrestrial energizable systems produce significant and useful GW according to the various designs of the devices to be described, even though they are orders of magnitude smaller and less massive than the extraterrestrial celestial systems. In the various designs of these devices, large numbers of small energizable elements are energized in sequence or in concert, by energizing or stimulating elements, to emulate the motion of a much larger and extended body in order to enhance the generation of GW.

The specific concept, which will be expanded upon, requires applying a long series of rapid "jerks" or "shakes" or third-time-derivative motion to a mass or series of masses, using relatively strong magnetic, electric, or nuclear forces. The devices described in the present paper will be shown to generate significant *High-Frequency Gravitational Waves* or **HFGW** without disruptive g loads. The effect will be measurable in the laboratory since it affects or warps the *spacetime* geodesic over very small distances (due to high frequency and short GW wavelength) and thereby will produce HFGW detectable by utilizing detectors described in this Conference. If the energizable elements are uncharged, then there may be little or no attendant electromagnetic (EM) radiation.

In order to illustrate the concept, a circular rim, which does not rotate, but ratchets or jerks, is described. This rim is then evolved into a practical gravitational-wave generator. The system of masses described in this paper (and subject to jerks) can be small or mini magnets micro- or nano-devices, molecules, sub-microscopic particles, electrons (e.g., in a superconductor; about 10^{20} per cubic centimeter), etc. The misconception that the laboratory generation of GW is not feasible is fed by the example of a spinning rod given in most introductory textbooks. Such a rod utilizes the change in the centrifugal force vector to generate GW and is torn apart well before any significant GW is generated. The devices discussed herein are completely different and utilize electromagnetic forces and reciprocating, not rotational, motion in order to generate GW.

2. JERK FORMULATION OF THE QUADRUPOLE EQUATION

There is no new Physics here, simply a different approach or formulation of the conventional equations utilized to estimate GW power in order to render engineering applications more apparent. I will employ the standard quadrupole equation, which was originally formulated by Einstein in 1918, to compute the HFGW power. I will formulate that basic quadrupole approximation in terms of a change in force, ?f, over a short time interval, ?t, which is defined as a "***jerk***." The derivation of this basic jerk equation will be accomplished by two separate analysis paths: one starting with the third derivative of the moment of inertia formulation of the quadrupole equation and the other starting with the spinning rod (or binary orbit) formulation of the quadrupole equation. The resulting jerk equation will be numerically checked against the known result for the binary star pair PSR 1913 + 16.

2.1 *Derivation from Third Time Derivative of the Moment of Inertia*

As is well known and noted specifically in a letter (dated January 19, 2000) to me from Dr. Geoff Burdge, Deputy Director for Technology and Systems of the *National Security Agency*: "Because of symmetry, the quadrupole moment can be related to a principal moment of inertia, I, of a three-dimensional tensor of the system and … can be approximated by

$$-dE/dt \approx -G/5c^5 (d^3I/dt^3)^2 = - 5.5x10^{-54} (d^3I/dt^3)^2." \quad (1A)$$

or from Eq. (110.16), p. 355 of Landau and Lifshitz [5] :

$$P = | - dE/dt | = (G/45c^5)(d^3D_{\alpha\beta}/dt^3)^2 \text{ [watts]} \quad (1B)$$

or

$$P = 1.76x10^{-52} (d^3I/dt^3)^2 \text{ [watts]}. \quad (1C)$$

This is Einstein's ***quadrupole equation***.

In Eq. (1A), k in Burdge's notation is G (not, however, the Einstein tensor) and the units in Eq. (1C) are in the MKS system [watts] not the cgs. In order to introduce the jerk concept let us consider the hypothetical example of a rim that, like the ratchet wheel of a mechanical watch, need not be uniformly rotating or, in fact, not rotating at all. In this case, for a collection of masses, which are small permanent magnets, along the rim,

$$I = \delta m\, r^2 \quad [kg\text{-}m^2], \quad (2)$$

where

δm = mass of an individual magnetic sites around the rim [kg], and

r = the distance from a pivot out to any single δm on the rim [m] (or more exactly, the *radius of gyration* of the rim). Thus

$$d^3I/dt^3 = \delta m d^3 (r^2)/dt^3 = 2r\delta m(d^3r/dt^3) + \ldots \quad (3A)$$

Approximately, by delta differentiation,

$$2r\{dm(d^3r/dt^3)\} \sim 2r\{dm?(d^2/dt^2)/?t\} \quad (3B)$$

and, by noting that by Newton's second law of motion,

$$f_r = dm(d^2r/dt^2), \quad (4A)$$

we have, again by delta differentiation,

$$dm?(d^2r/dt^2) = ?f_r \quad (4B)$$

where f_r = radial force on δm and $?f_r$ is the rapid increase in f_r over time ?t (**the jerk**). The third derivative of I is, therefore, approximated by

$$d^3I/dt^3 \cong 2r\,\Delta f_r/\Delta t, \quad (5)$$

in which Δf_r is the nearly instantaneous **increase** in the force on magnetic (or other energizable element) sites, δm, caused by the magnetic field of current-carrying coils (or other energizing elements) when they are turned on and off or pulsed by transistors or ultra-fast switches resulting in a jerk.

Let us now visualize a stack of such rims; each one composed of a circle of small permanent magnets that are surrounded by a close-by ring of coils (please see FIG. (3B)). In this regard, the coils adjacent to the periphery of each rim are sequenced (at the local GW speed, say the speed of light) along the stack of rims from one rim to the next in order to generate or build up the train of coherent HFGW as they move through the stack of rims (energizable magnetic sites). In order **not** to build up acceleration the jerks are reciprocating; but (arguably) due to the square in the kernel of the quadrupole equation, the GW radiates in both directions along the axis of the circular rims (through their centers) no matter which direction the peripheral magnetic masses are jerked. In summary, by substituting Eq. (5) into Eq. (1C),

$$P = 1.76x10^{-52} (2r\Delta f_r/\Delta t)^2 \text{ [watts]}, \quad (6)$$

which is the **jerk formulation of the quadrupole equation.**

2.2 *Derivation from a Spinning Rod*

An alternative derivation of Eq. (6) is as follows: From Eq. (1), p. 90 of Joseph Weber [1] one has for Einstein's formulation of the gravitational-wave (GW) radiated power of a rod spinning about an axis through its midpoint having a moment of inertia, I [kg-m^2], and an angular rate, ω [radians/s] (also please see, for example, pp. 979 and 980 of Misner, Thorne, and Wheeler [2], in which I in the kernel of the quadrupole equation also takes on its classical-physics meaning of an ordinary moment of inertia):

$$P = 32GI^2\,\omega^6/5c^5 = G(I\omega^3)^2/5(c/2)^5 \text{ [watts]} \quad (7)$$

or , with $I = r^2m$ (r being the radius of gyration of the rod)

$$P = 1.76x10^{-52}(I\omega^3)^2 = 1.76x10^{-52}(r\{rm\omega^2\}\omega)^2 \quad \text{[watts]} \quad (8)$$

where $\{rm\omega^2\}$ can be associated with the magnitude of the rod's centrifugal-force vector, $\mathbf{f_{cf}}$. Equation (8) is the *same equation as that given for two bodies on a circular orbit* on p. 356 of Landau and Lifshitz [5] ($I=\mu r^2$ in their notation) where $\omega = n$, the orbital mean motion [radians/s].

The $\mathbf{f_{cf}}$ vector reverses every half period at **twice the angular rate of the rod** (and a $\mathbf{f_{cf}}$ component's magnitude completes one complete period in half the rod's period). Thus the GW frequency is 2(ω/2p), where ? is in [radians/s]. The change in the centrifugal-force vector itself (which I call a "jerk" when divided by a time interval) is a differential vector at right angles to the $\mathbf{f_{cf}}$ vector and directed tangentially along the arc that the dumbbell or rod moves through. The differential change in, for example, the x-component of the change in centrifugal force, $?f_{cfx}$, is f_{cfx} ?? and the change in the y-component is $?f_{cfy}$ is f_{cfy} ?? , where ? is the central angle of the rotating rod in radians. By delta differentiation of $f_{cf}^2 = f_{cfx}^2 + f_{cfy}^2$,

$$f_{cf}?\ f_{cf} = f_{cfx}?\ f_{cfx} + f_{cfy}?\ f_{cfy} \qquad (9A)$$

and when one associates the components $?f_{cfx,y}$ with $f_{cfx,y}$?? and, after dividing by ?t` (t` being spinning-rod time), and noting that ??/?t` =? ,

$$f_{cf}?\ f_{cf} / ?t` = (f_{cfx}^2 + f_{cfy}^2)?\ . \qquad (9B)$$

Thus $?\ f_{cf} / ?t` = f_{cf}?$ ; but ?t` = ½?t since the period of the GW is half the period of the rod, so that

$$2?\ f_{cf} / ?t = f_{cf}? , \qquad (9C)$$

but $f_{cf} = \{rm?^2\}$ so

$$2?f_{cf}/?t = \{rm?^2\}? \qquad (9D)$$

and substituting Eq. (9D) into Eq. (8) yields

$$P = 1.76x10^{-52}(2r\Delta f_{cf}/\Delta t)^2, \qquad (10)$$

where $(2r\Delta f_{cf}/\Delta t)^2$ is the kernel of the quadrupole approximation equation and $\Delta f_{cf}/\Delta t$ is, again, the **jerk.** Equation (10) is identical to Eq. (6), but arrived at by a different analysis path.

Equation (6), like Eqs. (1), (7), (8) and (10), are approximations for GW power and may **only hold accurately** for $r << \lambda_{GW}$ and for speeds of the GW generator components far less than the speed of light, c. Please see, for example, Pais [3], p. 280 and Thorne [4], p. 357. (On the other hand, Leonid P. Grishchuk at this Conference suggested that the requirement that $r << \lambda_{GW}$ may not be a stringent one.)

2.3. *Validation Based on Orbit of PSR 1913+16*

As a numerical validation of Eq. (10), that is a validation of the use of a jerk to estimate gravitational-wave power, let us utilize the approach for computing the gravitational-radiation power of the pulsar **PSR 1913+16** observed by Hulse and Taylor [6] to demonstrate the existence of GW.

2.3.1 *Orbital Elements*

Since the observation of the binary pulsar PSR 1913+16 (identifies right ascension of 19 degrees 13 minutes and declination of 16 degrees North) represents the only *experimental confirmation* of gravitational waves, insight into the jerk approach can be found in the analyses of such a double-star system. Thus please bear with the following rather laborious arithmetic.

The pair of PSR 1913+16 stars will coalesce in $3.5x10^8$ years due to GW radiation and produce a rather continuous GW until that time. It is the pair's coalescing that **exactly** agrees with GW-generation theory (utilizing orbital mechanics) that indirectly confirms the existence of GW. According to J. H. Taylor, Jr. [6], the period of their mutual rotation is 7.75 hours (or $\mathbf{2.79x10^4}$ **[s]**), periastron is 1.1 solar radii (one solar radius is $6.965x10^8$ [m]), and apastron is 4.8 solar radii. It's radius of gyration is essentially the semi-major axis a = (1.1 + 4.8)/2 = 2.95 solar radii = $(2.95)(6.965x10^8)$ = $\mathbf{2.05x10^9}$ **[m]**. Each star exhibits a mass of about 1.4 solar masses (one solar mass is $1.987x10^{30}$ [kg]) so that together their mass is $m = m_1+m_2 = (2)(1.4)(1.987x10^{30})$ = $\mathbf{5.56x10^{30}}$ **[kg]**. According to a perusal of binary-star catalogs by John Mosley of the *Griffith Observatory*, the binary pulsar PSR 1913+16 is at a distance from

our Sun of 23,300 light years (one light year is $9.5x10^{15}$ [m]). If there was complete diffraction, then the reference area over which the GW would spread at the Sun's distance would be a sphere having an area of $(4\pi)(2.33x10^4 \text{ x } 9.5x10^{15})^2 = 6.2x10^{41}$ [m^2].

2.3.2 *Gravitational-Wave Power—the Quadrupole Equation*

In the case of a binary star pair such as PSR 1913+16, the magnitude of the GW power, P, is computed from the quadrupole equation, which for two masses on orbit about one another is given, for example, by an equation on p. 356 of L. D. Landau and E. M. Lifshitz [5] or Peters and Mathews [7]. The time-constant factor in the equation for P is

$$8G^4 m_1^2 m_2^2 \mu/(15c^5). \qquad (11)$$

The *time-variable factor* in P is a function of the true anomaly, v, and orbital eccentricity, e, as given in [5] :

$$(1+e\cos v)^4([1+\{e/12\}\cos v]^2+e^2\sin^2 v)/(a[1-e^2])^5. \qquad (12)$$

In conventional astrodynamic/celestial-mechanics notation (see Samuel Herrick [8]) this factor (i.e., Eq. (12)) is

$$p/r^6+(dr/d\tau)^2/12\mu r^4, \qquad (13)$$

where p is the orbital "parameter" or semilatus rectum (= $a\{1 - e^2\}$) in [AU], r is the radial distance between the two masses [AU], τ is the characteristic time measured in $k_s$days or in units of $5.022x10^6$ [s] for a heliocentric-unit system (utilized by Taylor [6] and others for PSR 1913+16), μ is the sum of the two masses, i. e., $\mu = m_1 + m_2$ [solar masses], and as usual G = $6.67423x10^{-11}$ [m^3/kg-s], and c is the speed of light = $3x10^8$ [m/s]. Note that one AU (astronomical unit) = $1.496x10^{11}$ [m].

The GW power radiated, P, which causes a perturbation in the semi-major axis, a, (and an attendant secular decrease in the orbital period) is obtained by integrating the time-variable factor, Eq. (13), over the orbital period using the mean anomaly, M, as independent variable, which is directly proportional to the time (that is, M = n [t-T], where n is the mean motion {ω in Landau and Lifshitz's [5] notation, p. 357} n= 2p/Period = $2p/2.79x10^4$ = **$2.25x10^{-4}$ [1/s]**, and T is the time of periastron passage).

2.3.3 *Accuracy of the Results*

The value of the average GW power, P, is computed from observations that define the eccentricity (based primarily upon Doppler-shift determination of the range rate at periastron and apastron), semi-major axis, and orbital orientation angles of PSR 1913+16. The error in the computed value of P is related to the observational error leading to the determination of the orbital elements as well as the determination of the masses of the pair of neutron stars. For example, a 0.1 percent change in the measurement of range rate at periastron results in a 0.28 percent change in GW power, P, and a 0.1 percent change in the mass of the stars results in a 0.33 percent change in GW power.

2.3.4 *Centrifugal Force and Acceleration*

The x and y average delta **centrifugal force** component(s), $\Delta f_{cfx,y}$ (which will later be utilized to validate the fundamental jerk equation numerically) are both

$$man^2 = (5.56x10^{30})(2.05x10^9)(2.25x10^{-4})^2 = \mathbf{5.77x10^{32}\ [N]} \qquad (14)$$

divided by *m* yields the average centrifugal acceleration = 103.78 [m/s^2] = 10.6 [g's]. At periastron, r = q = a(1-e) = $(2.05x10^9)(1-0.641)$ = $7.36x10^8$ [m] (with e = 0.641), the centrifugal acceleration is $q(dv/d\tau)^2$ where $dv/d\tau = \sqrt{(\mu p)}/r^2$ (please see Baker [9] , p. 13). In this latter case μ = 2.8 [solar masses], a = 2.95 [solar radii] = $(2.95)(6.965x10^8$ [m/solar radii])/$1.496x10^{11}$ [m/AU] = 0.01373 [AU], p = $a\{1-e^2\}$ = $0.01373\{1- 0.4109\}$ = 0.00809 [AU], and q = r = $7.36x10^8$ [m]/$1.496x10^{11}$[m/AU] = 0.00495 [AU]. After inserting these numbers I have $dv/d\tau$ = $(\sqrt{[2.8x0.00809]}/[0.00495]^2)/5.022x10^6$ [s/k_sday] = $1. 223x10^{-3}$ [radians/s]. Thus the centrifugal **acceleration** at periastron of the star pair is $q(dv/dt)^2$ = $(7.36x10^8$ [m] $)(1.223x10^{-3}$ [radians/s])^2 = $1.101x10^3$ [m/s^2] = **112 [g's]** – apparently *still within the weak-field approximation of Einstein's GW equations.*

2.3.5 *Comparison of Results*

From Eq. (14) I computed that each of the components of force change, $\Delta f_{cfx,y}$ = $5.77x10^{32}$ [N] (multiplied by two since the centrifugal force reverses its direction each half period) and Δt = (1/2)(7.75hrx60minx60sec) = $1.395x10^{4}$ [s] for the half period. Thus using the jerk approach:

$$P = 1.76x10^{-52}\{(2r\Delta f_{cfx}/\Delta t)^2 + (2r\Delta f_{cfy}/\Delta t)^2\} =$$

$$1.76x10^{-52}(2x2.05x10^{9}x5.77x10^{32}/1.395x10^{4})^2 x2$$

$$= \mathbf{10.1x10^{24}} \text{ [watts]} \quad (15)$$

versus the result of **$9.296x10^{24}$** [watts] using Landau and Lifshitz's more exact two-body-orbit formulation given by Eqs. (1.1) and (1.2) of Baker [10] integrated using the mean anomaly not the true anomaly as independent variable. The most stunning closeness of the agreement is, of course, fortuitous since due to orbital eccentricity there is little symmetry among the $\Delta f_{cfx,y}$ components around the orbit and there are small errors inherent in the approximations of Eqs. (3A) and (3B) and, of course Eq. (5) leading to Eq. (10). Nevertheless, since the results for GW power are so close, orbital-mechanic formulation compared to the utilization of a jerk, **the correctness of the jerk formulation is well demonstrated!**

3. COMPUTATION OF HFGW POWER

There are some very sophisticated and exact computer simulations of the generation of gravitational waves (please see, for example, S. F. Ashby, *et al* [11]). The quadrupole approximation utilized herein by me and, for example, by Romero and Dehnen [12] and others at this Conference is probably less exact. On the other hand, the computer simulations are less relevant to the devices involved in the generation and detection of HFGW in the laboratory. These computer simulations describe GW generation by strong-field astrophysical phenomena (e.g., neutron stars, black holes, etc.), coupled spacetime and general relativistic hydrodynamic equations, and are usually restricted to gravitational forces ; not non-gravitational forces involved in laboratory HFGW generation. I will first discuss the meaning of the term quadrupole

3.1 *Meaning of Quadrupole*

The basic physical process for generating a gravitational wave is the third (or higher) time derivative of the motion of a mass, termed a "jerk" or "shake" or ?f/?t, that is, ?f is an increase in force, f, on the mass carried out over a small time interval, ?t. As noted in Baker [10], that physical process produces a gravitational wave with a **power** given by, for example, the quadrupole approximation (as originally derived by Einstein) or it could be determined directly from the special and general relativity equations (using a computer-implemented numerical integration as, for example, discussed in. Ashby, *et al* [11]). As noted in Conference paper HFGW-03-101, the quadrupole is the lowest-order solution to the GW propagation problem That is, the quadrupole itself is **not** the physical process at all, but only one means of establishing the power of the generated gravitational waves – the lowest-order solution.

Other algorithms, often most complicated, can define other GW properties such as direction, polarization, constructive/ destructive interference, etc. This situation is similar to Newton's Laws, which govern the physical process of planetary motion. The effect of that motion can be computed using, for example, the two-body approximation, or it could be determined directly from the equations of motion described by Newton's Laws, using a computer- implemented numerical integration.

The two-body approximation itself is **not** the physical law at all, but only one means of describing the resultant motion – a "lowest-order solution." In the case of a nuclear-reaction-generated gravitational wave, in which a nuclear particle is ejected from a nucleus, it is like a small rocket, or in the case of electrons shaken in a resonance cavity, plasma beam, superconductor, etc., there is a third time derivative of the motion of the nucleus in the first case or electron mass in the second case, or a jerk, which produces gravitational waves whose power can be estimated, for example, by the quadrupole approximation. Thus when I mention a "quadrupole-produced gravitational wave" I'm really implying the fundamental

physical concept of the jerk and not the computational means for establishing the power of the gravitational wave.

3.2 *Harmonic Motion.*

As far as a harmonic motion of a mass or a pair of masses is concerned (harmonic oscillator), gravitational waves are generated. Just as in the case of a pendulum, the usual descriptor of harmonic motion, there exists a third time derivative of the pendulum bob. It is the jerk of that bob that produces the gravitational wave, which can be estimated using a quadrupole approximation or computed exactly by means of a rather complicated solution of the equations of special and general relativity.

4. LABORATORY MICRO- AND NANO-SCALE HFGW GENERATION DEVICES

In this section I will describe an Individual Independently Programmable Coil System or ***IIPCS*** (U. S. Patent No. 6,160,336), miniature integrated circuits, which provide for the emulation of a device that is much more extensive than the individual energizable elements (e.g., the small permanent magnets), and I will summarize what all of the HFGW-generation devices accomplish.

4.1 *Individual Independently Programmable Coil System*

I will now discuss HFGW generation devices that utilize, for example, microchip and nanotechnology in order to generate HFGW in the laboratory. For the very large number of ultra-small, sub-millimeter coil elements utilized in some of the devices discussed, a miniaturized integrated circuit can be utilized (please see, for example, the coil turn of *Al* utilized by Y. Acremann, *et al* [13]). They will be embedded in or imprinted on a silicon chip, organic material, or in connection with polymer-based or superconductor devices. They will consist of multiple layers with appropriate sequencing time delays to ensure near simultaneity of the magnetic fields interaction as the direct-current train of approximately one-picosecond or shorter pulses simultaneously traverse each coil set on the chip levels. The timing sequence could be integrated in the chip with the ultra-fast switches or transistors or through other semi-conductor devices. The myriad of these small coils in a three-dimensional array (please see FIG. (1)) act on the field of a small magnet to produce the jerk.

Since the jerk is generated by an electromagnetic process, there could be significant EM radiation generated that could reduce the efficiency of the device. It should, however, be emphasized that **it is <u>not</u> the magnetic field that generates the HFGW**, but rather the mass of the magnets (or other energizable elements) that are jerked that generates the GW. The magnetic material exhibits magnetic sites (perhaps on a molecular level or ferromagnetic atoms) that, of course, include electrons; but in this case (as opposed to a superconductor HFGW generator) it is not the electron mass being jerked that produce the GW, but rather the actual magnet's mass.

4.2 *Miniaturized Integrated Circuits*

A preferred design (U. S. Patent No. 6,417,597) utilizes conventional computer chips or wafers of a computer logic system, containing IIPCS circuit elements (U. S. Patent No. 6,160,336). These circuits are about 18 micrometers or less apart and include a synchronizing clock, input/output ports, and sub-millimeter coils on 50 to 100 micrometer centers. The chips are about 6 mm to 9 mm square and are obtained from silicon wafers. These chips are sewn into a circuit-board roll with an approximately 25-micrometer-diameter gold thread. Several layers of this roll (for example, 25) are connected in a fixed location or band adjacent to the moving or non-moving (jerking or non-jerking) spindle's rim and they form the IIPCS in the spindle rim's magnetic field. (The rolls of chips just mentioned are routinely fabricated by French-owned *Oberthur Card Systems* {a plant exists at Rancho Dominguez, California}, French-based *Gemplus*, *Schlumberger* {Paris and New York}, and California-based *Frost & Sullivan*.)

4.2.1 *Coil Sets*

In the proposed miniaturized integrated circuit devices, as exhibited in FIG. (1), there will be a very large number of ultra-small, sub-

millimeter or microscopic coil sets or elements, 56, embedded in or imprinted upon a silicon chip, 57, in multiple layers. Ultra-fast micro-switches or transistors of the IIPCS, 58, will launch a long a series of current pulses, 59, of approximately nanosecond to picosecond or less duration moving at the electron's mobility speed (approximately light speed, c) that will be timed to reach the individual coil sets or elements almost simultaneously (with the same rise time as discussed in Y. Acremann *et al* [13]). These pulses can travel along several individual conductors, as in FIG. (1), or along one single conductor per line, as in FIG. (2), and thereby interact with the magnetic field of a nearby magnet on the rim, 60, in concert.

This interaction will result in a third-time-derivative motion or jerk of the uncharged magnetic masses on the rim to generate a train of gravitational waves. **The effect is exactly the same as a rotating or ratcheting rim with the change in centrifugal force (jerks) replaced by the reciprocating jerks of the magnets attached to the rim.** The ultra-fast switches are preferably semiconductor-based, such as the semiconductor optical amplifier (SOA), a semiconductor nonlinear interferometer such as a nonlinear *Sagnac* interferometer on a phosphide semiconductor chip, etc. (please see, for example, D. Cotter, *et al* [14], pp. 1523-1528).

4.2.2 *Pulse Duration*

The pulse duration will be such as to completely energize any given coil set as it passes through it in order to produce a magnetic field interaction. As has been emphasized, the interaction will result in a third-time-derivative circumferential motion or jerk of a cylindrical stack of rims, 63, shown in FIG. (3A) (figure 2 of US Patent 6,417,597) and generate a long GW train of successive GW pulses having axis, 29. This stack or barrel is surrounded by and immediately adjacent to a sheath of IIPCS-controlled coil sets, 64. The cross–section of the barrel or an individual rim of the stack is shown in FIG. (3B) (figure 8A of US Patent 6,160,336). The coils (myriads of them represented by a single coil) 26, interact with the tiny rim magnets, 24; produce jerks along axes, 27, which emulate a ratcheting rim, 15. In the case of a design with the current-pulse train on a single conductor interconnecting a line of coil sets, FIG. (2), there will be a build up of impulses to full value as the current-impulse train progresses down the line of coil sets. Use of a single conductor wire for each line of coil sets reduces the resistive power loss. In each line of coils set in series 61 there will be time delays, 62, between coil sets to ensure simultaneity of the current pulses reaching any given coil set. The myriad of miniature coil sets (incased in layers of chips) will energize (jerk) each tiny rim magnet.

4.2.3 *Parallel-Conductor Stacks*

In FIG. (4), ultra-fast switches or transistors of the IIPCS, 58, will launch a long series of direct-current pulses acting in either direction, 59, of approximately nanosecond or picosecond or less duration moving at the electron's mobility speed along individual conductors or single interconnecting computer wires in order to produce current pulses, 59, acting in concert to generate modulated jerks and resulting HFGW (GHz to THz and higher frequencies) with axis, 29 (or perpendicular to that axis). The current pulses will be timed to reach parallel-plate conductors, 66, which may have different masses or may have ballast, 67, attached and/or carry different current, and/or have different modulus of elasticity and/or are constructed differently in their mountings for the purpose of exhibiting asymmetrical mass displacements, jerks or "hammer blows." The asymmetry is required in order to avoid the null situation to be discussed in Section 9. (Such a concept of utilizing the force between parallel current-carrying conductors is similar to the nanowire or nanoplate devices to be described in Section 8.)

4.3 *Emulation of a Much More Extensive Body*

As a GW front passes by the energizable, e. g., in the case of parallel-plate, elements (schematically shown in FIGS. (5A) and (5B) as 80, 84, 86, and 88) or individual members of a stack of (jerking) rims as shown in FIG. (3A), they are energized in sequence thereby increasing the wave's amplitude. In FIG. (5B) such an effect is schematically illustrated as GW 83 ,85, 87, and 89 build up to accumulate the GW, 82, wave front shown also in FIG. (5A).

Thus a linear device having a much longer effective length (or radius of gyration), r, or a cylindrical stack of rims having a much larger mass than any single rim is emulated. Again, this is all subject to experimental verification. It is to be emphasized that **any unwanted EM radiation can be screened out.**

In FIG. (6), ultra-fast switches or transistors of the IIPCS, 58, will launch a long series of current pulses, of approximately picosecond duration along individual conductors or single, interconnecting conductor wires that will be timed to reach individual, sub-millimeter micro- or nano-electromechanical elements, or piezoelectric crystals, etc. 56. This will be in sequence to reinforce and cause a *build up* of the amplitude of a **coherent** GW beam (as in FIG. (5B)) having axis, 29. The ensemble of electromechanical elements (including other kinds of energizable elements such as nanomachines) will also be embedded in or imprinted on a silicon chip in multiple layers. FIGS. (7A) and (7B) (figures 7A and 7B of US Patent 6,160,336) exhibit the ultra-fast, micro-switches (1.1d,u to 1.4 d,u and 1.5 *l*,r to 1.8 *l*,r) set so no current flows through the coils and ultra-fast, micro-switches (2.1 d,u to 2.4 d,u and 2.5 *l*,r to 2.8 *l*,r) set so that the current flows through the coils right to left. Other switch setting can reverse this current direction.

4.4 *Summary*

The problem, which all of the devices discussed in this paper solve, is to cause a system of masses, which could be mini-magnets, micro-devices (e.g., small plates), nano-devices (e.g., nanowires), individual molecules, submicroscopic particles, or individual electrons (as in a superconductor) to move in concert with a jerk in order to *build up* (generate) HFGW with either planar or cylindrical wave propagation. Such jerking masses produce a very long sequence of HFGW pulses having significant average power without generating incapacitating heat, causing disruptive g loads, or producing overpowering EM radiation.

As I have emphasized, the problem is solved in several alternative ways by utilizing an array of energizable elements (e. g., rim-magnets, coils, parallel plates, piezoelectric crystals, dielectrics, capacitors, nanomachines, high-temperature superconductors, electrons, nuclear particles, laser beams, etc.) to be activated by energizing elements (e.g., coils, submicroscopic particles, laser beams, etc.) under comp uter-logic-system control.

As already noted, these energizable elements are activated or energized in the correct sequence with correct timing by the IIPCS computer (computer-controlled logic system) to accumulate a GW (moving at local GW speed in the energizable mass, which may or may not be near to the vacuum light speed) as the GW front moves in the mass or collection of masses. Essentially, the IIPCS causes the entire mass or collection of masses, or rims, or molecules to jerk effectively in unison or in step with the GW wave front and generate coherent HFGW. That is, the jerk will progress in step with the GW front and build the GW amplitude up – somewhat similar to a cyclotron pulsing a charged particle as it circles around in its magnetic field, or, possibly, like a traveling-wave amplifier and similar to the coherent GW generation suggested by Romero and Dehnen [12]. Energizable elements (that jerk when energized) are energized in sequence as the GW front passes. As has been seen, these elements taken together emulate a much larger, more extensive mass. **That is, the entire mass "appears" to the GW (as it passes) to be a single larger mass (e.g., a solid massive cylindrical flywheel) being jerked cohesively.** Experiments suggested at this Conference would not only shed light on such HFGW characteristics, but also, as suggested by Y. Acremann, *et al* [13] in their discussion of the processional motion of the magnetization vector "… forms the basis for realistic models of magnetization dynamics in a largely unexplored but technologically increasingly relevant (picosecond) time scale."

5. MAGNETIC FIELD BUILD UP AND HEAT LOSS

I will commence the analysis using the theoretical example of the ratcheting or jerking rim and then evolve the device into both a stack of rims and into a linear form. It should be recognized again that a rotating rim could generate GW, but in order to generate significant and continuous GW its rotational rate would need to be so large that the rim would be torn apart! Thus a rotating rim has been replaced by a ratcheting or jerking rim and that rim will be replaced by a stack of rims composed of

individual jerking rim elements and finally by a linear motor.

5.1 *Magnetic Field Build Up*

Although of little concern in most applications, the length of time to "build-up" the magnetic field of the coils is important here as it is in the experimental work of Y. Acremann [13]. The electrons must complete sufficient coil turns (moving at the current pulse speed – about $2.3x10^8$ [m/s] or 77% of light speed) in approximately a picosecond to "launch" most of the magnetic field that produces the impulsive force (like a "hammer blow") or jerk when it interacts with the static magnetic field of permanent or electromagnets as effectively "carried around" by the ratcheting rim. Thus, they must be very tightly wound with each coil "set" having a total length of less than 0.3 mm (0.0003[m] or 300 micrometers). The coils are tightly wound in order to react rapidly enough as the current pulses move through the coils at electron migration (for the ultra fast switch semiconductors) or current pulse speed, about 0.77c according to some experiments by Spring [19] who found current speeds from 0.66c to 0.9c. Note the electrons themselves, like water molecules in an ocean wave, do not move with the wave and have drift speeds on the order of only one m/s. If each of the ultra-small, sub-millimeter coil sets consist of two coils or turns, as exhibited in FIGS. (7A) and (7B), then their diameters are on the order of $d = 0.3/2\ \pi = 0.05$[mm] = 50 [μm] or less. (Note that the single-turn coil of *Al,* utilized by Y. Acremann, *et al* [13] was about 6 [μm] in diameter.) The coil wire could be made of gold having about a 0.015-mm or 15-micrometer diameter. The resistance for such wire at room temperature is about 135 [ohms/m] -- high-temperature superconducting (HTSC) material would be useful here. As will be seen from Section 5.4.2, in the spin-up jerk mode the IIPCS will need to build up **0.26 [Tesla]** flux density, at the appropriate polarity and interval, e. g., every 0.044 [m] for magnets of that rim spacing (the requirements for the spin-down jerk mode are essentially the same, but reversed). The magnetic flux density, B, is given by

$$B = \mu_o n i/l \text{ [Tesla]} \qquad (16)$$

where $\mu_o = 4\pi x10^{-7}$ (permeability of free space), n is the number of coil turns, i is the current through the coils [amps], and l is the length of the coil conductors [m]. The double coil sets will be placed on 50 to 100 [micrometer] centers, so that there will be about $2x100x100 = 2x10^4$ coil turns on each square-centimeter level of the stack of 25 coil levels or layers. With $l = 0.044$ [m], $n = 25x2x10^4 = 5x10^5$, $i = 9.1x10^3/5x10^5 = 0.018$ [amps] or 18 milliamperes, , $ni = 9.1x10^3$ [amp turns], so that Eq. (6) yields **B = 0.26 [Tesla].**

5.2 *Heat Loss*

The total length of 15-micrometer-diameter gold wire across any given layer or level is 100(rows) x100 (coil and jumper/time-delays)x(600 micrometers) = 6 [m]. For the 25 layers or levels there will 150 [m] of wire with a resistance of 150[m] x135[ohms/m] = $2.025x10^4$ [ohms]. Since on average every other pulse interval across a conductor wire will carry no current (resulting of course, in a lower average GW power), the heat loss per centimeter of chip stack or semi-conductor layers is

$$(1/2)i^2R = \mathbf{3.28\ [watts]}. \qquad (17)$$

This heat loss can be reduced by 32% by using 25-micrometer-diameter wires for the time-delay jumpers, but high-temperature superconductors (HTSCs) for this purpose are contemplated. In addition there may be some energy loss or resistance occasioned by EM radiation generated during the GW-generation process **– reduced or eliminated since the jerked masses are uncharged**. Such an EM energy loss can be reduced by the design of the energizing coil elements and controlling the direction of current pulses by the IIPCS. Concerns of the influence of magneto resistance (MR) of both the conductors and the semiconductor circuits and the dynamics of the impulsive magnetic field buildup should be addressed during experiments as would be the aforementioned EM radiation, which could significantly reduce the efficiency of the HFGW generator. Note that alternating currents are **not** utilized (only direct-current, positive pulses) in order not to drive the electrons to the conductor's skin and thereby increase resistance. This is probably not a problem if superconductors are utilized and their utilization is contemplated in most of the HFGW devices described in this paper.

5.3 *Direction of the Generated HFGW*

The HFGW is expected to progress both ways along the axis of the rims (or cylindrical stack of independent rims) since there is a square associated with the kernel of the quadrupole equation—so there is no preferred direction along the axis of the cylinder. Such a concept will be subject to experimental verification and the propagation direction may be dependent upon whether or not there is circular polarization or cross "+" polarization or a combination. Between the rims HTSC lenses can be inserted to concentrate the HFGW along the axis of the rings. As has been emphasized a large number of ultra-fast switches, preferably semiconductor based (exhibited in FIGS. (7A) and 7(B)), would be activated simultaneously along the progressing gravitational wave front in one of the two directions by the coil-control computer, with communication lines of nearly equal length to all switches. The coil-control computer logic system of the IIPCS could also activate coil sets inside and outside the rim, not just outside as shown in FIGS.(3A) and (3B) and concentric "layers" of rims and coils could be utilized.

The coils, which are closely adjacent to magnets or magnetic sites in the rim or rims, are to be sequentially activated in order to generate coherent HFGW in one direction (non-coherent HFGW will propagate in the other direction). Depending upon the proximity of the coils and the duration of the current pulses, there may be currents induced in one coil juxtaposed to another. *Any induced currents will produce deterministic reverberations for which the computer logic system of the IIPCS that can be programmed to account for*. In any event, the reverberations would subside as the current-produced magnetic pulses either collapse or clear the ensemble of chip layers at light speed.

5.4 *Linear-Motor, Linear-Jerk GW*

The foregoing discussion of a ratcheting rim is included first in order to bridge the gap between the rather conventional celestial GW mechanisms involving circular motion and the terrestrial laboratory cylindrical stack of "rotating" or jerking rims. Another laboratory device is similar to that proposed by Romero and Dehnen [12] and involves a linear motor device involving linear motion. (Yet another variant of the ratcheting rim is a ratcheting rod shown in FIG. (8), which could be oriented at various angles.) In the following subsections I discuss the linear-motor concept, estimate the coil-magnet force (utilized for all the devices discussed in this paper), and by means of a numerical example, determine the material acceleration.

5.4.1 *Concept*

The linear-motor design of the HFGW-generation device, sometimes referred to as a *linear induction motor* or LIM, is visualized to involve a single sector of the ratcheting rim with the impulsive forces, ?f, being longitudinal and tangential to the ring of energizable elements, $\Delta f_{l,}$ rather than radial. If the rim magnets and adjacent coils were peeled off from the rim and laid out flat, then the result would be a linear motor. Please see FIGS. (9A) – (9D) for a schematic of the progression of such a "peeling." In a very hypothetical case , a 2000-meter-radius exemplar device once peeled would be 2pr = 2px2000 = 6283 [m] in length and, since for this linear mass distribution $I = (1/3)mr^2$ and $d^3I/dt^3 \cong (2/3)r\,\Delta f_l\,/\Delta t$, the effective radius or radius of gyration is 6283/3 = 2094 [m] ~ 2000 [m] (a measure of the mass distribution) and I assume that it is a tube 3 [m] in diameter. One-centimeter-wide chip rolls would be placed longitudinally along the sides of central, cylindrical, permanent- (or electro-) magnetic tube, core, piston, or barrel, 63, consisting of an array of magnetic energizable element sites, 57, as shown in FIG. (3A) if one replaces the stack of jerking rims by a solid cylinder of magnets surrounded by a sheath of coils. The thin (approximately one cm thick) band of Alnico 5 permanent magnets could be replaced by far stronger electromagnets that face outward as in FIG. (3B).

5.4.2 *Estimate of Force*

In general, permanent magnets exhibit irregular magnetic fields and associated forces. As a rule of thumb a band of juxtaposed 1.75-inch-long (0.044[m]) magnets will lift a weight in excess of 30 pounds per 1.75 inches or {30x12"/1.75" = 206 pounds)/(2.2 pounds per kilogram)} {3.28 feet per meter} = 307 [kg/m]

x{ 9.8 Newtons per kilogram weight}or produce about **3000 [N/m]** of longitudinal force, f, per meter. Each 1.75-inch permanent magnet has a flux density, B, of about 2,600 gauss or **0.26 [Tesla]** developed every 4.4 [cm]. This matches the magnetic flux density of the juxtaposed coils from Eq. (16). Thus since each meter-long, square-centimeter segment of the roll would produce about **3000 [N/m]** of longitudinal force, f_l, per meter and all together they form a sheath of sub-millimeter coils (energizing elements) surrounding this central magnetic core, tube, piston, or barrel of a stack of rings of juxtaposed magnets. I will be extrapolating these numbers to micro- or nano-magnets so it is important to establish a specific magnetic force per unit volume, which of course would be much larger if electromagnets replace the permanent magnets and HTSCs were introduced. The impulsive force per unit volume for the meter long square-centimeter cross-section magnet and closely adjacent coil combination, is $?f_l/?V = 3000[N/m]/(0.01[m])^2 = \mathbf{3x10^7\ [N/m^3]}$. As mentioned already, rings of such uncharged elements, whose planes are parallel to the passing GW crest, will be energized or jerked tangentially to the rings as the GW crest passes and add to its amplitude so as to generate coherent HFGW. Note that in this case the motion of the magnetic mass is asymmetrical (either "in" or "out") so that there is a quadrupole moment without GW cancellation. (In this regard, please see Section 9.) Pinto and Rotoli [15] (p. 567) indicate that "... the quadrupole formula is only valid provided a suitable surface integral (vanishes), which is the case for a series of point sources" such as the energizable elements of the subject device and that of Romero and Dehnen [12].

5.4.3 *Numerical Example*

As a numerical example for the linear-motor design, there would be about one roll or 25-layer strip of chips spaced around and adjacent to the cylindrical barrel of the linear motor (64, shown in FIG. (3A)) in a longitudinal direction (parallel to the barrel axis) every two centimeters forming the sheath. There would be πx3[m]x100[cm/m]/2[cm] = 471 strips around the barrel's circumference, each one having a length of 2px1000 = 6283 [m] so that

$$\Delta f_l=(471)(6283[m])(3000[N/m]) = \mathbf{9x10^9\ [N]} \quad (18)$$

and with κ_{mr3dot} = 32 (the theoretical quadrupole-approximation value to be established experimentally since r may not be less than λ_{GW}),

$$P= 1.76x10^{-52}\ (?\ x6283x9x10^9/10^{-12})^2 = 0.25\ [watts]. \quad (19)$$

Thus, with the reference area being the two 3 [m] diameter "barrels" or "pipes" or "tubes" or cylindrical ends (GW propagating in both directions so the area is doubled) with a thickness of one centimeter, area = 2 (3p) (0.01) = 0.19 [m^2], the generated HFGW flux is about 0.25/0.19 = 1.3 [watts/m^2] near the hypothetical device. The average HFGW flux or signal would be about 1 [watt/m^2]. As a point of reference I again compare our terrestrial HFGW generator to celestial Low-Frequency Gravitational Wave or LFGW generation. Thus, for the sake of argument (although admittedly, it is like comparing "apples to oranges") the 1 [watt/m^2] is compared to $\mathbf{4x10^{-16}\ [watts/m^2]}$ maximum signal from a 500 mega parsec [Mpc] distant, 1000 black-hole (BH) radius semimajor-axis binary black hole (BBH) osculating orbit and $\mathbf{5x10^{-5}\ [watts/m^2]}$ from a 6-BH radius osculating orbit ([10], pp. 19 and 27) – or over **ten-thousand times stronger** than the LFGW signal from a 6 BH-radii BBH osculating orbit just before merger**!**

For cylindrical GW, in case the barrel magnets participated in harmonic oscillation (each end's uncharged magnetic sites moved in and out harmonically relative to the other), the reference area would be (6283)(3π) = $6x10^4$ [m^2] and the GW flux would be $0.25/6x10^4 = 4x10^{-6}$ [watts/m^2]. Although the jerked masses are uncharged, the high-frequency electromagnetic fields may generate significant EM radiation that will be studied in any experimental effort.

5.4.4 *Material Accelerations*

The acceleration, *a*, caused by the jerk is obtained by multiplying the activation time, dt, by the time rate of change of acceleration. The time rate of change of acceleration is $da/dt \sim ?a/?t$ and by Newton's second law $?f = m?a$ so $?a = ?f/m$ and

$$da/dt \sim \Delta f/m\Delta t. \quad (20)$$

From Eq. (18) ?f = $9x10^9$ [N], m (mass) per

meter for the cylinder of magnets is equal to (3.8[kg/m] of magnet strips)(471 strips per meter of cylinder)(6283 [m] cylinder length) = 1.12 x 10^7 [kg], and ?t = 10^{-12} [s]. Thus

$$da/dt = 9x10^9/(1.12x10^7)(10^{-12}) = 8x10^{14}\ [m/s^3] \quad (21)$$

Let us suppose that the total activation time for jerking a magnet in one direction, dt, is three picosecond pulse lengths or $3x10^{-12}$ [s]. Therefore, a = (d*a*/dt)dt = $(8x10^{14})(3x10^{-12})$ ~ $2.4x10^3$ [m/s^2] or 245 g's and far less than, say, the acceleration experienced by a bullet in the barrel of a gun. Thus the magnet would not disintegrate. The acceleration is also probably within the weak-field limit of Einstein's equations since for PSR 1913 + 16 the acceleration at periastron is over 100 g's (Section 2.3.4) and probably much grater acceleration is encountered for a spinning neutron star for which the Einstein equations presumably hold.

In the *extreme case* of 100 picoseconds of continuous jerk (in the same direction), dt = 10^{-10} [s], the speed would build up to

$$ds/dt = (da/dt)\delta t^2/2 = (8x10^{16})x10^{-20}/2 = 0.0004\ [m/s] \quad (22)$$

and the displacement of the magnetic mass (composed of many magnetic surface sites, 57, of the linear motor, piston, or barrel shown in FIG. (3A)) is

$$s = (da/dt)\delta t^3/6 = (8x10^{16}/6)x10^{-30} = 1.3x10^{-16}\ [m]. \quad (23)$$

Again there could be considerable "motion" of the magnetic mass, but even in the most unlikely case of an extremely long series of jerks in the same direction (100 pulses), it goes a very small distance before the IIPCS reverses the built-up acceleration, speed, and displacement and *the stresses in the material of the device would be minimal.*

In general, for permanent-magnet and coil combinations of all of the devices discussed in this paper, which exhibit an N-pulse long activation time, the acceleration is

$$da/dt = \{(?f \text{ per meter})/(\text{mass per meter})\}N \quad (24)$$

with dt = N ?t. We have calculated that ?f per meter = 3000 [N/m}, that mass per meter = 3.8 [kg/m], and with N = 3 (the ?t's cancel out), d*a*/dt = (3000/3.8)x3 = 2368 [m/s^2] or 245 g's as before. **Since the ?t (and, therefore, the frequency) cancel out, the material (magnet) acceleration is only dependent upon the ratio of force to mass of the magnets and the number of current pulses, N, in the total time that the magnet is activated (jerked) in one direction before the IIPCS reverses the jerk.**

6. HIGH-INTENSITY HFGW GENERATOR

A high-intensity HFGW-generation would necessarily involve a much shorter pulse duration, e.g., ten attoseconds or 10^{-17} [s] (100 PHz or QHz frequencies). In this regard, Raymond Lewis told us during this Conference (5/7/03) that "... quantum jump might greatly reduce ?t to, say, 10^{-18} [s]...." I will configure the generator as before as a barrel composed of a stack of individual and separate rims whose edges are again covered with a juxtaposed array of ultra-small micromagnets (energizable elements) surrounded by a sheath of ultra-small microcoils (energizing elements). The device is again represented by the schematic drawn in FIG. (3A) whose cross section or individual separate rims are shown in FIG. (3B) except that there are multiple concentric rims or rings around the cylinder axis. If the HFGW spreads out from one rim to the next, then a thin HTSC lens (please see paper HFGW-03-120) can be inserted between the rims in order to concentrate the HFGW down the axis of the stack as its intensity is built up. At the end of the stack of rims or rings there is a final HTSC lens that concentrates the HFGW on a focal plane.

The power of the device is given by a variant of Eq. (6). Each rim or ring has magnets on its periphery that are energized by an adjacent shell of coils (using the IIPCS for timing). As already noted there are many concentric rims or rings at, say, two-centimeter intervals along the axis of the rim or ring stacks to allow for a one-centimeter thick (maximum thickness) HTSC lens to be sandwiched in between the one-centimeter thick, d*l*, ring sets. I will set the overall length of the generator to be *l* = 500 [m] so that there are n = (*l*/d*l*)/2 = 25,000 rims (or sets of concentric rings) along the axis of the cylinder (FIG. (3A)). I utilize the force per meter that has been calculated for the (rather weak) permanent magnets of F = 3000 [N/m] and set the radius of the outermost rim to be r_0 = 10 [m],

so that the rims or rings in any cross section number $n = (r_0/dl)/2 = 500$. The power of the HFGW generator is given by (half goes the opposite way)

$$P = \tfrac{1}{2}x1.76x10^{-52}\sum_{k=1,\,step2}^{k=500}\{2r_k\,Fn n(2p r_k)/?t\}^2\ [watts] \qquad (25)$$

where $r_k = 2k\,dl$ [m] and $?t = 10^{-17}$ [s]. The numerical result is about **380 kW**.

At the focus of the last or end lens, the size of the diffraction pattern on the focal plane defines the maximum HFGW flux. The diameter of the diffraction pattern is $1.22?_{GW}$, where $?_{GW} = c\,?t$ and for the ten-attosecond (100Qz), $?_{GW} = 3x10^{-9}$ [m]. Ideally all of the HFGW power is concentrated in this diffraction pattern, which has an area of $p(1.22x3x10^{-9}/2)^2 = 1.05x10^{-17}$ [m^2]. So the flux is **$3.7x10^{22}$ [watts/m^2]**. Such a hypothetical and ideal flux density compares favorably with the ultra-intense laser pulses of 10^{23} [watts/m^2], which produce proton energies of "... up to 58 MeV..." [18].

7. MINITURIZED HFGW GENERATOR

For the purpose of having a specific numerical example of a miniaturized HFGW generator, suppose that the dimensions of the transmitter or miniaturized device involve an energizable-element stack of tiny rims (e.g., rings or circles of microscopic magnets) that is 6 [mm] thick surrounding a 3 [mm] radius energizing-element core (e.g., microscopic coils). The diameter of the device is 2(3+6) = 18 [mm]. The radius of gyration would be 6 [mm]. Let us also suppose that the device is 18 [mm] in length. At the receiver, which I assume to be 7 [km] away, I will introduce a d = 18 [mm] diameter superconducting lens to gather and focus the HFGW in order to concentrate or amplify the signal at the receiver. I will consider that $?f_l/?V$ can be increased ten fold by increased magnetic efficiencies due to the use of superconducting electromagnets (rather than rather weak permanent magnets) to $3x10^8$ [N/m^3]. I will also consider a reduction in pulse time to one 100 attoseconds or $?t = 10^{-16}$ [s]. The longitudinal-force pulse, $?f_l$ = (Volume) x($?f_l/?V$) = $(p[(9x10^{-3})^2 - (3x10^{-3})^2]\,[0.018])\,x(3x10^8) = (4.07x10^{-6})(3x10^8) = 1.22x10^3$[N]. Thus from Eq. (6) I find (with half the GW, the non-coherent half, going in the opposite direction)

$$P = \tfrac{1}{2}x\ 1.76x10^{-52}\{(2)(0.006)(1.22x10^3)/10^{-16}\}^2 = \mathbf{1.89x10^{-18}}\ [watts]. \qquad (26)$$

This power from the forward, "coherent-radiation" end is distributed over an area defined by the diffraction pattern at a distance of 7 [km] or range, $R = 7x10^3$ [m]. The diffraction angle, a_d, at the apex of a cone of HF GW is given by (please see Conference paper HFGW -03-120) $a_d \sim ?_{GW}$ /device-diameter = $c?t/(0.018) = (3x10^8)(10^{-16})/(0.018) = 1.67x10^{-5}$ [radians].

The area of the conical spread of the HF GW is

$$a = p(a_d\,R/2)^2 = p(1.67x10^{-5}x7x10^3/2)^2 = \mathbf{1.07x10^{-2}}\ [m^2]. \qquad (27)$$

The 18 [mm] diameter lens, which concentrates the HF GW at the receiver, has a grasp or GW gathering power, or amplification of $(d/?_{GW})^2 = \{(0.018)/(3x10^8)(10^{-16})\}^2 =$ **$3.6x10^9$** . Putting it all together the signal at the receiver is $\{(1.89x10^{-18})/(1.07x10^{-2})\}\{3.6x10^9\} =$ **$6.3x10^{-7}$ [watts/m^2]**, which is about an order of magnitude larger than a ten-watt isotropic EM transmitter at a 7 [km] distance ($1.6x10^{-8}$ [watts/m^2], p.42 of [10]).

Note that *the HFGW signal at the receiver is inversely proportional to the **sixth power** of the system's pulse length, ?t,* (including the lens at the receiver). The foregoing is a bit of a simplification since, like the discussion of the high-intensity design in Section 6, one would turn to a concentric, cylindrical-layer construction – not to a simple sheath and single rim configuration. Thus the energizing elements (e.g., coils) and energizable elements (e.g., magnetic sites on the rims) would be close enough for the GW waves (of wavelength $c?t = (3x10^8)\,(10^{-16}) = 3x10^{-8}$ [m] or 30 nanometers – probably much smaller in a superconductor) marching down the cylinder coherently, to build up with an electron migration distance of only $(2.38x10^8)(10^{-16}) = 23.8$ nanometers [nm].

8. NANOMECHANICAL RESONATOR

A recent paper by Melosh, *et al* [17] raises the possibility of utilizing high-

frequency nanomechanical resonators for generating HFGW. They indicate some 10^{11} junctions (presumably where resonators could be located) per square centimeter of wafer or chip. The resonance frequency of the wires is "... expected to range from tens of MHz to GHz." At the GHz frequency, $?t \sim 10^{-9}$ [s]. The ?f is more difficult to estimate. Let us assume that the force applied to the resonators is like the force between two parallel current-carrying conductors mentioned in Section 4.2.3 and exhibited schematically in FIG. (4). In this case the classical equation for the force (impulse) is

$$?f = \mu_0 l i_a i_b/2pd, \quad (28)$$

where $\mu_0 = 4px10^{-7}$, l is the length of the wire section, d is the distance between wires, and i_a and i_b are the currents flowing through any adjacent pair of wires. The wires can be as small as 20 [nm] in diameter for a wire cross section of about $3x10^{-16}$[m^2]. If one were able to conduct a TAmp/m^2 or 10^{12} Amps/m^2 (a most difficult problem especially if superconductors are contemplated), then the current in the two wires would be three tenths of a milliamp or $3x10^{-4}$ [A]. I will assume that at the resonator the wire section, l, subject to the force and the distance, d, between wires are about equal. Thus Eq. (28) yields

$$?f = (4px10^{-7})\,(3x10^{-4})^2/(2p) = 3.6x10^{-21}[N] \quad (29)$$

and if I had about a three-meter stack of these (assumed 1 [mm] thick) wafers or chips (so that the radius of gyration for a computer-logic system control to build up a coherent GW along the stack, would be r = 1 [m]), and with 10^{11} resonators per wafer, Eq. (6) yields

$$P= 3x10^3 x1.76x10^{-52} x\{2(3.6x10^{-21})(10^{11})/10^{-9}\}^2$$

$$= 6.8x10^{-50} \quad [watts]. \quad (30)$$

Clearly this is **not** a viable HFGW generator. Even if one could impress a QHz frequency on the nanowires one could only expect a 10^{12} improvement – not enough.

A better way to implement a system like this would be to utilize an array of parallel plates that are, for example, one centimeter on a side and one millimeter thick. A two-meter square plate would hold about ten thousand of them plus associated circuitry and, again, there could be a three-meter stack for a one-meter radius of gyration for the build up of a coherent beam. In this case the area of the "wire" would be (0.01) (0.1) = 10^{-3} [m^2]. Assuming only 10^5 [A/m^2], a 100 [A] current would pass through each pair (probably superconducting to avoid heat). Let us suppose that I can separate the plates by 100 [nm] or 10^{-7} [m] and that for the centimeter plates l = 0.01 [m]. Thus evaluation of Eq. (28) yields

$$?f = (4px10^{-7})(0.01)(100)^2/2px10^{-7}=200 \text{ [N]} \quad (31)$$

with QHz current pulses $?t = 10^{-15}$ [s]. There are 10^4 of the energizable elements on each plate as the GW wave passes by and if the plates are one-half centimeter apart (therefore 3[m]/0.05 = 600 of them in the stack) , so that Eq. (6) yields

$$P= 600x1.76x10^{-52}\{2x10^4 x200/10^{-15}\}^2 = 1.7x10^{-6} \text{ [watts]}. \quad (32)$$

All of this is very hypothetical, but much closer to a realistic HFGW generator.

9. SYMMETRY AND NULL GW GENERATION

There exist some situations in which a jerk exists in a system of masses, but there is no attendant GW generation. One often refers to these as *symmetrical situations.* A situation in which a system is so symmetrical that one can think of the GW as canceling out and becoming null. Of course there are reactive jerks when a star collides with a black hole resulting in some acceleration of both bodies, or one neutron star orbits another with action and reaction on both bodies and in both cases GW is generated. Also GW would be expected to be generated with the reactive jerks of coils and magnets, motion of resonate cavity walls, Cooper pairs in a superconductor, electrons in a dielectric, etc. But there are situations, such as an isotropic explosion of a star, in which there is a jerk due to an expanding shell of gas and **no** GW is generated.

This situation warrants some attention. Consider FIG. (10A) in which there is shown the cross section of an exploding shell of gas having diameter, d. I consider two opposite small incremental masses of the shell, $?m_1$ and $?m_2$, which are jerked to the top and bottom of the

figure. Let us suppose that they are jerked so that each mass generates two oppositely moving GWs, normal to the direction of the jerk in a plane perpendicular to the plane of the figure. I show as $?_{GW}$. The usual assumption for the efficacy of the quadrupole approximation for estimating GW power is that $?_{GW}$ »d, which is the case for most celestial LFGW generators. Thus I have the situation shown in FIG. (10B) and the GW cancel out and become null.

10. CONCLUSIONS

The jerk formulation of the quadrupole approximation was derived in two alternative ways for the HFGW power of a laboratory HFGW generation device. The formulation was numerically validated by analysis of a well-known GW-generating binary pulsar, PSR 1913+16. By means of numerical examples, it was shown that the resistive heat loss and device component acceleration are well within tolerable limits.

Micro- and nano-scale HFGW generator components have been described in connection with a computer logic system to facilitate the generation of coherent HFGW. A device consisting of a cylindrical stack or jerking rims was also described in connection with two specific designs: a high-intensity HFGW generator and a miniaturized HFGW generator. Moreover, the outputs of HFGW fluxfrom these devices range from $6.3x10^{-7}$ [watts/m^2] to $3.7x10^{22}$ [watts/m^2]. In either case the fluxes are greatly increased by increasing the frequency of the jerks to the QHz or higher and by including a HTSC lens to concentrate the HFGW. Linear motor HFGW-generator designs were configured and studied. The situation in which component symmetry prohibits the generation of GW due to destructive GW interference was examined. A nanomechanical resonator concept is analyzed, but not found to be especially efficient. And finally, the major conclusion is that **laboratory HFGW generation devices are feasible, practical, and warrant experimental investigation**.

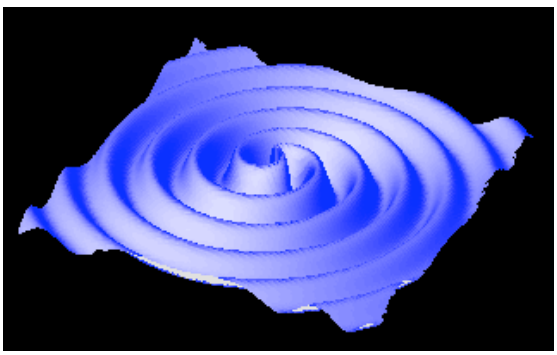
Le onde gravitazionali

NAUTILUS

CHE COSA SONO LE ONDE GRAVITAZIONALI?

Perturbazioni del campo gravitazionale che si propagano alla velocità della luce, previste dalla **Teoria della Relatività Generale** formulata da **Albert Einstein**.
Einstein rivoluzionò i concetti di **spazio** e di **tempo** ipotizzando che uno stesso fenomeno, osservato da sistemi di riferimento diversi, potesse apparire diverso, al punto che anche il tempo potesse scorrere in modo diverso.
Al sistema di riferimento che descrive un fenomeno si deve quindi aggiungere, alle tre coordinate spaziali, una coordinata temporale passando da tre a quattro dimensioni **(spazio-tempo).**
La teoria della relatività generale, che descrive i fenomeni connessi con la gravitazione, prevede che la forma dello spazio-tempo dipenda dalla distribuzione della materia in esso presente: la massa di una stella incurva la trama dello spazio-tempo come se questo fosse un telo invisibile.
Quando tale distribuzione viene modificata, ad esempio perché una massa si sposta molto rapidamente, la forma dello spazio-tempo cambia di conseguenza. Questa variazione non è istantanea in tutto l'Universo ma si propaga, dal luogo dove ha avuto origine, alla velocità della luce. La propagazione della variazione della forma dello spazio-tempo prende il nome di onda gravitazionale e possiamo assimilarla all'increspatura sulla superficie di un lago dopo il lancio di un sasso.



QUALI SONO LE SORGENTI DI ONDE GRAVITAZIONALI?

Qualunque massa in movimento genera onde gravitazionali ma il segnale emesso è talmente debole che per avere la speranza di osservarlo è necessario avere come sorgenti grandi masse in movimento, come i buchi neri, o eventi catastrofici, come l'esplosione di supernove.

SI POSSONO RIVELARE LE ONDE GRAVITAZIONALI?

Le onde gravitazionali interagiscono debolmente con la materia. Per fare un esempio un'onda gravitazionale che attraversasse il Sole perderebbe soltanto una parte su 10^{16} della sua energia. La rivelazione di tali onde pone dunque problemi fisici e tecnologici d'eccezione.

A COSA SERVE RIVELARE LE ONDE GRAVITAZIONALI?

La loro rivelazione potrebbe essere una scoperta scientifica fondamentale per lo studio del nostro universo.
E' grazie alla loro caratteristica di interagire debolmente con la materia che, viaggiando praticamente indisturbate nello spazio, attraversano qualunque corpo celeste si trovi lungo il loro cammino.
Ciò permette di poterle utilizzare come sonde per fare osservazioni di zone del nostro universo al momento nascoste dalle stelle o dalla materia interstellare, come ad esempio gli interni delle galassie, fornendone una radiografia.
Questa conoscenza permetterebbe di studiare la distribuzione di materia nell'universo e contribuirebbe agli studi sulla sua origine ed evoluzione. Si è infatti ipotizzato che negli istanti immediatamente successivi al Big Bang sia stata emessa una rilevante quantità di onde gravitazionali. La rivelazione di queste onde di origine cosmologica fornirebbe una fotografia dell'universo nei suoi primissimi momenti di vita.
La debolezza, unita alla bassa interazione con la materia, non ha consentito, finora, una rivelazione diretta delle onde gravitazionali.

LNF-INFN Divulgazione e Pubbliche Relazioni – Silvia Miozzi

COME SI RIVELANO LE ONDE GRAVITAZIONALI?

Le onde gravitazionali possono essere rivelate utilizzando **rivelatori risonanti** o interferometrici.
Un rivelatore risonante funziona come un'antenna: il passaggio dell'onda gravitazionale provoca una variazione nelle dimensioni del rivelatore nel piano perpendicolare alla direzione di propagazione dell'onda.
Un rivelatore interferometrico misura la variazione della distanza relativa fra due masse libere, indotta dal passaggio dell'onda nello spazio che le separa.
In entrambi i tipi di rivelatori le variazioni indotte dall'onda sono inferiori alle dimensioni di un atomo.

CHE COS'E' NAUTILUS?

E' il rivelatore di onde gravitazionali risonante ultracriogenico istallato ai Laboratori Nazionali di Frascati dell'INFN dal 1992.
NAUTILUS fa parte di una rete internazionali di rivelatori che include ALLEGRO (Louisiana, USA), AURIGA (INFN, Legnaro), EXPLORER (CERN, Ginevra).

COME E' FATTO NAUTILUS?

NAUTILUS è una barra cilindrica di alluminio lunga 3 m con diametro di 0,6 m e del peso di 2770 Kg.
Il segnale da raccogliere è talmente debole che per poter essere rivelato è necessario eliminare tutti i disturbi, sia quelli dovuti alla stessa agitazione termica del materiale di cui è fatta l'antenna, sia tutti quelli provenienti dall'esterno (traffico, eventi microsismici, anche il semplice calpestio).
Per risolvere il primo problema l'antenna deve essere mantenuta ad una temperatura molto bassa. **NAUTILUS** può essere raffreddata fino a 0,1 gradi sopra zero assoluto ed in queste condizioni è l'oggetto di grandi dimensioni più freddo all'interno dell'Universo.
L'isolamento dell'antenna dalle perturbazioni esterne richiede poi l'uso di sospensioni e ammortizzatori di grande efficacia.
Sotto l'effetto dell'onda gravitazionale l'antenna entra in vibrazione. Le vibrazioni vengono convertite prima in un segnale elettrico e poi in uno magnetico che viene successivamente misurato da un dispositivo detto SQUID (Superconducting Quantum Interference Device). Misurando variazioni di lunghezza pari a 10^{-18} m, **NAUTILUS** è tra gli oggetti più sensibili finora mai costruiti.

ESISTONO LE ONDE GRAVITAZIONALI?

In diversi laboratori sparsi per il mondo si stanno eseguendo esperimenti sulla rivelazione di onde gravitazionali utilizzando sia antenne risonanti, sia interferometri. Nessuno di questi apparati è ancora riuscito ad individuare un segnale inequivocabilmente interpretabile come il passaggio di un'onda gravitazionale.
Effetti indiretti delle onde gravitazionali sono stati già osservati: per esempio la perdita di energia di un sistema binario di stelle che, ruotando molto rapidamente l'una attorno all'altra, irraggiano nello spazio onde gravitazionali.
I successi della relatività generale in altri campi ci rendono fiduciosi del fatto che tali onde esistano.

LIGO AND THE DETECTION OF GRAVITATIONAL WAVES

Large detectors on opposite sides of the country are about to start monitoring the cosmos for the gravitational waves that general relativity tells us should be emanating from catastrophic astrophysical events.

Barry C. Barish and Rainer Weiss

The idea of gravitational waves was already implicit in the 1905 special theory of relativity, with its finite limiting speed for information transfer. The explicit formulation for gravitational waves in general relativity was put forward by Einstein[1,2] in 1916 and 1918. He showed that the acceleration of masses generates time-dependent gravitational fields that propagate away from their sources at the speed of light as warpages of spacetime. Such a propagating warpage is called a gravitational wave.

The best empirical evidence we have of the existence of gravitational radiation is indirect. It comes from the 1974 discovery and beautiful observations, by Russell Hulse and Joseph Taylor,[3] of the first binary pulsar ever found. (See PHYSICS TODAY, December 1993, page 17.) Exploiting the clockwork pulsar signal from the neutron star, they were able to monitor the orbital period of the binary star system with exquisite precision and confirm that it was indeed gradually speeding up at just the rate predicted for the general-relativistic emission of gravitational waves.

The *direct* detection of gravitational waves will mark the opening of a new window on the near and far reaches of the cosmos. For physics, its most important promise is the direct observation of gravitation in highly relativistic settings, so that one can test general relativity in the strong-field limit, where it is not merely a small correction to Newtonian gravity. (See the companion article in this issue by Clifford Will, on page 38.) In that limit, the strong curvature of the spacetime geometry should show us fundamentally new physics.

By the time they reach us, the gravitational waves are, of course, only very weak perturbations on our local flat space. But they will provide information about the strong-field regions where they began. The detection of the waves will also allow us to determine the wave properties of the gravitational radiation—for example, their propagation velocity and polarization states.

For the astrophysicist, the observation of gravitational waves will provide a new and very different view of the universe. These waves arise from motions of large aggregates of matter, rather than from the particulate sources that produce electromagnetic waves. Because gravitational waves are not scattered as they propagate between source and observer, they should provide information about what's happening in the innermost and densest regions of the astrophysical source. Probing the universe in this very different way, gravitational radiation is likely to bring us exciting surprises and unanticipated new astrophysics.

A new generation of detectors based on suspended mass interferometry promises to attain the requisite sensitivity for observing gravitational waves. (See figure 1.) These new detectors are the fruit of a quarter-century of worldwide technology development, design, and construction. The US effort, called LIGO (Laser Interferometer Gravitational-Wave Observatory), is a joint Caltech–MIT project, supported by the National Science Foundation. LIGO is a pair of L-shaped laser interferometers: one in Hanford, Washington, the other, some 3000 km away, in Livingston, Louisiana. (See figure 2.) Each evacuated interferometer arm is 4 km long.

The LIGO facilities at both sites have now been completed, and detector installation is under way. Following a two-year commissioning program, we expect the first sensitive searches for astrophysical gravitational waves to begin in 2002. This initial search, sensitive to changes (strains) as small as a part in 10^{21} in the lengths of the interferometer arms, will be the first attempt to detect gravitational waves at a sensitivity that reaches plausible estimates for astrophysical source strengths. It will mark a 100- to 1000-fold improvement over previous searches—both in sensitivity and bandwidth.

The two LIGO interferometers will operate in coincidence, so as to filter out local noise. In fact, to provide additional coincidence surety, a third independent interferometer, half as long as the other two, will share the vacuum system of the full-size interferometer at Hanford. Also, one determines the direction and polarization of a gravitational wave by measuring arrival-time differences between geographically dispersed detectors. At the Hanford and Livingston support facilities, efforts will continue on the development of improved and special-purpose detectors of increased search and follow-up sensitivity.

Gravitational radiation

The gravitational wave plays a role in gravitation similar to that of the electromagnetic wave in electricity and magnetism. But because mass, unlike charge, comes in only one sign and the momentum of a free system must be conserved, the lowest-order source of gravitational radiation is quadrupolar.

The radiation field causes a strain in space itself, transverse to the propagation direction. The strain pattern contracts space along one transverse dimension while expanding it along the orthogonal direction in the transverse plane. One way of imagining this distortion of space

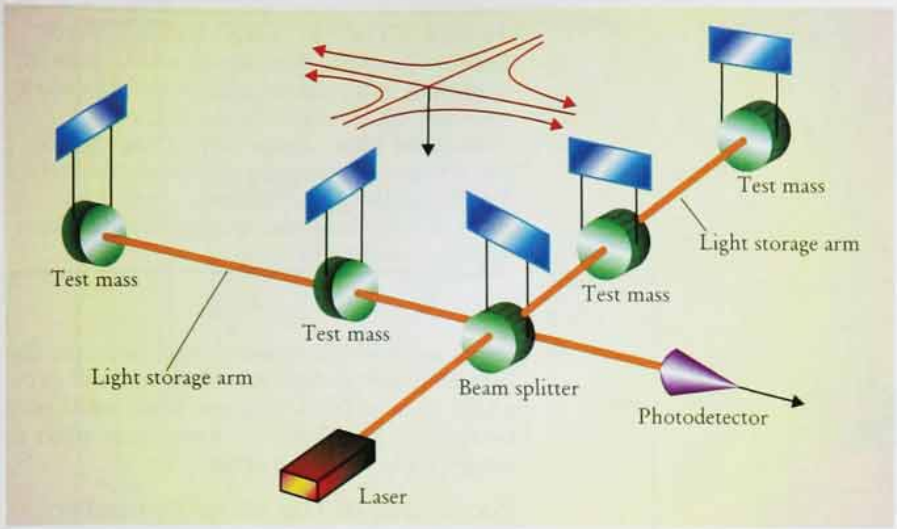

FIGURE 1. THE LIGO GRAVITATIONAL-WAVE DETECTORS are equal-arm Michelson laser interferometers whose hanging mirrors serve as the gravitational test masses. An incident gravitational wave, indicated in red by the stress pattern coming down from above, stretches one interferometer arm and compresses the other, causing a difference between light travel times in the two orthogonal arms. This time difference is manifested in the interference pattern when the two laser beams recombine on the way to the photodetector, which can measure phase shifts to a few ten-billionths of an interference fringe.

is to look at the weave in a piece of cloth when it's pulled along one dimension. The little squares of the weave distort in just this way. Furthermore the strain is quite uniform, so that the relative motion of points in the cloth depends linearly on their separation.

It is this linear increase in the relative motion that provides the motivation for LIGO's 4 km interferometer arms. Such ambitious length is intended to provide adequate sensitivity to passing gravitational waves in the face of inevitable local perturbations. The tensor character of gravity (the putative graviton is a spin-2 particle) means that the push/pull pattern of the strain field for a plane gravitational wave has two orthogonal polarizations. If a candidate signal really is a gravitational wave, and not just noise, the half-length auxiliary interferometer at the Hanford site should see a coincident displacement half as large as that experienced by its full-length neighbor.

One can also think of the gravitational wave as producing a tidal force field such that the relative force between masses grows as their separation. The field will pull masses together along one transverse direction while pushing them apart along the orthogonal direction. How one chooses to view the wave–matter interaction is really a matter of taste. But one must be careful to maintain consistency in one's view and not mix the geometric and tidal representations.

The strength of the gravitational field is expressed by the dimensionless strain

$$h = \left(\frac{GM}{Rc^2}\right)\left(\frac{v^2}{c^2}\right)$$

where the factor in the first pair of brackets is the Newtonian potential due to a source mass M at a distance R, divided by the square of the speed of light. On the surface of the Earth, that comes to 10^{-8}, a very weak field. But, at the surface of a neutron star, it can be as large as 10^{-1}. And at the horizon of a black hole, it is close to unity—the ultrarelativistic limit of a strong gravitational field. The factor in the second bracket pair—an estimate of the system's kinetic energy in asymmetric motion relative to its rest energy—is a measure of the strength of the relativistic dynamics.

This expression gives us an immediate estimate of the scale of the strains we might encounter. Consider, for example, a solar-mass source at a Galactic distance, moving at about 10% of the speed of light. In such a case, the strain we would observe halfway across the Galaxy would not exceed a part in 10^{18}. This simple estimate explains why we have to take such heroic measures to detect the strains. Even over the 4 km span of a LIGO arm, the relative displacement of two objects would be only a few times 10^{-13} cm, just about the size of an atomic nucleus! It's even worse than that. As discussed below, plausible sources typically lead to strains of only 10^{-21}, corresponding to LIGO displacements a thousand times smaller than the width of a nucleus.

Candidate sources

There is a large range of processes in the universe that should produce detectible gravitational waves.[4] Terrestrial interferometers like LIGO will search in the frequency range from 10 Hz to 10 kHz for characteristic signals from a variety of astrophysical sources for which one might hope to discern the signatures of gravitational radiation over the background noise. (See figure 3.)

▷ **Chirp signals.** The terminal spiraling of a star into a "compact" binary partner (a neutron star or a black hole) will produce radiation that increases in amplitude and frequency as the two move toward final coalescence. This chirp signal can be well characterized, depending on parameters such as the mass, separation, and orbital eccentricity. That makes it possible to formulate efficient detection templates.

▷ **Burst signals.** The collapse of a supernova may produce gravitational radiation. Type II supernova collapses can generate strong gravitational radiation, *if* the core collapse departs sufficiently from axial symmetry. Estimates suggest that detection might be possible for such collapses as far out as the Virgo Cluster of galaxies, some 50 million

Initial parameters for the LIGO detectors

Arm length	4000 m
Arm cavity storage time	880 μs
Laser type and wavelength	Nd:YAG, $\lambda = 1064$ nm
Input power at recycling cavity	6 W
Power recycling gain	30
Mirror mass	10.7 kg
Mirror diameter	25 cm
Mirror loss	$< 1\times10^{-4}$
Mirror internal Q	1×10^{6}
Cavity input mirror transmission	3×10^{-2}
Pendulum Q (structure damping)	1×10^{5}
Pendulum period (single)	1 s
Seismic isolation system	–110 dB at 100 Hz

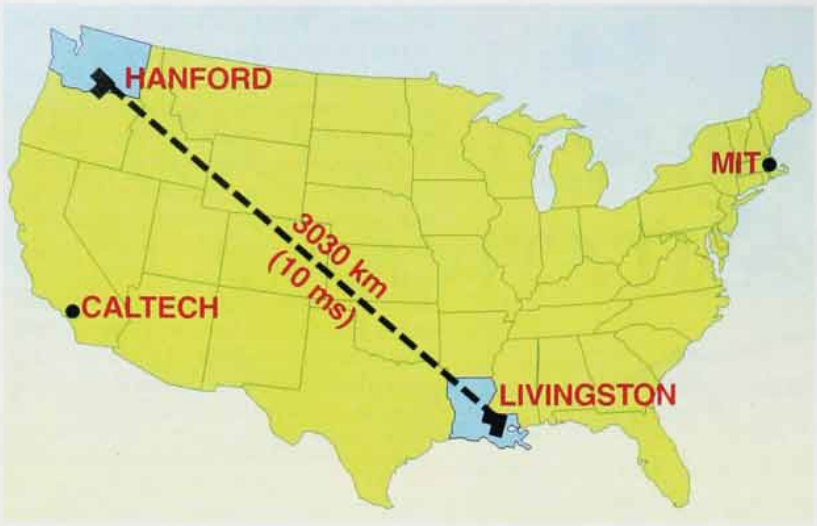

FIGURE 2. THE TWO LIGO SITES, 3030 km apart, in Hanford, Washington and Livingston, Louisiana, will work in coincidence. The recent photo of the Hanford site shows the two orthogonal 4 km vacuum pipes going off into the distance. The vacuum system also houses a smaller auxiliary interferometer, with 2 km arms to help distinguish true gravitational wave signals from noise.

light-years away. That would yield type II supernova observation rates of one or more per year. Another possible burst source accessible to LIGO is the brief, burplike oscillation of a black hole's event horizon just after it swallows a star. The detection of supernova or postprandial black hole events will require coincident observation of burst signals in several geographically dispersed interferometers.

▷ **Periodic signals.** Radiation from the nonaxisymmetric motion of a neutron star, or of the nuclear fluid on its surface might produce periodic signals in the detectors. Happily, for many known pulsars the frequency of such periodic signals lies within LIGO's sensitivity band. The searches for periodic gravitational signals from identified neutron stars will be facilitated by the fact that one can track the system continually over very many cycles, taking account of the gradual slowing of the pulsar's spin and the Doppler shifts and amplitude variation due to the Earth's diurnal and annual motions. We expect to perform general sky searches as well as targeted searches of known pulsars.

▷ **Stochastic signals.** Signals from gravitational waves emitted in the first instants of the early universe—as far back as the Planck epoch at 10^{-43} seconds—can be detected by way of correlations of background signals from two or more detectors. Some models of the early universe predict detectable signals. Such relic gravitational radiation would provide us with an exciting new cosmological probe.

The initial parameters for the LIGO interferometers have been chosen to provide a sensitivity with a reasonable chance for detecting gravitational waves. (See the table on page 45.) The anticipated rates for the various sources, however, are burdened with large uncertainties. As future advances in detector sensitivity increase the distance over which one can find sources, the rate at which events are observed will grow *as the cube* of LIGO's reach. That lends particularly high priority to a vigorous effort to improve the system's sensitivity.

Basic idea of the interferometer

A Michelson interferometer operating between freely suspended masses is ideally suited to detect the antisymmetric compression and distension of space induced by gravitational waves.[5] Figure 1 is a schematic drawing of the LIGO equal-arm Michelson interferometer. The two interferometer arms, each 4 km long in the full-length detectors, have identical light-storage times. Light sent from the laser light source to the beam splitter is divided evenly between the two arms.

Having traversed the arms, the light is reflected back to the splitter by mirrors at their far ends. On the return journeys to the photodetector, the roles of reflection and transmission in the splitter are interchanged for the two beams and, furthermore, the phase of the reflected beam is inverted by 180°. Therefore the recombined beams heading toward the photodetector interfere destructively, while the beams heading back to the laser source interfere constructively. If the interferometer arms are of precisely equal length, the photodetector ideally sees no light, all of it having been diverted, by perfect interference, back to its source.

One would get this kind of perfect interference if the beam geometry provides a single phase over the propagating wavefront. An idealized uniphase plane wave has this property, as does the Gaussian wavefront in the lowest-order spatial mode of a laser. Then, provided the arms are equal in length (or their length difference is a multiple of half the wavelength of the monochromatic beam), the photodetector sees no light at all. The destructive interference over the entire beam wavefront is complete.

If, in the absence of any disturbance, the interferometer is carefully balanced so that no light appears at the photodetector, a sufficiently strong gravitational wave passing though the interferometer can disturb this balance and cause light to fall on the detector. That, in essence, is how LIGO will sense gravitational waves. To obtain the required sensitivity, we have made the arms 4 km long, and we have included two refinements:

▷ First, the intensity change at the photodetector due to a gravitational wave depends on the interaction time of the wave with the light in the arms. The longer this interaction time—up to half the period of the gravitational wave—the larger is the resulting optical phase shift and the consequent change of the light intensity at the photodetector. To gain further interaction time, beyond what one gets simply from the 4 km arm length, the initial

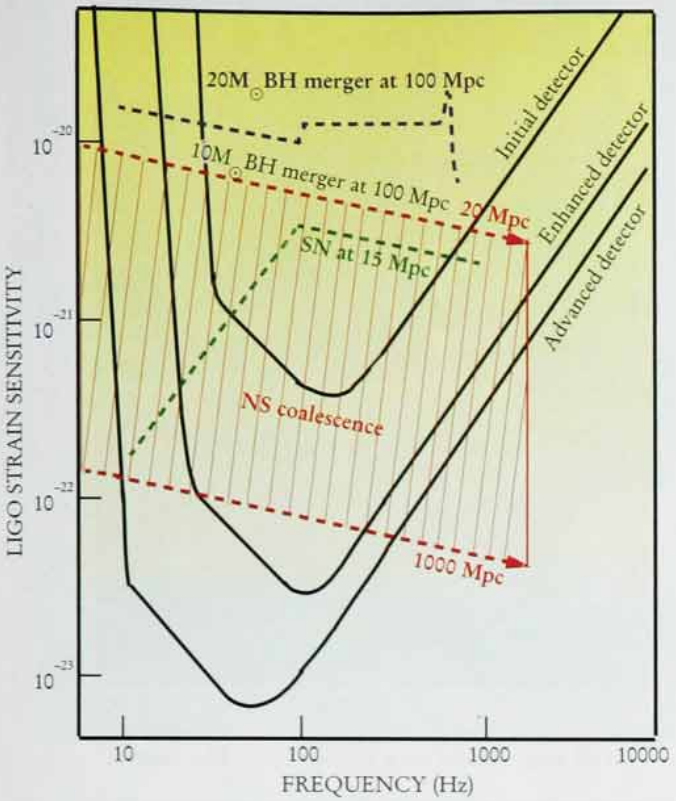

FIGURE 3. RMS STRAIN SENSITIVITY LIMITS as a function of signal frequency, for three LIGO generations indicated by the U-shaped black curves, are compared with signal estimates for various astrophysical sources. The "enhanced" detector is anticipated for 2006, and the "advanced" detector four years later. The shaded red region indicates the strain signal expected from the coalescence of two neutron stars at distances from 20 to 1000 megaparsecs (1 Mpc = 3×10^6 light-years), and from the merger of two 10 $M_\odot$ black holes at least 100 Mpc away. The larger and more structured signal expected from the merger of two 20 $M_\odot$ black holes at 100 Mpc is indicated by the purple dashed curve. The green dashed curve indicates the signal expected from an asymmetric supernova 15 Mpc away. One expects a few events per year within the red parallelogram.

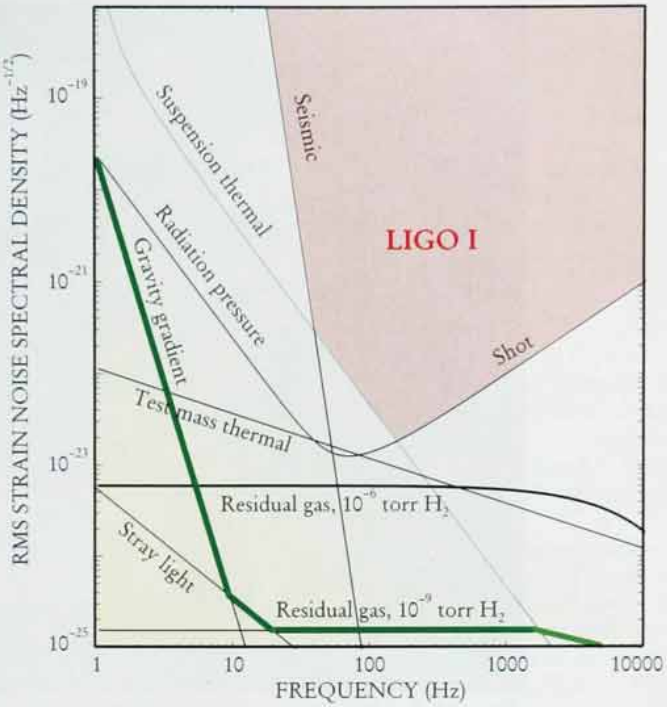

FIGURE 4. LIMITING NOISE SOURCES for the initial LIGO interferometers are shown on a plot of frequency against spectral noise density. The vertical axis denotes the RMS strain noise in 1 Hz of bandwidth. The noise increases as the square root of bandwidth, so that the noise in a typical 100 Hz window would be 10 times that shown on the axis. At the lowest frequencies, sensitivity is limited by geophysical and man-made seismic noise; at intermediate frequencies by thermal noise; and at the highest frequencies by the shot noise of photon statistics. The green line represents the minimum noise at the present LIGO facilities, irrespective of eventual detector upgrades.

LIGO interferometers will also fold the optical beams within the arms by means of optical cavities. This trick results in a light-storage time of about 1 millisecond. That's about 50 times longer than a simple straight transit through a 4 km arm.

▷ A second refinement increases the interfering light intensity by making the entire interferometer a resonant optical storage cavity. Most of the light interferometrically diverted from the photodetector direction—when the arms are unstrained—returns toward the light source. That makes it possible to achieve a significant gain by placing another mirror between the laser and the beam splitter. By properly choosing this extra mirror's position and making its transmission equal to the optical losses inside the interferometer, one can match the losses so that no light at all is reflected back to the laser. This is equivalent to increasing the laser power by about a factor of 30, without adversely affecting the frequency response of the interferometer to a gravitational wave.

Sensitivity limits

The success of the detector will ultimately depend on how well we can control the noise in the measurement of the exceedingly small strains we have been discussing. That has been the prime technological challenge in this field for the past several decades, and it is the central focus of our development of the technology for LIGO. The noise we have to contend with is broadly divided into sensing noise, random force noise and, ultimately, quantum noise. Sensing noise involves the various phenomena that limit our ability to sense and register the small motions in question. Random force noise, on the other hand, results from disturbances that cause small motions of the suspended masses. Eventually one confronts the ultimate quantum noise limit. This orderly classification presumes that one is careful enough in the design and execution of the experiment to reach the fundamental limits. The quantum limit will not be an issue for the first or second generation of LIGO detectors. So we do not address it in this article. There is, however, important ongoing work that seeks to understand the quantum noise limit and develop techniques to circumvent it in measuring the strain.

In order to approach the fundamental limits, we have made extensive use of two concepts in experimental physics promoted by Robert Dicke (1916–97) of Princeton University. The first is the technique of modulating the signal to be detected at frequencies far above the $1/f$ noise due to the drift and gain experienced by all instruments. For example, we measure the optical phase to determine the motion of an interference fringe at radio frequency rather than near DC.

A second concept is to apply feedback to physical vari-

FIGURE 5. LIGO'S SEISMIC ISOLATION SYSTEM consists of four layers of masses and springs. Each of the coil springs seen here is made by lining the inside of a straight metal tube with rubbery damping material and then filling the lined tube with a line of metal slugs strung on a rubber core. The tube is then coiled and sealed.

ables in the experiment in order to control and damp large excursions at low frequencies. The variable is measured by way of the control signal required to hold it stationary. A good example is the position of the interferometer mirrors. At low frequencies, we maintain the interferometer fringe at a fixed phase by holding the mirrors at fixed positions with coil/magnet actuators.

Sensing noise

Our ability to determine the relative motions of the mirrors at the ends of the arms interferometrically is limited by the smallest change in optical phase that we can measure. The light emitted by a conventional laser is in a coherent state in which the photon occupation number n obeys a Poisson distribution with variance

$$\Delta n = \sqrt{n} = \sqrt{\dot{n}\tau}$$

where $\dot{n}$ is the rate at which photons encounter the beam splitter and τ is the integration or observation time. Because the phase and photon occupation number are conjugate variables obeying an uncertainty relation, one gets

$$\Delta\phi = 1/\sqrt{\dot{n}\tau}$$

for the variance in the interferometric measurement of the relative phase of the recombining beams at the photodetector. We expect the optical-phase variance in the initial LIGO detector to be about 3×10^{-10} radians, corresponding to a strain variance in a 10-millisecond measurement of about 2×10^{-22}. That would be the fundamental Poisson limit. It is sometimes called the shot-noise limit, because it can also be derived from the statistics of photon counting in the photodetection. This shot noise determines LIGO's sensitivity limit for frequencies above 300 Hz. (See figure 4.)

Before one reaches this limit, however, one has to deal with a host of practical problems, such as laser frequency fluctuations, laser amplitude noise, and stabilization of the beam geometry. We must also reduce additional sensing noise terms that can occur in the beam propagation—for example, scattering by residual gas molecules and scattering off the vacuum tube walls driven by seismic and acoustical noise. We limit these effects by using baffling and low-scatter optics in the evacuated beam tubes. But even if one controls these noise terms and achieves the fundamental Poisson noise limit, one cannot easily reduce the noise any further by simply increasing the laser power to get more photons. That remedy raises problems of optical heating in the mirrors and coatings and, finally, radiation pressure fluctuations.

Random force noise

At lower frequencies, the sensitivity limit is set by how well the motions of our test masses—the hanging mirrors—are controlled. At the lowest frequencies (about 10–100 Hz), the largest disturbances come from "seismic noise"—the motion of the Earth's surface driven by wind, water flow, and human activities, as well as by low-level earthquakes. At intermediate frequencies (100 Hz), the principal culprit is thermal noise—that is, Brownian motion driven by thermal excitations. Less important for the initial LIGO interferometers, but increasingly significant as the detectors are upgraded, will be fluctuations in the Newtonian gravitational forces on the mirrors resulting from density fluctuations in the ground and the atmosphere and, ultimately, the radiation pressure fluctuations.

In general, these random forces are not correlated at the different mirrors, and they are independent of the length of the interferometer arms. By contrast, displacements due to gravitational waves grow linearly with the arm length. That's our principal motivation for going to the expense and trouble of having 4 km arms.

The LIGO suspended mirrors, which serve as the test masses, are isolated from motions of the Earth by cascaded stages of vibration isolation. The first level of isolation, consisting of four stages of springs and masses, reduces the seismic motion a millionfold at frequencies around 100

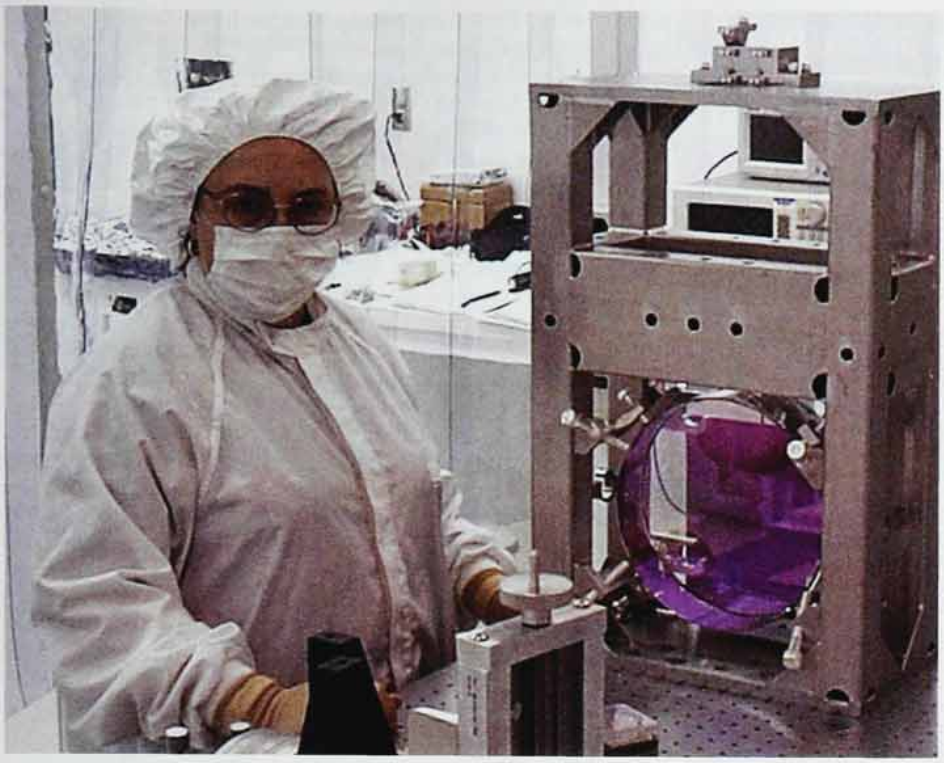

FIGURE 6. A LIGO MIRROR, 25 cm in diameter and 10 cm thick, is made of ultrapure fused silica. Its purple coating is a highly reflective multilayer stack of dielectric materials. Absorption and scattering losses must not exceed a few parts per million.

Hz, and progressively more at higher frequencies. (See figure 5.) This isolation works much like the suspension in a car. The final stage of the isolation system is the hanging mirror itself. Each test mass is, in effect, a pendulum suspended by flexures. The pendulum provides another stage of vibration isolation. But, more important, it also serves to reduce the influence of thermal noise.

Mechanical thermal noise enters the system by exciting the pendulum, causing the test mass to move, and by exciting acoustic waves that disturb the mirror surface. The acoustic noise can be represented as a superposition of the motions induced in the normal modes of the mass. The strength of the perturbation is estimated by taking the overlap of the acoustic-mode shape with the optical wavefront. The equilibrium thermal excitation of each normal mode at temperature T is $kT/2$, yielding significant motion at the principal resonant frequencies. Therefore we choose these frequencies to be outside LIGO's detection band for gravitational waves.

The thermal noise is a more fundamental and difficult problem than the seismic noise. Our primary techniques for reducing the thermal noise are to cool specific modes and to design systems with low dissipation. The seismic noise, by contrast, is motion relative to the inertial frame. So one can use the inertial frame as a reference to reduce the driving accelerations.

Detection strategies and confidence

In developing LIGO's search techniques, statistical tests, and detection criteria, we seek to minimize false observations. Within the statistics associated with the instrument noise, a viable gravitational wave signal from a distant astrophysical source must appear in the data streams of all three LIGO interferometers in the US, and of any other detectors in a worldwide network of comparably sensitive instruments.

For specific astrophysical searches, we will require signals consistent with calculated expectations of how the frequency varies with time. For the terminal in-spiraling of a binary system with a neutron star, for example, one can calculate the waveform as a function of the system parameters. So we can compare a candidate chirp signal over thousands of cycles, as it crosses LIGO's sensitivity band, with detailed templates of calculated waveforms.

Futhermore, the geographically dispersed detectors will have to exhibit consistent waveforms in proper coincidence. There will also be anticoincidence vetoes to weed out environmental effects. The hardest problem in a burst search is the elimination of false signals associated with non-Gaussian noise in the individual interferometers. By requiring multiple-detector coincidence, we can reduce the rate of such spurious events to less than one per decade.

Periodic sources will have to satisfy a very special set of criteria. The observed signal must exhibit amplitude modulation and Doppler frequency modulation consistent with the effects of the Earth's rotation and revolution around the Sun.

A stochastic background of gravitational waves can be detected by searching for a common "noise" in a set of interferometers. The detection requires the cross-correlation of two or more interferometers. In the LIGO geographic configuration, the cross correlation will be made between the Washington and Louisiana interferometers, with some penalty in bandwidth due to the large separation. We will also be able to correlate the two interferometers at the Washington site, assuming that their independence is not overly compromised by correlated perturbations at the same location.

Plans for the future

At first, LIGO will carry out a broadband search, because we do not know what kinds of astrophysical or cosmological sources we are most likely to see first. The LIGO facilities have been designed for a lifetime of 30 years, during which time, we expect, there will be a continuing and active program of detector development. The facilities can accommodate detectors operating at the quantum limit of a 1 ton mass and at the Newtonian limits imposed by the terrestrial environment. The vacuum and optical systems have been designed so as not to compromise eventual operation at these ultimate limits. It should be possible eventually to operate improved LIGO detectors that are several hundred times more sensitive than what we will start with next year.

Our initial detector design is a compromise between performance and technical risk. It incorporates some educated guesses as to what directions we should take to arrive at a reasonable probability for finding gravitational waves. It is a broadband system with modest optical power in the interferometer arms and a low-risk vibration isola-

science serving society

POSTDOCTORAL POSITION IN EXPERIMENTAL PHYSICS/CHEMISTRY

The Chemical Science and Technology (CST) Division is seeking qualified postdoctoral candidates to perform research involving the optical and magnetic trapping of selected radioactive atoms. The successful applicant will join a multidisciplinary research team composed of atomic physicists, nuclear physicists, and nuclear chemists. Our research is concentrated on fundamental electroweak interaction measurements (beta-decay asymmetry and beta-neutrino correlations of polarized atoms) and on the sympathetic cooling and Fermi degeneracy studies of cold atoms. The ultra-sensitive detection and quantitative isotopic ratio measurements of selected species is also under development. Applicants must have a strong background in experimental physics and/or chemistry with experience in using single-frequency lasers and in performing high-precision atomic spectroscopic measurements. Expertise in laser cooling, trapping, and fluorescent detection of atoms is highly desirable. For additional technical information, please contact **Dr. David J. Vieira** at **vieira@lanl.gov.**

A Ph.D. completed within the last three years or soon to be completed is required. Further details about the Postdoctoral Program may be found at: http://www.hr.lanl.gov/postdoc/. For consideration, submit a resume and publications list along with a cover letter outlining current research interests, including the names of three people who will provide references to postdoc-jobs@lanl.gov (no attachments, please!) OR submit two copies to: **Postdoc Program Office, AIP-PD995065, MS P290, Los Alamos National Laboratory, Los Alamos, NM 87545**. NOTE: Reference **#AIP-PD995065** in the e-mail Subject line (or the address) and cover letter.

NATIONAL LABORATORY
Operated by the University of California for the Department of Energy

UCI
University of California, Irvine

University of California, Irvine Major Initiative in the Physics and Chemistry of Materials

As part of a new major multidisciplinary initiative in materials physics and chemistry, the School of Physical Sciences at the University of California, Irvine, invites applications for at least five new faculty openings at all levels. Applications are encouraged from candidates in all areas of materials physics and chemistry, including but not limited to the areas of biomaterials, nanomaterials, electronic, photonic and magnetic materials, polymers, ceramics, atomic scale manipulation, novel applications of materials to technology, and theoretical work related to these topics. At the Assistant professor level we are seeking outstanding Ph.D.s who will establish vigorous research programs in areas that will complement existing strong programs in both the Department of Physics and Astronomy and the Department of Chemistry. The ability to effectively teach physics or chemistry at the undergraduate and graduate levels is required. Applicants for Assistant Professor positions should send their curriculum vitae, a list of publications and a research proposal to **Dean Ronald Stern, Materials Search Committee, School of Physical Sciences, University of California, Irvine, California, 92697-4675.** Applicants should also arrange to have three letters of recommendation submitted on their behalf. Candidates for the senior faculty openings should submit their curriculum vitae including a short description of their present research activities, and a list of potential references to the address above. To ensure full consideration during the 1999/2000 academic year, applications and all supporting materials should be received by **November 15, 1999.**

The University of California is an Equal Opportunity Employer committed to excellence through diversity.

tion system. The mirror suspensions have been well tested in prototype interferometers.

We expect to make improvements in the LIGO interferometers following the first scientific data run, which is scheduled to end in 2004. These improvements will include a new suspension system, provided by the collaborating GEO project, to further reduce the thermal noise. We may also, at that point, change to sapphire test masses. We also expect that significant improvement in the seismic isolation of the test masses will extend LIGO's sensitive observation band down to 10Hz.

We plan to reduce the sensing noise by going to a new interferometer configuration and by applying higher-power lasers in conjunction with improved optical materials and techniques to handle the higher power.

We expect that LIGO's sensitivity at 100 Hz will be improved by about a factor of 15, and that the overall high-sensitivity band will be expanded significantly to both lower and higher frequencies. That should expand the cosmic volume LIGO can search at a given sensitivity—and hence the discovery rate—by a factor close to 3000.

In the longer run, greater changes in the detector might use still newer interferometer configurations to drive the system to the ultimate limits dictated by quantum fluctuations and fluctuations in terrestrial gravity. It will be particularly interesting to improve LIGO's sensitivity for detecting periodic sources and possibly even a stochastic background of primordial gravitational waves. Searching for this speculative primordial background at high frequencies, where stochastic noise is tolerable, can be accomplished by using interferometers that greatly reduce the phase noise of the interference fringes at the cost of reduced bandwidth.

The scientific collaboration

As we enter LIGO's commissioning phase, we have expanded the scientific community's involvement by creating the LIGO Scientific Collaboration. It presently consists of about 30 research groups comprising more than 200 physicists and astrophysicists. We expect the collaboration to continue to grow and become the scientific center of LIGO as it develops over the next decade.

It is, of course, difficult to predict how LIGO will really evolve. But we believe we have set out on a course that has bright prospects for the early detection of gravitational waves. We plan a flexible approach toward improvements that will either let us follow up sources that have been detected or, if we find nothing at first, undertake more sensitive searches.

There are plenty of opportunities for new technical ideas and search methods. We look forward to developing an international collaboration with other gravitational-wave detectors to form a world-wide network. After LIGO's first data run, we plan to interleave subsequent searches with a series of detector upgrades that promise to lead to ever-enhanced sensitivity, making the direct detection of gravitational waves a reality within the next decade.

ABSTRACT

Although convective clouds are known to generate internal gravity waves, the mechanisms responsible are not well understood. The present study seeks to clarify the dynamics of wave generation using a high-resolution numerical model of deep convection over the Tiwi Islands, Australia. The numerical calculations presented explicitly resolve both the mesoscale convective cloud cluster and the gravity waves generated. As the convective clouds evolve, they excite gravity waves, which are prominent features of the model solutions in both the troposphere and stratosphere. The source location is variable in time and space but is related to the development of individual convective cells. The largest amplitude gravity waves are generated when the cloud tops reach the upper troposphere.

A new analysis technique is introduced in which the nonlinear terms in the governing equations are taken as the forcing for linear gravity waves. The analysis shows that in the present calculation, neither the shear nor the diabatic heating are the dominant forcing terms. Instead, the wave source is most easily understood when viewed in a frame of reference moving with the wind at the level of neutral buoyancy, whereupon the source may be described as a vertically oriented, oscillating convective updraft. This description is consistent with the properties of the modeled stratospheric waves.

1. Introduction

Vertically propagating gravity waves are accompanied by a vertical flux of horizontal momentum, with horizontal momentum transferred to the mean flow whenever the waves are transient or experience attenuation (by dissipation, saturation, wave breaking, or absorption at a critical level). The force exerted by such waves plays an important role in shaping the mean flow in the middle atmosphere, and for this reason, nearly all general circulation models (GCMs) include, albeit crudely, parameterizations of gravity wave drag. However, most researchers have focused on orographically generated gravity waves even though waves generated by nonorographic sources are thought to contribute significantly to the total momentum budget of the atmosphere (Fritts 1993). Such nonorographic sources include midlatitude frontal systems (e.g., Reeder and Griffiths 1996), upper-level jets (e.g., Guest et al. 2000), and dry boundary layer convection (e.g., Clark et al. 1986; Kuettner et al. 1987; Hauf and Clark 1989). Deep tropical convection is another wave source and is the focus of the present paper.

It is likely that deep tropical convection is an important source of gravity waves. According to Gray (1973), precipitating convective clusters occupy about 15%–20% of the tropics between 5° and 25° latitude, and numerous observational studies link gravity wave activity[1] to tropical convection (e.g., Larsen et al. 1982;

Pfister et al. 1993; Sato et al. 1995; Karoly et al. 1996). Moreover, idealized two-dimensional modeling shows that tropical squall lines are strong gravity wave radiators (Fovell et al. 1992; Alexander et al. 1995; Alexander and Holton 1997). Among other things, gravity waves generated by deep tropical convection are thought to be important in driving the quasi-biennial oscillation (e.g., Dunkerton 1997).

As well as contributing to the drag in the middle atmosphere, convectively generated gravity waves modify the region around the convective cloud, communicating the effect of latent heating within the cloud to the environment (e.g., Bretherton and Smolarkiewicz 1989; Mapes 1993; Shutts and Gray 1994). Mapes (1993) showed that a heating profile typical of a mesoscale convective system generates gravity waves that displace low-level parcels upward. He argued that these displacements reduce the convective inhibition (CIN), thereby increasing the possibility of further convection. In this way, convectively generated gravity waves may be important in organizing convection and initiating new cells (e.g., Lin et al. 1998).

Although the gravity waves generated by convective clouds are thought to be important, it is not possible to observe the wave field in sufficient detail in both time and space to determine how much these waves contribute to the global momentum budget. Current observational techniques make simplifying assumptions about the wave field and hence introduce uncertainty in the deduced wave parameters, especially the momentum flux. Furthermore, convective systems are complicated, and it is difficult to accurately observe their evolution and internal structures. At present, explicit cloud-scale modeling is the only way to describe the cloud and wave field in sufficient detail to explore the dynamics of the wave source and quantify the drag exerted by the waves on the middle atmosphere.

The approach adopted in the present study is to simulate deep tropical convection using a high resolution three-dimensional numerical model and to use the numerical solution to investigate the generation of gravity waves by the convection. The calculations presented are initialized using an idealized sounding motivated by the conditions observed during the recent Maritime Continent Thunderstorm Experiment (MCTEX), and follow the evolution of a convective cloud cluster over the Tiwi Islands just north of Darwin, Australia. The convection is initiated by sea-breeze convergence, and the numerical model explicitly resolves the process by which the waves are generated.

MCTEX was an international field experiment held during November and December 1995 focusing on the deep multicellular thunderstorms that form regularly over Bathurst and Melville Islands, which together comprise the Tiwi Islands [see Keenan et al. (1994) for details on MCTEX]. These thunderstorms are known locally as ''Hectors,'' and they develop during the months leading up to the summer monsoon and during monsoon breaks; a climatology of these storms and a description of their evolution is presented by Keenan et al. (1990) [see also the numerical modeling study by Golding (1993) and Crook (1997) and the recent review by Reeder and Smith (1998)]. Convection generally develops in the early afternoon along a line of sea-breeze convergence. Thereafter, the convection is initiated and controlled by the evaporatively driven cold pools. Later on, individual storms merge and may form squall-like structures that move off the islands. Keenan et al. (1994) found that the vertical velocity and radar structure have more similarity to continental convection than to oceanic convection. In particular, maximum updraft velocities are nearly an order of magnitude larger than those typical of oceanic convection. The environment in which the storms develop typically has moderate convective available potential energy (CAPE) (approximately 1500 J kg^{-1}), low to moderate shear (ranging from 0.25 to 2.5 $\times$ 10^{-3} s^{-1}), and high low-level moisture (approximately 20 g kg^{-1}) (Keenan et al. 1990).

A detailed understanding of how convective clouds generate gravity waves is a prerequisite to parameterizing their effects in GCMs. At present, there are at least three different hypotheses in the literature. Perhaps the most common hypothesis is that gravity waves are forced by temporal variations in the diabatic heating within the cloud (e.g., Salby and Garcia 1987; Bretherton 1988; Lin et al. 1998; Pandya and Alexander 1999). This idea forms the basis of a gravity wave parameterization developed recently by Chun and Baik (1998). A second possibility is the so-called *obstacle effect.* It is argued that if the cloud updraft develops in shear, as is usually the case, then the cloud will partially block the flow, producing a cloud-relative flow across the top of the cloud (e.g., Clark et al. 1986; Hauf and Clark 1989). With this idea in mind, it is sometimes said that clouds behave like *moving mountains* (e.g., Pfister et al. 1993). A third hypothesis, first proposed by Pierce and Coroniti (1966), was explored by Fovell et al. (1992). These authors argued that when individual updrafts within a convective system strike the tropopause, they decelerate quickly, subsequently oscillating about their level of neutral buoyancy. Fovell et al. described the individual clouds as *mechanical oscillators.*

The central aim of the present study is to clarify how convective clouds generate gravity waves. The present paper presents an analysis of the wave source. Evaluation of these source terms shows that the dominant terms are related to the idea of a mechanical oscillator of Fovell et al. (1992). The nonlinear analysis developed here is motivated by Lighthill's theory for the generation of sound (Lighthill 1952, 1954). In his theory, Lighthill treated sound waves as linear disturbances forced by (nonlinear) unstratified turbulent motion and introduced a radiation tensor to characterize the wave source. We show that a similar radiation tensor can be formulated, which describes the source of linear motions forced by convective clouds, including the generation of gravity

waves. The ideas behind Lighthill's radiation tensor have been adapted previously in a number of problems dealing with the generation of gravity waves by internal circulations. For example, Stein (1967) used a similar approach to investigate the generation of gravity waves in an isothermal (solar) atmosphere, and Ford (1994) recently applied the method to the emission of inertia-gravity waves by vortical flows in a rotating shallow water system. Reeder and Griffiths (1996) adapted Lighthill's approach to study the generation of gravity waves by fronts and jets.

All previous numerical studies on gravity wave generation by deep tropical convection modeled intense two-dimensional squall lines (Fovell et al. 1992, Alexander et al. 1995; Alexander and Holton 1997). Such systems are highly organized and appear to be strong gravity wave radiators. The present paper explores the generation of gravity waves in three-dimensional cloud systems, such as those that develop over the Tiwi Islands. Such systems are only weakly organized when compared with squall lines, but they are much more common in the Tropics. The convective clouds modeled here are, in essence, highly transient point gravity wave sources, whereas the squall lines modeled previously are long-lived line sources.

The paper is organized as follows. Section 2 briefly summarizes the numerical model used and outlines the numerical experiments considered. Section 3 discusses the evolution of the convective system and the structure of the gravity waves generated. The vertical flux of horizontal momentum in the stratosphere is calculated, and the structure and evolution of a particular convective cell is examined in detail. In section 4, a forced, linear wave equation is formulated, and a *source tensor* is introduced. The modeled convection is analyzed in terms of wave forcing, and the dynamics of wave generation are clarified. In section 5, the wave response in the stratosphere is shown to be consistent with the forcing mechanisms identified in section 4. Finally, our conclusions are summarized in section 6.

2. The numerical model

a. Model description

The numerical model used was originally developed by Clark (1977). In brief, the model is three-dimensional, nonhydrostatic, and anelastic. It is formulated in terms of terrain following height coordinates, and the finite difference approximations are second order in both space and time. The model includes parameterizations of the boundary layer physics, warm rain processes, ice microphysics (Koenig and Murray 1976), and subgrid scale turbulence (Lilly 1962; Smagorinsky 1963). For simplicity, the calculations presented here assume an f-plane approximation and neglect internal absorption and scattering of solar radiation. Over land, the calculations assume that the Bowen ratio is 1 and the albedo is 0.2.

An important feature of the numerical model is its capacity for two-way interactive grid nesting [see Clark and Farley (1984) for details]. Numerical solutions calculated on lower-resolution ''coarse'' grids are interpolated to higher-resolution ''fine'' grids using quadratic or cubic polynomials, depending on the variable being interpolated. These interpolated fields provide initial and boundary conditions for the higher-resolution domains. To complete the two-way interaction, the fine grid numerical solutions are averaged onto the coarse grid during the numerical integration. The averaging is defined in such a way as to conserve mass. Accordingly, the coarse grid solutions are affected by the fine grid solutions. Moreover, grid refinement and grid stretching are used in the vertical direction [see Clark and Hall (1996) for details].

All numerical experiments described are initialized with a single thermodynamic sounding taken at 0400 Local Standard Time (LST) 27 November 1995 during MCTEX (LST = UTC + 9.5 h). The radiosonde sounding on this day reached a height of 24 km. Above this height, isothermal and dry initial conditions are assumed. Figures 1a and 1b show the initial profiles of water vapor mixing ratio and potential temperature. The tropopause is located at a height of 16 km, and the moisture profile is conditionally unstable. Due to the high surface moisture, the lifting condensation level (LCL) is only 700 m above the surface. The level of free convection (LFC) ranges from 1.5 to 3.0 km, depending on the origin of the lifted parcel; likewise the level of neutral buoyancy (LNB) ranges from 10 to 14 km.

The intent of the study is not to simulate the details of the convection observed on 27 November but instead, to use this case to investigate how deep tropical convection excites gravity waves. With this in mind, an idealized wind profile was chosen for the present study. The wind profile retains the basic features of the observations, but its idealized form simplifies the analysis by reducing the number of active source terms, hence clarifying the source mechanism of the waves (see sections 4 and 5). Such an idealization allows the modeled stratospheric waves to be related unambiguously to certain properties of the wind profile. The initial wind profile is easterly at all heights and is shown in Fig. 1c. Above the boundary layer, the flow is 5 m s^{-1} throughout most of the troposphere. Just below the tropopause, the flow increases linearly through a 3-km deep layer to 10 m s^{-1} in the stratosphere. The main difference between the idealized wind profile and that taken during MCTEX is that the observed profile has a low-level easterly jet. This jet probably plays an important part in organizing the convection and determining the way in which the convective line propagates. These effects are neglected here.

Numerical cloud models commonly include a local-

ized low-level buoyancy perturbation (often called a warm bubble) as part of the initial conditions. The warm bubble subsequently rises and initiates convection. However, the present study is concerned principally with the waves generated by deep convection, and therefore, it is critical not to introduce unrealistic gravity waves in the initial conditions. The gravity waves generated in the model must be unequivocally due to the clouds and not to an artifact of the initialization. For this reason, we chose to initiate the convection by explicitly modeling the island sea breeze similar to that observed during MCTEX, where deep convection develops once the circulation becomes strong enough to overcome the low-level CIN.

b. Experimental design

This paper describes the results of three numerical experiments. The primary difference between the experiments is the resolution and size of the model domains.

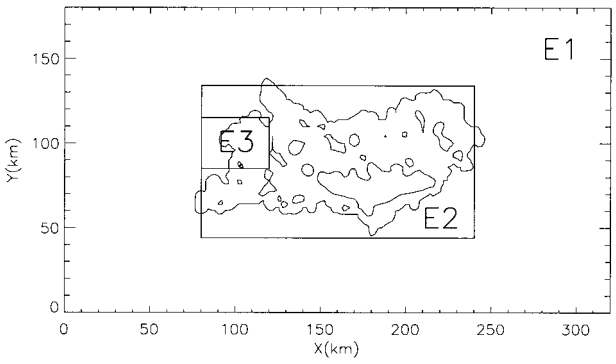

FIG. 2. Outline of model domains. Shown are domains initialized in experiments E1 to E3 (denoted Domains 1 to 3 in text). Also shown are topographic contours of 0 and 50 m.

Experiment E1 is the lowest resolution experiment considered here. It is designed to test the sensitivity of the modeled clouds, and the waves they generate, to changes in spatial resolution. Furthermore, the reduced computational cost of E1 allows the momentum flux to be calculated over a longer time interval than is possible with the other higher-resolution numerical experiments. Experiment E1 uses only one domain (Domain 1) surrounding the Tiwi Islands and is centered at (11.55°S, 130.56°E). Figure 2 shows the size and extent of the model domains relative to the Tiwi Islands. For simplicity, all surrounding topography not directly associated with the Tiwi Islands has been neglected. Domain 1 has 2-km horizontal resolution and extends vertically to 50 km. The vertical grid is stretched so that the grid spacing varies from 50 m at the surface to 800 m in the stratosphere (Fig. 3). The uppermost 10 km of the vertical grid includes a Rayleigh-friction sponge to absorb vertically propagating disturbances without reflection. The vertical grid is designed to resolve three important components of the flow field: the boundary layer convergence, the convective mixing in the troposphere, and the gravity waves in the stratosphere. Experiment E1 is initialized at 0700 LST and is integrated for 15 h until 2200 LST.

Experiment E2 is designed to resolve both the convective clouds and excited gravity waves. In this experiment, a second domain (Domain 2) is nested within Domain 1 (see Fig. 2), and the two domains interact in the way described earlier in section 2a. Domain 2 uses 1-km horizontal resolution with a vertical grid that extends to 19 km (see Fig. 3). Although both horizontal and vertical resolution remain unchanged in the upper

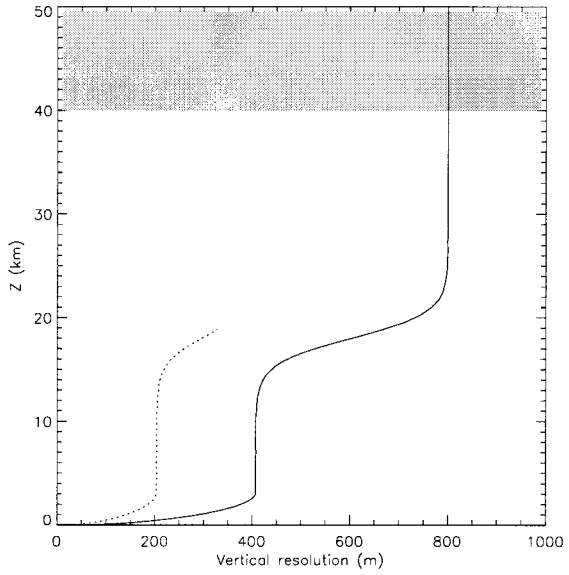

FIG. 3. Vertical grid spacings for Domain 1 (solid) and Domains 2 and 3 (dashed). The region of the sponge absorber is shaded.

stratosphere, the convective clouds, which are the source of the gravity waves, are better-resolved in E2 than in E1. This experiment begins at 1100 LST, taking its initial conditions from experiment E1, and is integrated until 1330 LST.

Experiment E3 uses three interactive grids to focus on one particular convective cell identified in E2. The purpose of E3 is to examine in detail how the cloud generates gravity waves. In this experiment, a third domain (Domain 3), with horizontal resolution of 0.5 km, is nested within Domain 2 (see Fig. 2) taking its initial conditions from E2 at 1230 LST. Experiment E3 is integrated until 1330 LST. The vertical grid remains the same as Domain 2 of E2. Domain 2 is, in turn, nested within Domain 1.

3. Numerical experiments

After the initialization of experiment E1, the islands are slowly heated, and a sea-breeze circulation develops. The dominant circulation appears as two zonally oriented convergence lines, which propagate inland in opposing directions from the northern and southern coastlines. By 1100 LST, the two convergence lines have penetrated inland approximately 20 km in the meridional direction, and at this time, the maximum meridional wind speed near the surface is approximately 5 m s^{-1}. The depth of the sea breeze is approximately 0.5 km, with weaker return flow aloft. The distance between the leading edges of the two sea breezes is approximately 15–20 km. Prior to collision of the sea breezes (approximately 1200 LST), the convergence causes sufficient vertical displacement of parcels to overcome the CIN, and the convection deepens rapidly.

a. Evolution of the convective clouds

Most of the modeled convection forms over the Tiwi Islands. Accordingly, our analysis of the convection focuses on experiment E2, which has an intermediate resolution domain covering the islands (Fig. 2). Prior to the initialization of experiment E2 at 1100 LST, shallow boundary layer convection is scattered over the islands, and the convection remains relatively shallow until about 1200 LST. After this time, the convection develops rapidly, and by 1300 LST, it reaches its maximum intensity. Thereafter, the convection decays while being advected by the easterly background flow.

Figure 4 shows the total cloud water (liquid water plus ice) in a horizontal cross section 10 km above mean sea level and depicts the temporal variation in the spatial position of deep convective cells. Note that those cells through which the cross section passes have nearly reached their LNB. At 1200 LST, a number of deep cells are located over the western half of the islands. Half an hour later, some of these cells arrange themselves in a north–south line, and by 1300 LST, the cells merge to form a convective line approximately 40 km long. The convective line continues to move westward, with a large cell developing at its northern end. In addition to the convective line, there are a number of other deep cells scattered across the islands.

A zonal cross section through $y = 100$ km illustrates the vertical structure of the convection and, in particular, the large cell at the northern end of the convective line (Fig. 5). At 1200 LST, the zonal cross section of vertical velocity and total moisture (water vapor, cloud water, and ice) shows a number of cumulus cells over the islands (Figs. 5a and 5b). These cells have cloud bases around 4 km and cloud tops between 9 and 12 km. Their updraft velocities are relatively small, and the cells are scattered with little organization.

By 1300 LST, there are a number of convective cells over the islands in various stages of development (Figs. 5c and 5d). A very deep cell is evident at approximately $(x, y) = (100, 100)$ km. This is the large cell at the northern end of the convective line (Fig. 4c), which will be examined in detail in section 3c. It is rapidly developing and has strong updrafts with vertical velocities on the order of 20–30 m s^{-1}. There are also two smaller cells upstream of the large cell. The updraft velocities in these two cells are less than 1 m s^{-1}, and they do not appear to be developing further. All cells in Figs. 5c and 5d are separated by approximately 35 km, and for this cross section, they are located at approximately $x = 100, 135, 170$ km, with another growing cell evident in the boundary layer at $x = 205$ km. It is unclear whether this spacing is caused by resonance between the clouds and the generated gravity waves (cf. Clark et al. 1986) or whether it is simply the natural scale set by the convection alone.

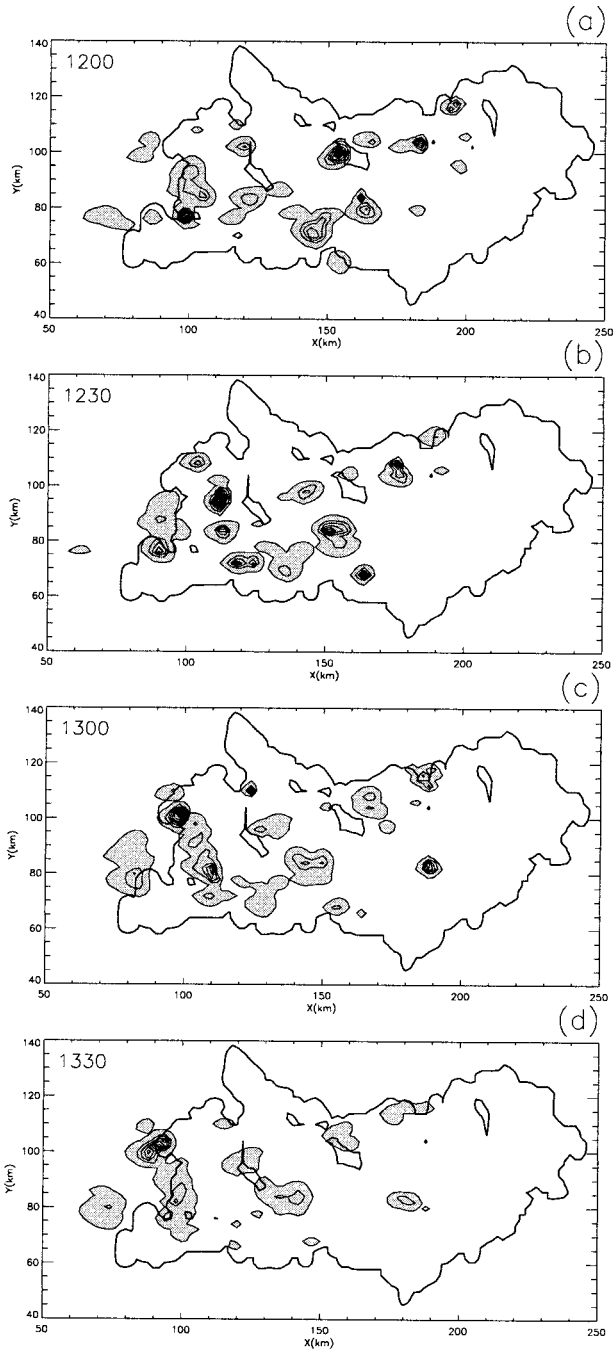

FIG. 4. Horizontal cross section of total cloud water (ice and liquid water) through $z = 10$ km of Domain 1 for experiment E2. (a) 1200 LST, (b) 1230 LST, (c) 1300 LST, and (d) 1330 LST. Contour intervals of 1 g kg^{-1} with the minimum level equal to 0.1 g kg^{-1}. Also shown is the zero topographic contour (thick).

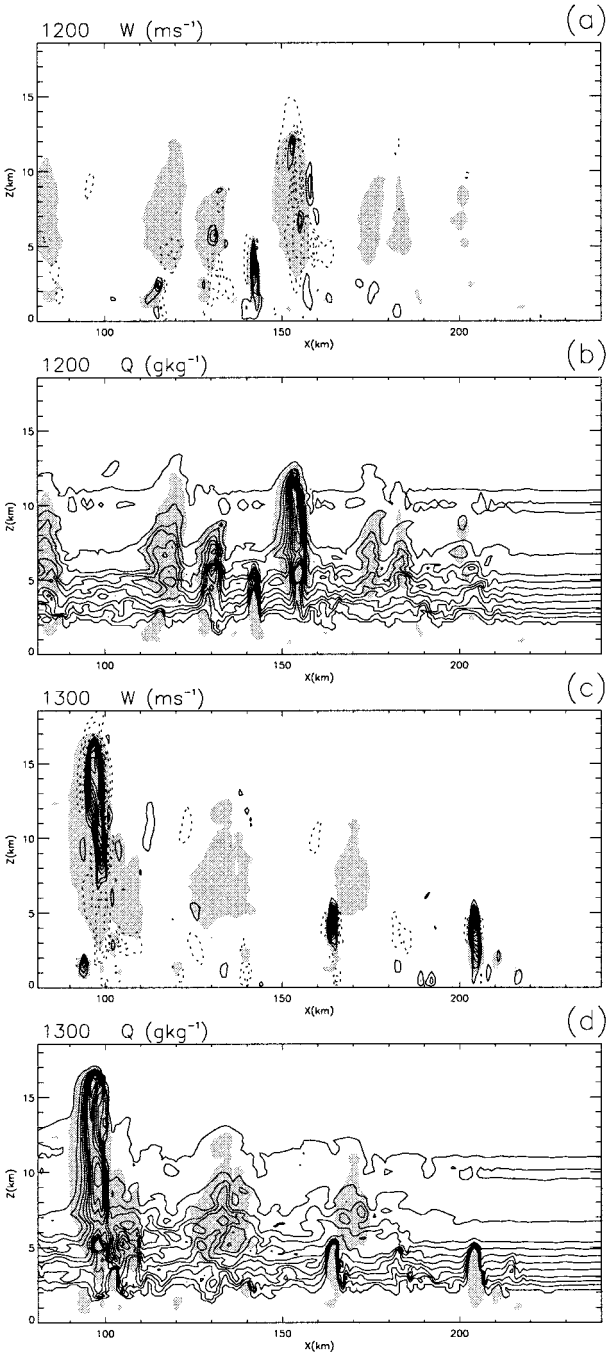

FIG. 5. Zonal cross section through $y = 100$ km for Domain 2 experiment E2. (a) Vertical velocity, w (1 m s^{-1} interval) at 1200 LST; (b) total moisture, Q (1 g kg^{-1} interval) at 1200 LST. (c) and (d) are the same as (a) and (b) except at 1300 LST. The shaded area in all plots is the 0.1 g kg^{-1} total cloud water contour.

b. Sensitivity to spatial resolution

The sensitivity of the modeled convection to changes in the resolution can be determined by comparing the numerical solutions from Domain 1 of experiments E1 and E2. The numerical solutions on Domain 1 from E2 should better represent the convection due to the two-way interactive nesting of the intermediate resolution domain (Domain 2) within it. A horizontal cross section of the cloudy air in the plane $z = 10$ km in E1 at 1300 LST (Fig. 6) can be compared directly to Fig. 4c to

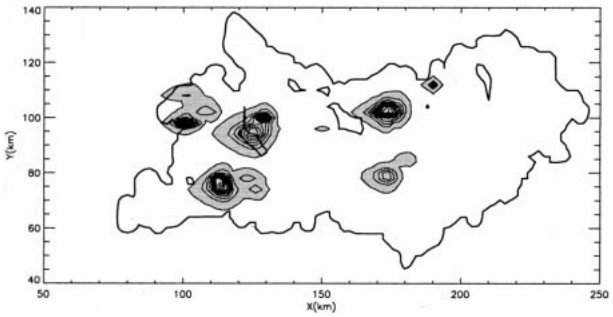

FIG. 6. Horizontal cross section of total cloud water (ice and liquid water) through $z = 10$ km of Domain 1 for experiment E1; for 1300 LST. Contour intervals of 1 g kg^{-1} with the minimum level equal to 0.1 g kg^{-1}. Also shown is the zero topographic contour (thick).

determine the sensitivity of the convection to spatial resolution. The comparison shows that the number and position of deep convective cells is sensitive to the spatial resolution, although the size and position of the largest cells are similar. Experiment E2 better resolves the boundary layer convergence and consequently more accurately represents those processes that initiate convection. Golding (1993) concluded that 4-km horizontal grid spacing was sufficient to qualitatively resolve these convective clusters over the Tiwi Islands. A similar conclusion was reached by Weisman et al. (1997), who suggested that 4-km horizontal grid spacing is required to resolve the mesoscale structures of squall lines. Although 4 km may be the upper limit for resolving the gross features of such convective clusters, it is not sufficient to resolve internal cloud structures such as convective updrafts, which may have spatial scales of only a few kilometers. It will be shown in section 4 that the individual updrafts play central roles in generating gravity waves and must be resolved when investigating the dynamics of the wave source.

c. Generated gravity waves

Three horizontal cross sections of the vertical velocity half an hour apart and at a height of 20 km are shown in Fig. 7. The cross sections lie in the stratosphere well above the top of the clouds, and velocity perturbations are produced by vertically propagating gravity waves. The wave fronts are almost circular and appear to be radiating outward (and upward) from highly localized sources. At 1230 LST, there is a strong, localized wave source at approximately $(x, y) = (90, 75)$ km (Fig. 7a). Half an hour later, another source develops at approximately $(x, y) = (100, 100)$ km (Fig. 7b), and by 1330 LST, this source dominates the wave generation (Fig. 7c). This source is advected downstream by the background flow, and at 1330 LST, is located at approximately $(x, y) = (90, 100)$ km. This source corresponds to the large cell at the northern end of the convective line discussed in section 3a. Throughout the integration, the wave sources remain highly localized, although their number and position are highly variable. These wave sources are strongly correlated with deep individual convective cells. Furthermore, the temporal variability suggests that clouds do not generate waves throughout their entire evolution, but instead, gravity waves are generated during a particular part of clouds' life cycles.

At a height of 20 km, the wave field is incoherent. According to linear wave theory, the vertical component of the group velocity is a function of the horizontal and vertical wavelength. Consequently, a wave packet will disperse into its constituent waves as it propagates upward. For this reason, the wave field at 40 km appears more coherent than at lower levels (Fig. 8). Crook et al. (1991) noted this effect for gravity waves in the lower troposphere, and Prusa et al. (1996) found that waves generated by a localized source at the tropopause were dominated by one wavelength after they had propagated vertically into the middle atmosphere. The increased coherence of the waves underscores the highly localized and variable nature of the source. The wave signature, and hence the apparent source of the waves, lags the corresponding signature at 20 km due to the time taken for the waves to propagate vertically.

Recently, Dewan et al. (1998) analyzed gravity waves in the satellite observations from the Midcourse Space Experiment. The density and temperature fluctuations, which were measured in the upper stratosphere (at approximately 40 km), showed wave fronts arranged in concentric circles centered over a large thunderstorm. These observations are remarkably similar to the cross sections shown in Fig. 8 and lend support to the numerical solutions presented here.

We consider now zonal and meridional cross sections of the vertical velocity at 1300 LST. The two cross sections intersect at $(x, y) = (100, 100)$ km (Figs. 9a and 9b). The zonal cross section (Fig. 9a) shows a wave packet centered over the group of convective cells and an upstream bias to the waves. In contrast, the gravity wave field in the meridional cross section (Fig. 9b) is approximately symmetric about the source. The amplitude of the waves is small, approximately 0.3 m s^{-1}, and their wavelength spectra (in the stratosphere) have peaks in the horizontal (both zonal and meridional) and vertical at approximately 17 and 5 km, respectively. These will be determined more accurately later in this section.

The zonal velocity and the buoyancy are shown in Figs. 9c and 9d. Upstream from the source, the horizontal velocity exhibits wave-like perturbations similar to those in the vertical velocity, although the wave signature in zonal velocity of the downstream propagating waves is more pronounced than the upstream propagating waves. The reason is that the phase lines of the downstream propagating waves are more horizontal. As the phase lines become more horizontal, the relative amplitude of the horizontal velocity increases and vertical velocity decreases. This is important because an analysis restricted to vertical velocity signatures may

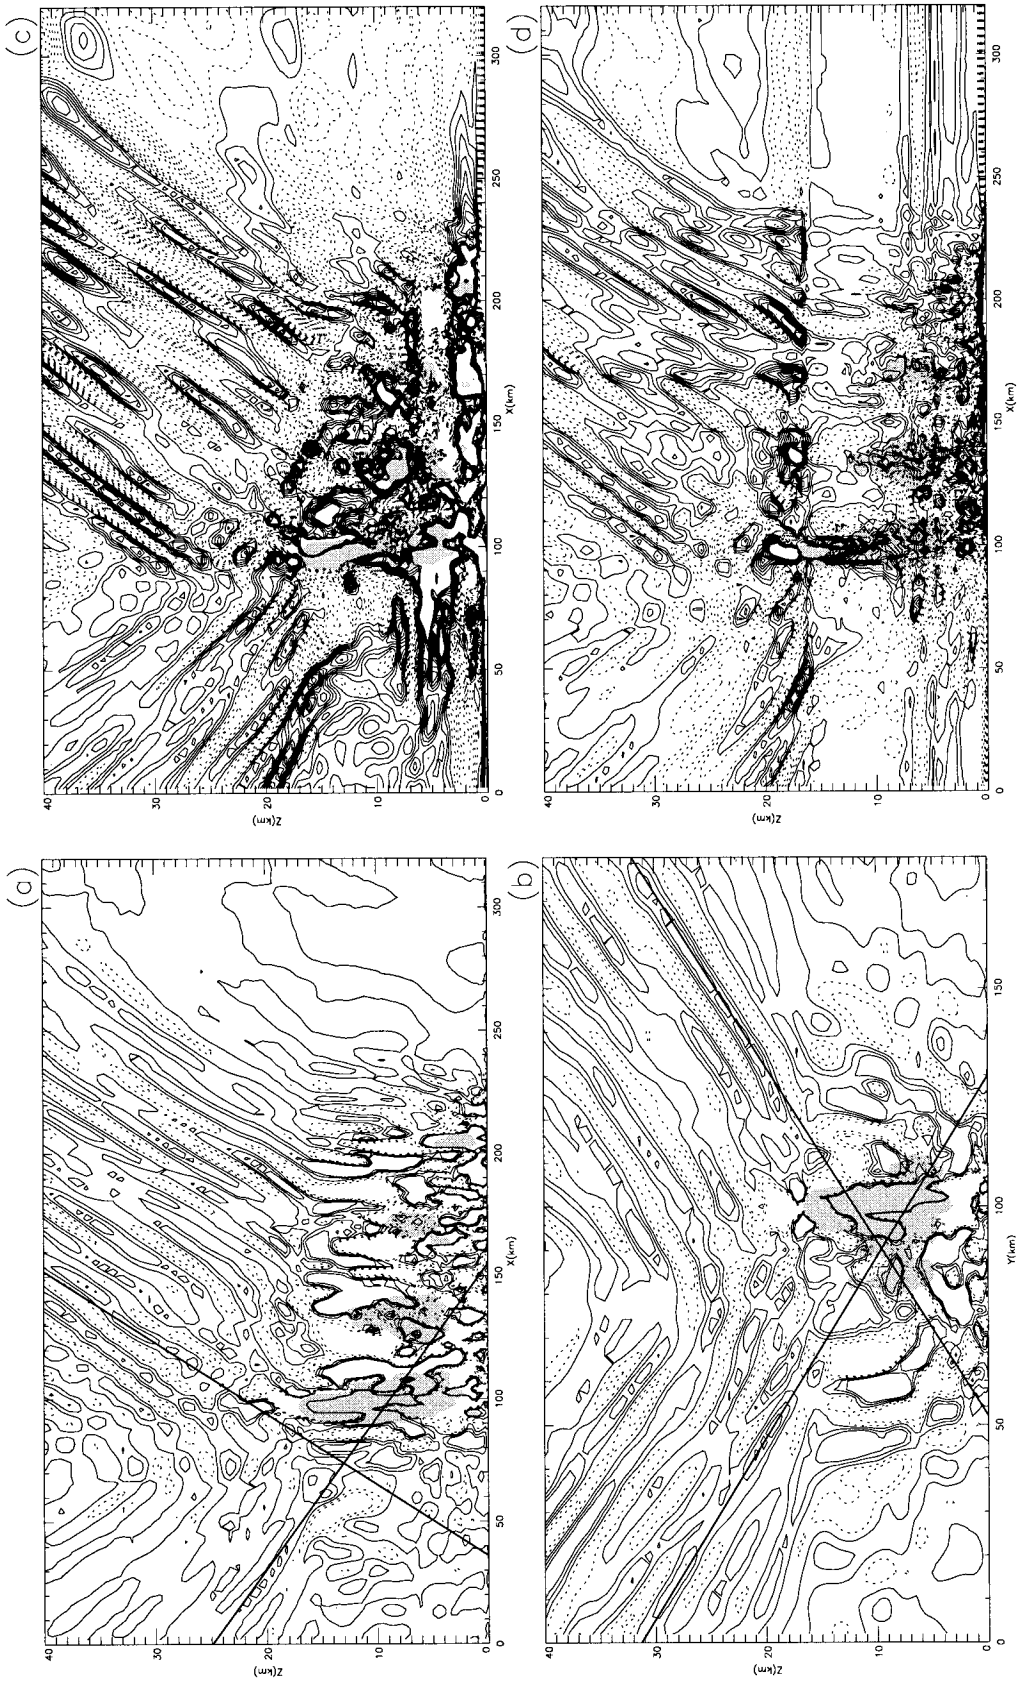

FIG. 9. (a) Zonal cross section of vertical velocity through $y = 100$ km for Domain 1 experiment E2. (b) Meridional cross section of vertical velocity through $x = 100$ km for Domain 1 experiment E2. (c) and (d) show perturbation zonal velocity and dry buoyancy, respectively, for the same zonal cross section as (a). All plots are valid at 1300 LST and feature the 0.1 g kg^{-1} total cloud water contour (shaded). Negative contours are dashed with velocity contours having a 0.1 m s^{-1} interval and buoyancy contours having a 5×10^{-3} m s^{-2} interval. (a) and (b) also have solid lines representing the angles of some phase lines for later analysis. Note that (b) has a different horizontal scale from (a), (c), and (d).

miss the downstream propagating waves. As buoyancy perturbations reflect parcel displacements, the wave signatures in the buoyancy field are in quadrature with the vertical velocity. These ideas are discussed further in section 5a.

Power spectra of the vertical velocity for Domain 1 E2 are calculated to determine more accurately the dominant horizontal and vertical wavelengths in the stratosphere. Two-dimensional m–k (zonal) and m–l (meridional) spectra[2] are shown in Fig. 10. These spectra are calculated using the zonal and meridional cross sections of vertical velocity shown in Fig. 9 for heights of $20 < z < 40$ km. These spectra are smoothed over three adjacent wavenumber bins, squared, and then normalized. Note also that in these spectra, $m < 0$, which corresponds to negative vertical phase speed, and therefore $k > 0$ represents westerly propagating waves and $k < 0$ represents easterly propagating waves. Both of these spectra (Figs. 10a and 10b) have maximum power at a horizontal wavenumber of approximately 3.7×10^{-4} m^{-1} (wavelength of 17 km) and vertical wavenumber of approximately 1.3×10^{-3} m^{-1} (wavelength of approximately 5 km). The zonal spectrum is asymmetric, about $k = 0$, due to the stratospheric flow. Upstream propagating waves have smaller wavenumbers and larger wave signatures. This is due to wave refraction and will be discussed in more detail later in the section. The meridional spectrum is approximately symmetric in terms of the location of the vertical wavenumber maximum, except the southerly propagating waves ($l > 0$) appear to have more power. This is probably due to the focus of the gravity waves in the upper stratosphere being south of the center of the domain, thus there are more southerly propagating waves in the domain. (Note that the position of the focus of the waves in the upper stratosphere lags the position of the source in the troposphere due to the finite vertical group velocity of the waves.)

The zonal cross section of vertical velocity (Fig. 9a) shows that the gravity waves are refracted strongly as they propagate from the troposphere to the stratosphere. In the troposphere, the phase lines are oriented almost vertically, implying that the waves are trapped or evanescent or that the vertical wavelength is very long. One should bear in mind that in the troposphere, it is difficult, and probably not dynamically meaningful, to distinguish convective updrafts from gravity waves. In the stratosphere, the phase lines are oriented at an angle to the vertical, implying that the waves are propagating vertically. This refraction of the waves at the tropopause is due to a change in static stability and will be discussed in more detail in section 5a. The mechanism that selects the horizontal wavelength of the gravity waves is discussed in section 5b. The convective cells in the troposphere appear to be separated by a distance equal to twice the dominant horizontal wavelength (approximately 17 km) in the stratosphere (Fig. 9a), and there is a signature of this in the power spectrum (Fig. 10a). However, as noted earlier in section 3a, it remains unclear at present what role (if any) the gravity waves play in organizing the convection. This is a topic for future research.

d. Momentum fluxes

The vertical flux of horizontal momentum (or simply momentum flux) is an important quantity when considering how gravity waves affect the large-scale circulation. The horizontally averaged (zonal) momentum flux is defined as $(\overline{\rho}uw)$, where $\overline{\rho}$ is the background density; u and w are the zonal and vertical perturbations from the background flow ($U(z)$, 0, 0), respectively; and $\overline{(\ )}$ represents a simple horizontal average. Quantifying the momentum flux due to convectively generated gravity waves is crucial for the development and verification of GCM parameterizations.

The evolution of the horizontally averaged (zonal) momentum flux for Domain 1 from experiment E1 is shown in Fig. 11. The momentum flux is largest in the troposphere, and its evolution strongly reflects the life cycle of the convection over the island. Prior to approximately 1000 LST, the momentum flux is associated with the well-mixed boundary layer. After this time, the tropospheric momentum flux is associated mainly with transport by the convective clouds. Between approximately 1000 and 1200 LST, the convection deepens slowly, reaching a height of about 9 km. At 1200 LST, the sea-breeze convergence is sufficiently strong to overcome the CIN, and the convection deepens rapidly to the tropopause. The convection remains deep until approximately 1400 LST, after which it begins to decay. By 2200 LST, vertical mixing is confined to heights below the middle troposphere.

In the stratosphere, the momentum flux is associated principally with vertically propagating gravity waves. Early in the model run, the stratospheric momentum flux is produced by small-amplitude gravity waves generated by the sea breeze. However, after about 1200 LST, the convection deepens rapidly, and the stratospheric momentum flux increases sharply, reaching a maximum at approximately 1400 LST. The upper-stratospheric momentum flux lags that in the lower stratosphere because it takes time for the waves to reach these heights. The stratospheric momentum flux decreases during the afternoon to nearly zero by the end of the model integration at 2200 LST.

The model calculation employs open lateral boundaries, allowing waves to propagate out of the model domain without significant reflection. Some waves propagate through the lateral boundaries of the model and therefore do not contribute to the momentum flux shown

[2] Note that k, l, and m are the zonal, meridional, and vertical wavenumbers, respectively.

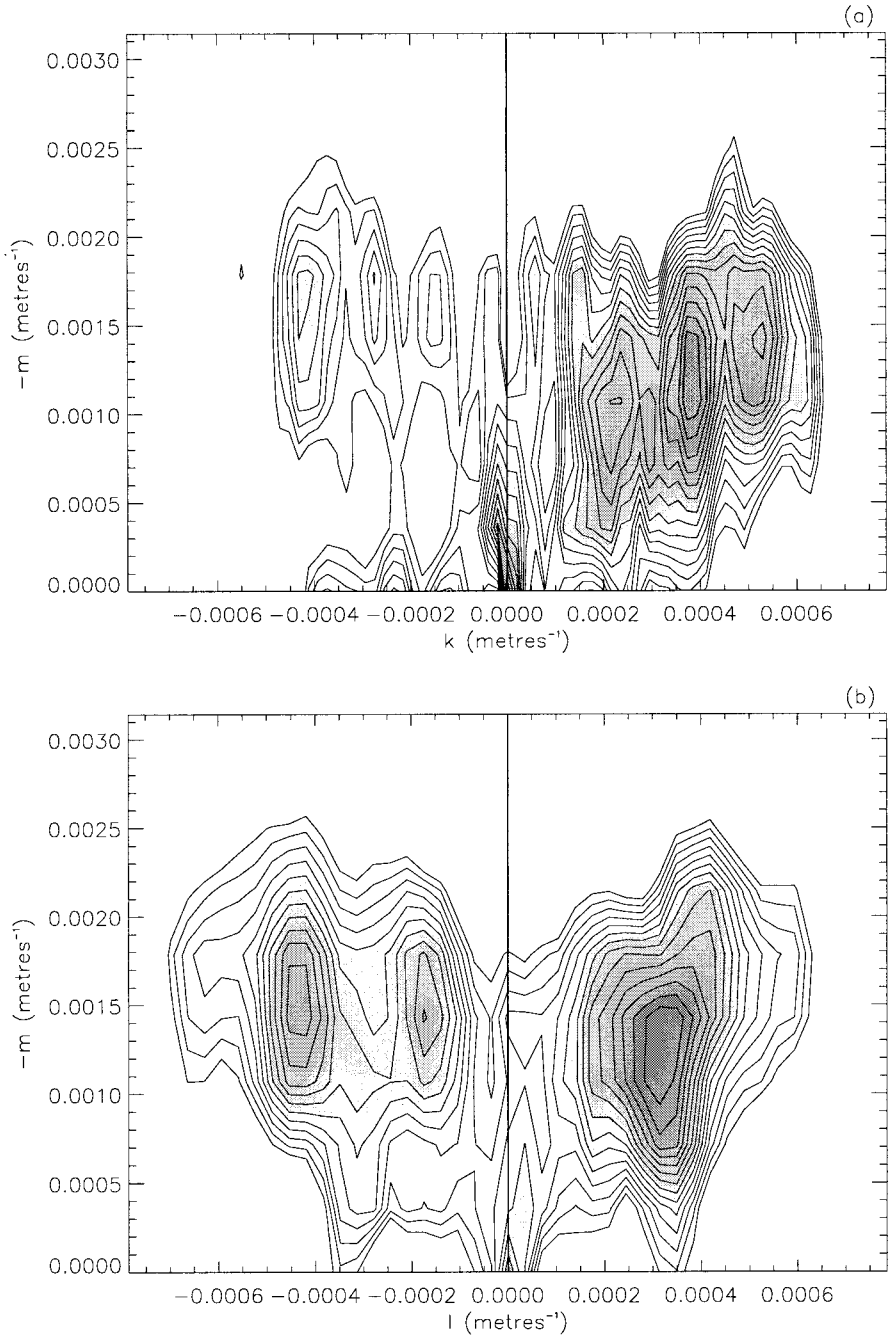

FIG. 10. Normalized two-dimensional power spectra of vertical velocity at 1300 LST. (a) *m–k* (zonal) spectrum calculated at $y = 100$ km and $20 < z < 40$ km. (b) *m–l* (meridional) spectrum calculated at $x = 100$ km and $20 < z < 40$ km. To aid interpretation, the spectra are normalized with logarithmic contours, and only the largest 1.5 orders of magnitude are shown ($10^{-1.5}$–1 in 15 contours).

in Fig. 11. Hence, the calculated momentum flux should be considered a lower bound on the magnitude of the total momentum flux. Also, such calculations of the momentum flux are sensitive to the size of the region over which the average is taken, particularly if the wave source is not in the center of the averaging region. Figure 12 shows the meridional average of the momentum flux for Domain 1 in experiment E2 at 1300 LST. The pattern of momentum flux is highly variable in space because the individual convective clouds, which generate the

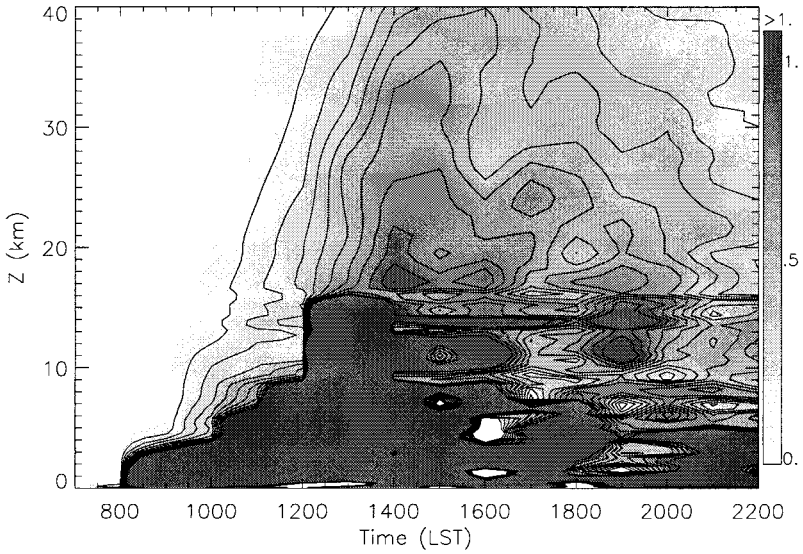

FIG. 11. Temporal evolution of the horizontally averaged (zonal) momentum flux for experiment E1 ($\times 10^{-3}$ Nm^{-2}); contour interval is 1×10^{-4} Nm^{-2}, with the zero contour omitted.

waves, are highly transient. Upstream from the wave source, the momentum flux is generally positive, while downstream from the source, it is generally negative.

The dominant wave-generating cloud is not in the center of the domain at 1300 LST (Fig. 12). Instead, the main wave source is located at approximately $x =$ 100 km. The relative contribution of the upstream and downstream propagating waves to the momentum flux can be estimated by averaging the momentum flux over two different regions. The first region is between $x =$ 0 km and $x = 100$ km and principally comprises those waves propagating downstream from the dominant source. The second region lies between $x = 100$ km and $x = 200$ km and mainly includes those waves propagating upstream from the dominant source. These averages and their sum are shown in Fig. 13a. The upstream component of the momentum flux is largest, and the downstream component acts to reduce the total momentum flux only in the lower stratosphere. This is a rather crude method of separating the upstream com-

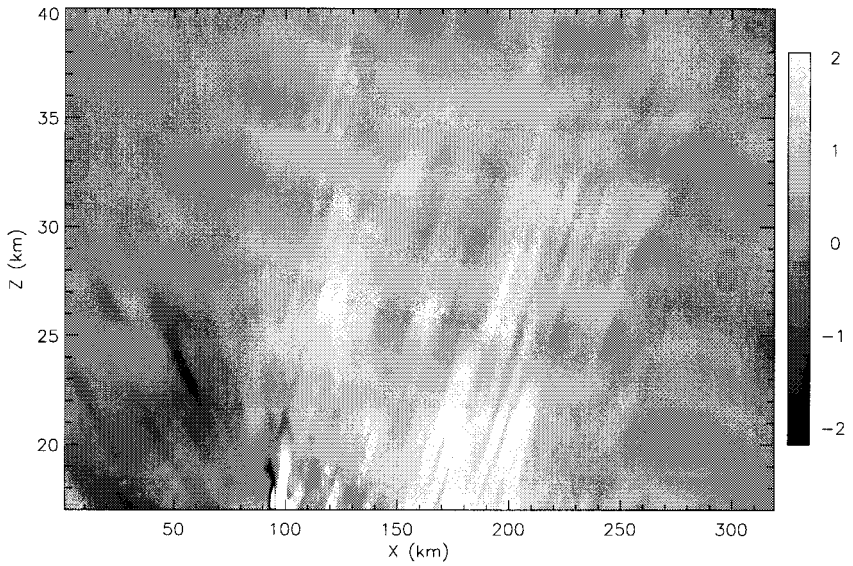

FIG. 12. Meridional average of the momentum flux for Domain 1 experiment E2 at 1300 LST ($\times 10^{-3}$ Nm^{-2}).

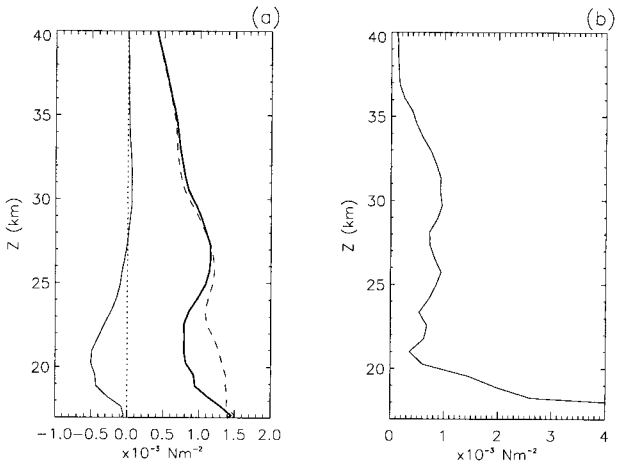

FIG. 13. Profiles of the momentum flux for experiment E2 at 1300 LST. (a) The horizontal average is calculated over $0 \leq x \leq 100$ km (solid), $100 \leq x \leq 200$ km (dashed), and $0 \leq x \leq 200$ km (bold) for $0 \leq y \leq 180$ km. (b) The horizontal average is calculated in the stratosphere over the region of Domain 3 in E3.

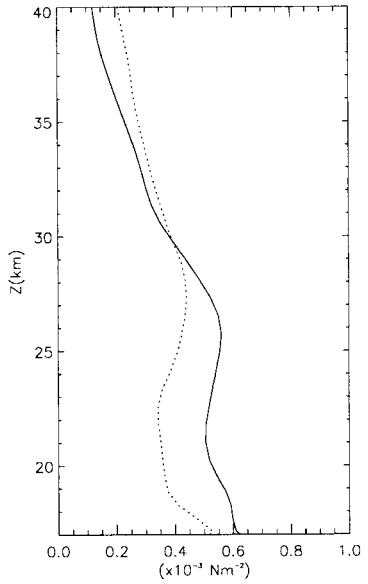

FIG. 14. Vertical profile of the horizontally averaged (zonal) momentum flux at 1300 LST for Domain 1 experiment E1 (solid) and experiment E2 (dashed).

ponents of the momentum flux, in particular, considering that the wave source is not a true point source but rather a cluster of sources.

The momentum flux generated by an individual cloud is estimated by taking a horizontal average for E2 in the region above Domain 3 of E3 (described in more detail in the next section). This average is calculated at 1300 LST and is shown in Fig. 13b. At this time, the convective cloud chosen is the strongest wave source in the model domain, and this strength is reflected in the large momentum flux in the lower stratosphere. Such a localized average of the momentum flux can be compared to localized observations of gravity wave momentum fluxes taken close to convective clouds (for example from aircraft or radiosondes). However, this profile has little value in terms of the momentum budget of the middle atmosphere because it does not incorporate the reduction in momentum flux due to radial propagation of the waves. As time continues, the magnitude of the momentum flux reduces as the waves disperse and radiate outward. Eventually, the pattern of momentum flux resembles one of the pulses in Fig. 12.

Experiment E1 has been used to illustrate the temporal evolution of the momentum flux. However, as shown earlier, smaller-scale convective structures are sensitive to the numerical resolution. To determine the sensitivity of the stratospheric momentum flux to tropospheric resolution, a profile of momentum flux in the stratosphere from E1 at 1300 LST is compared to a profile at the same time from E2 (Fig. 14). Although the two profiles have similar numerical values and similar vertical gradients, they show important differences. These differences can be explained by the slightly different positions and stages of development of the convective cells in the two experiments. For example, any change in the position of the clouds will change how much momentum is transported through the lateral boundaries by the waves, which in turn, will change the horizontally averaged momentum flux. Unfortunately, the computational cost of these large numerical calculations made it impracticable to explore resolution sensitivity further.

e. High-resolution convection and the wave-generation mechanism

In section 3c, experiment E2 was used to identify a dominant wave source at approximately $(x, y) = (100, 100)$ km. In order to better resolve the structure of this source, a higher-resolution domain surrounding this region is initialized at 1230 LST. This domain is the basis of experiment E3. However, when higher-resolution domains are initialized from lower-resolution outer domains, the modeled atmosphere takes some time to adjust. Typically, this adjustment time is on the order of the buoyancy period, $2\pi/N$, which is approximately 10 min in the troposphere. The maximum convective updraft at initialization is about 30 m s^{-1}, and therefore in 10 min, a parcel moving at this velocity would traverse the depth of the troposphere. Thus, by about 1240 LST, the flow has adjusted to the finer computational grid.

Zonal cross sections of vertical velocity (Figs. 15a–d), potential temperature (Figs. 16a–d), and total moisture (Figs. 17a–d) depict the evolution of the large cell at the northern end of the convective line, discussed earlier in section 3a. This cell is the strongest wave-producing cloud in the model runs. At 1240 LST, there is a strong updraft at approximately $x = 100$ km, with maximum vertical velocity of approximately 40 m s^{-1} (Fig 15a).

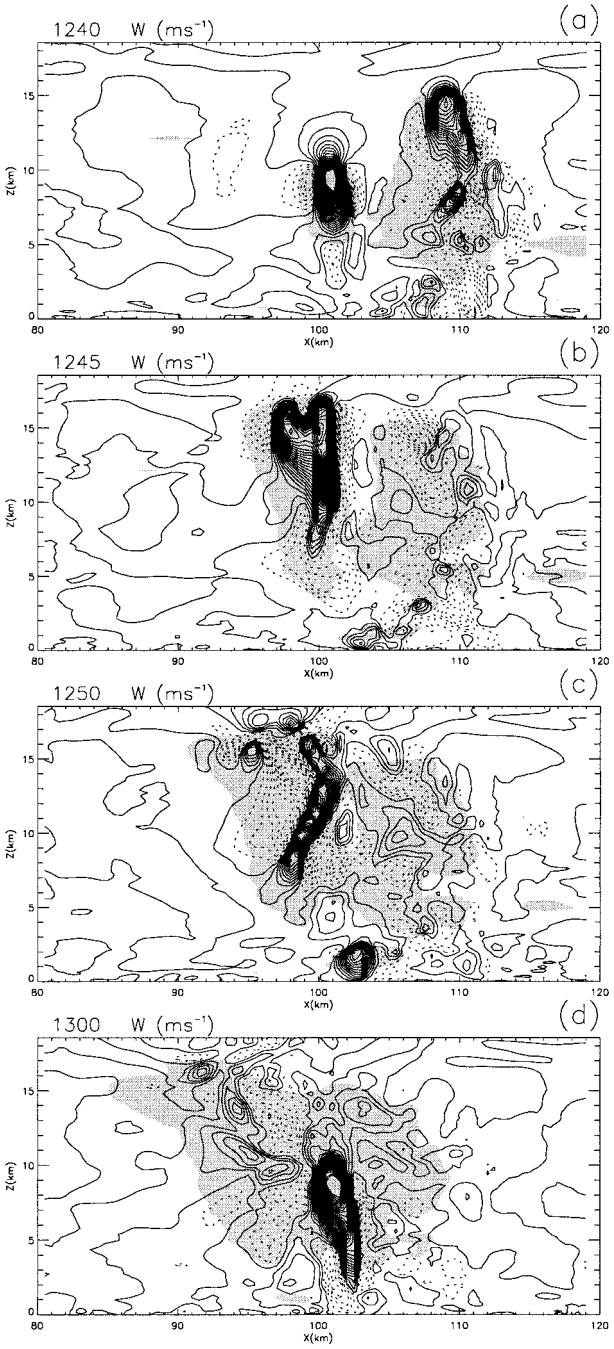

FIG. 15. Zonal cross section of vertical velocity, w, through y = 98 km of Domain 3 experiment E3 for (a) 1240 LST, (b) 1245 LST, (c) 1250 LST, and (d) 1300 LST. Contour intervals are 1 m s^{-1} with negative values dashed. Shaded is the 0.1 g kg^{-1} total cloud water contour.

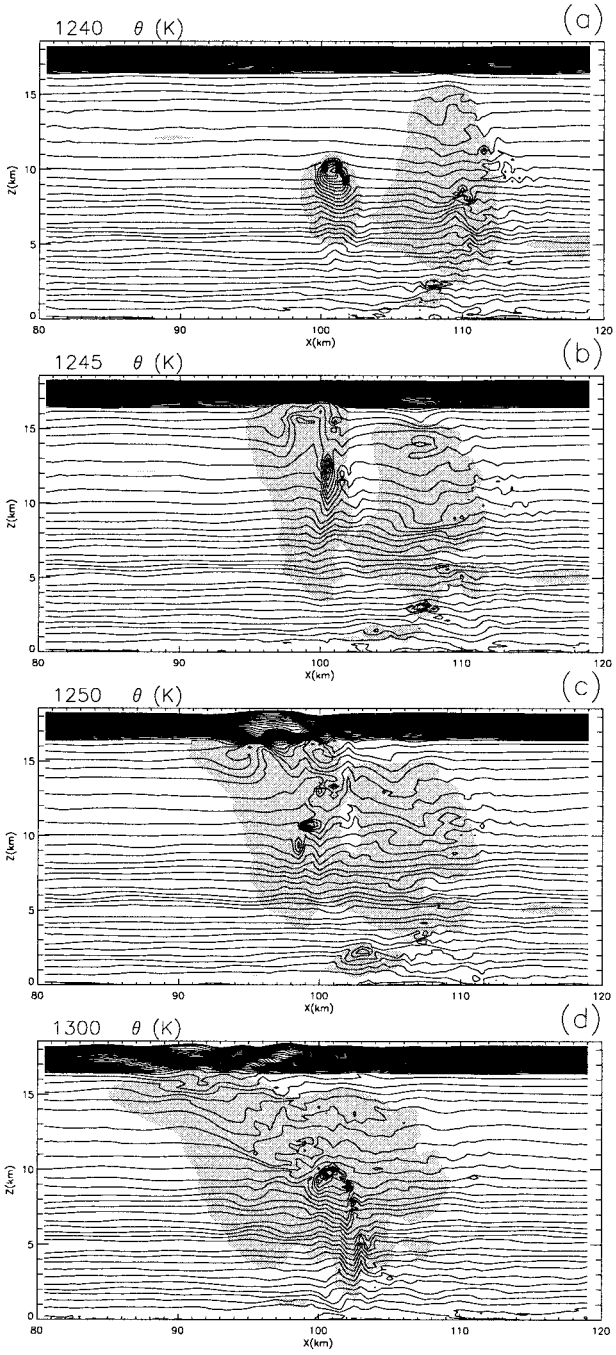

FIG. 16. Same as Fig. 15 except potential temperature, θ, with 2 K intervals.

At this time, the updraft has not mixed moisture above z = 12 km (Fig. 17a). However, the cell is rapidly developing, and there is a well-defined unstable bubble of potentially warm air at the top of the cloud (Fig. 16a). Therefore, further vertical mixing can be expected. Weak subsidence on the edges of the updraft indicates that stable air is being displaced laterally and downward around the vertically moving column of air. There is another deep cell to the east of the updraft at approximately x = 110 km. This cell is in its later stages of development and will not be considered in this analysis.

The updraft has overshot its LNB (Fig. 16b) at 1245 LST and has mixed air vertically to the tropopause. The updraft has penetrated the stratosphere, with cloudy air

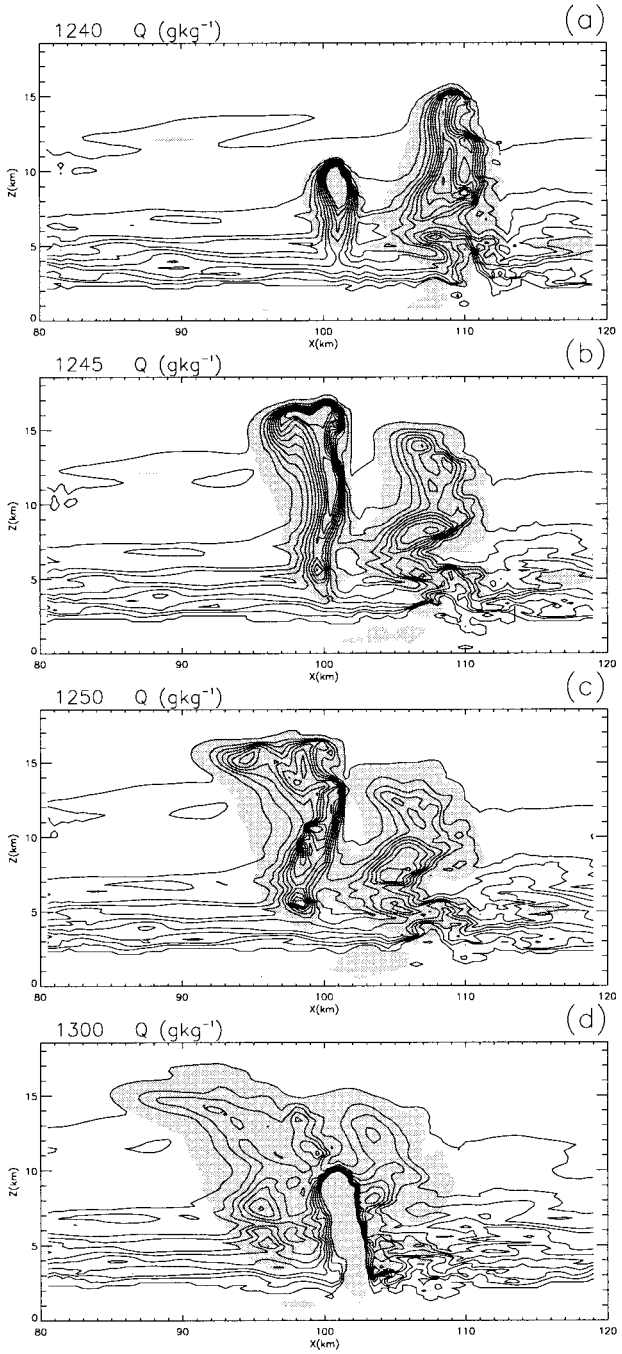

FIG. 17. Same as Fig. 15 except total moisture, Q, with 1 g kg^{-1} intervals.

evident in the lowest 1 km (Fig. 17b). To some extent, the tropopause acts like a lid, with stable air above the updraft being forced laterally and downward at 3–4 m s^{-1} by the upward moving mass of air. The displaced air was neutrally buoyant just below the tropopause, and after being displaced downward, has become positively buoyant. There exists an upper-tropospheric bulge in the cloudy air, indicating that cloudy air is forced outward while being decelerated. The maximum vertical velocity of the updraft is approximately 16 m s^{-1} (Fig. 15b), and Fig. 16b shows that the LNB of this air mass is approximately $z = 13$ km. Consequently, the net force on the upward-moving air above $z = 13$ km will be downward. In fact, a small portion of this updraft has already reversed its direction at $(x, z) = (99, 16)$ km.

At 1250 LST, the upward moving air of the main updraft has reversed due to over shooting its LNB, and a large downdraft exists (Fig. 15c) in the same region as the strong updraft at 1245 LST. This downdraft has a maximum value of approximately 11 m s^{-1} near the LNB of this air ($z = 13$ km). The downward displaced air of Fig. 15b has now reversed direction forming two weak updrafts (approximately 4 m s^{-1}), with the maximum value located at approximately $z = 15$ km. Located laterally adjacent to these two weak updrafts are two downdrafts of equivalent strength and spatial scale.

At 1300 LST, the dominant motions observed during the evolution of the convective cells are no longer present. The convective cells now exist as a large mass of cloudy air with a pronounced anvil. This large mass begins to merge with adjacent masses of cloudy air while being advected by the easterly background flow.

During the development of the updraft, two separate modes of oscillation are evident. First, there is the very strong oscillatory motion of the updraft about its LNB (approximately $z = 13$ km). This oscillation has approximate vertical orientation and has a vertical velocity amplitude of 10–15 m s^{-1}. Second, an oscillation occurs when stable air is displaced by the rising updraft at the tropopause. This displaced air oscillates about its original height (approximately $z = 15$ km) with a vertical velocity amplitude of 4 m s^{-1}. This secondary oscillation is of a much smaller spatial scale than the main updraft and appears to be generating external wave modes of equivalent amplitude, which propagate horizontally away from the updraft. Furthermore, the main oscillation has generated a vertical velocity component directly above it in the stratosphere. This region of vertical velocity appears to be the source of stratospheric gravity waves.

4. Analysis of the gravity wave source

The previous section focused on the structure and evolution of the convection and the stratospheric wave field and showed that the individual convective cells generated waves. The present section seeks to answer the question: how do the convective cells generate waves? Answering this question is central to understanding how convection modifies its environment, and is a prerequisite to developing accurate and physically realistic parameterizations of convectively generated waves.

a. The source tensor

The following analysis is motivated by Lighthill's (1952) theory for the aerodynamic generation of sound and by Ford's (1994) adaptation of Lighthill's theory to inertia-gravity waves in rotating shallow water. In linear gravity wave theory, all nonlinear terms in the governing equations are neglected. This assumption is generally valid for small-amplitude waves far from their source but may not be satisfied close to their source. Indeed, as we shall see, these nonlinear terms can be interpreted as the source of linear motions, including gravity waves. In the remainder of this section, these ideas are applied to convective clouds, which are of course highly nonlinear systems.

We begin by separating the velocity components into a vertically varying background flow plus a (finite amplitude) perturbation,

$$\mathbf{u} = (U(z) + u, V(z) + v, w),$$

and rewriting the governing equations with all nonlinear terms on the right-hand side. The resulting expressions are

$$D_t u + U_z w + \phi_x = F_u, \tag{1}$$

$$D_t v + V_z w + \phi_y = F_v, \tag{2}$$

$$D_t w + \phi_z - b = F_w, \quad \text{and} \tag{3}$$

$$D_t b + wN^2(z) = \dot{b} + F_b = F_B, \tag{4}$$

where

$$F_u = -\left[(u^2)_x + (uv)_y + \frac{1}{\overline{\rho}}(\overline{\rho}uw)_z\right],$$

$$F_v = -\left[(uv)_x + (v^2)_y + \frac{1}{\overline{\rho}}(\overline{\rho}vw)_z\right],$$

$$F_w = -\left[(uw)_x + (vw)_y + \frac{1}{\overline{\rho}}(\overline{\rho}w^2)_z\right],$$

$$F_b = -\left[(ub)_x + (vb)_y + \frac{1}{\overline{\rho}}(\overline{\rho}wb)_z + \frac{wb}{g}N^2(z)\right].$$

Here, u, v, and w are the perturbation velocity components in the three coordinate directions x, y, z, respectively. Note that these perturbations need not be small-amplitude. The variable b is the (dry) buoyancy defined as $b = g(\theta - \overline{\theta})/\overline{\theta}$, where θ is the potential temperature and $\overline{\theta}$ is its background profile. The variable N^2 is the Brunt–Väisälä frequency, defined as $(g/\overline{\theta})(d\overline{\theta}/dz)$, and $\phi = p/\overline{\rho}$, where p is the perturbation pressure and $\overline{\rho}$ is the background density. The term D_t is the linear operator representing the material derivative following the background flow and is defined as $D_t = \partial_t + U(z)\partial_x + V(z)\partial_y$. The term $\dot{b}$ is the total rate of change of (dry) buoyancy due to diabatic processes. The variables F_u, F_v, F_w, and F_b are written in flux form and physically represent the advection of the perturbation velocity and perturbation buoyancy by the perturbation wind fields. The term F_B is simply the sum of diabatic and nonlinear buoyancy terms. The turbulence closure terms in the governing equations have been neglected for simplicity, since in all cases presented later, these terms are at least one order of magnitude smaller than the nonlinear forcing terms. Similarly, coriolis effects are small and have been neglected in the analysis.

The individual flux terms, which comprise the nonlinear right-hand side of Eqs. (1)–(4) (e.g., $(u^2)_x$, $(uv)_y$, and $(1/\overline{\rho})(\overline{\rho}uw)_z$ combine to form F_u), are all equally important. This is probably due to the isotropic nature of deep convection. However, when the convection is most intense, the terms that involve vertical velocity are generally larger in magnitude than those that do not. The one exception is the term $(wb/g)N^2$ from F_b, which is approximately one order of magnitude smaller than the other terms that comprise F_b.

The continuity equation is

$$u_x + v_y = -\frac{1}{\overline{\rho}}(\overline{\rho}w)_z = -w_z + \frac{1}{H_s}w, \tag{5}$$

where $H_s(z) = -\overline{\rho}(\partial\overline{\rho}/\partial z)^{-1}$ is the density scale height. Combining Eqs. (1)–(5) gives a single, forced linear wave equation for w,

$$D_{tt}\left[\nabla^2 w - \left(\frac{w}{H_s}\right)_z\right] - D_t\left[\mathbf{U}_z \cdot \boldsymbol{\nabla}\left(\frac{w}{H_s}\right) + \mathbf{U}_{zz} \cdot \boldsymbol{\nabla} w\right] + N^2\nabla_h^2 w = \mathcal{F}. \tag{6}$$

Note that the homogeneous form of Eq. (6) (in the limit as $H_s \to \infty$) is identical to Eq. (8) from Bretherton (1966). The source function $\mathcal{F}$ can be concisely written by a simple change in notation. Let

$$(x, y, z) = (x_1, x_2, x_3),$$

$$(u, v, w) = (u_1, u_2, u_3),$$

$$(F_u, F_v, F_w) = (F_1, F_2, F_3),$$

$$(U, V, 0) = (U_1, U_2, U_3).$$

Then

$$\mathcal{F} = \frac{\partial^2 T_{ij}}{\partial x_i \partial x_j}, \tag{7}$$

where

$$T_{ij} = \delta_{ij}(D_t F_3 + F_B) - \delta_{i3}\left(D_t F_j + \frac{dU_j}{dz}F_i + \delta_{ij}F_B\right) + \frac{dU_j}{dz}F_i. \tag{8}$$

Alternatively, the components of the tensor can be written in matrix form as

$$T_{ij} = \begin{bmatrix} (D_t F_w + F_B + U_z F_u) & \frac{1}{2}(U_z F_v + V_z F_u) & -\frac{1}{2} D_t F_u \\ \frac{1}{2}(U_z F_v + V_z F_u) & (D_t F_w + F_B + V_z F_u) & -\frac{1}{2} D_t F_v \\ -\frac{1}{2} D_t F_u & -\frac{1}{2} D_t F_v & 0 \end{bmatrix}.$$

We will call T_{ij} the source tensor. It is second order, symmetric, and analogous to Lighthill's (1952) radiation tensor. Equations (6), (7), and (8) imply that the generation of linear motions, including gravity waves, can be associated with the source tensor. In general, the perturbation velocities and the buoyancy will be relatively large within a convective cloud, and consequently, the source tensor (and hence $\mathcal{F}$) will be important within the cloud. However, away from convective clouds, the source tensor will be small, provided the waves remain small amplitude, in which case the forcing is negligible. Thus, the forcing will appear as a compact source confined to the convective clouds. However, it is important to bear in mind that the source function will force a range of linear circulations as well as gravity waves.

The background flow is unidirectional in the model calculations. Consequently, the source function and source tensor reduce to (in Cartesian notation)

$$\mathcal{F} = \nabla_h^2(D_t F_w + F_B) + (U_z F_u)_{xx} + (U_z F_v)_{xy} - (D_t F_u)_{xz} - (D_t F_v)_{yz}, \tag{9}$$

and

$$T_{ij} = \begin{bmatrix} (D_t F_w + F_B + U_z F_u) & \frac{1}{2} U_z F_v & -\frac{1}{2} D_t F_u \\ \frac{1}{2} U_z F_v & (D_t F_w + F_B) & -\frac{1}{2} D_t F_v \\ -\frac{1}{2} D_t F_u & -\frac{1}{2} D_t F_v & 0 \end{bmatrix}, \tag{10}$$

respectively. Equation (10) is used to determine the relative importance of shear, convective updrafts and diabatic heating in generating gravity waves. Note that F_b and F_B are calculated directly from the perturbation fields, whereas $\dot{b}$ is defined as a residual.

b. Source analysis of the modeled convection

Experiment E3 is a high-resolution numerical integration that focuses on a particular deep convective cell. The convective cell chosen is the strongest wave radiator in the coarser-resolution experiments E1 and E2. A deep updraft is generated during the evolution of the cell and has the appearance of an unstable bubble of moist air (Figs. 15–17). The updraft overshoots its LNB and subsequently decelerates. This particular updraft is crucial in the generation of the gravity waves observed in the calculations. Using the source function, we now analyze this convective cell using the data from Domain 3 in experiment E3.

The source function, $\mathcal{F}$, can be used to identify the region in which the waves are generated. The value is calculated using second-order differences in time and space, and zonal cross sections through $y = 98$ km at 1240, 1245, 1250, and 1300 LST are shown in Figs. 18a–d. Note that $\mathcal{F}$ is relatively noisy because its calculation requires fourth derivatives of model data. At 1240 LST (Fig. 18a), the developing updraft has a distinct signature in $\mathcal{F}$, with a maximum at a height of approximately 10 km. Once the updraft has overshot the LNB (Fig. 18b) and the direction of the updraft has been reversed (Fig. 18c), $\mathcal{F}$ is nonzero between heights of approximately 8 and 16 km (the tropopause). However, $\mathcal{F}$ is consistently largest in the region of 10 km $< z <$ 13 km, which is the region of the LNB. Perhaps the most important point is that although the updraft reaches the tropopause and displaces the isentropes in the lower stratosphere (Figs. 16b and 16c), the magnitude of $\mathcal{F}$ is a maximum well below the tropopause. After the oscillating updraft has dissipated, the dominant feature of $\mathcal{F}$ is another developing updraft (Fig. 18d). Given that $\mathcal{F}$ has a consistent maximum at the LNB of the oscillating updraft, it is likely that this oscillation is the dominant wave producing mechanism. As shown later in section 5a, this idea is consistent with the structure of the waves generated.

The source function [Eq. (9)] can be used to determine the principal physical processes responsible for the gravity waves. The terms that comprise Eq. (9) are grouped according to the physical process they represent, that is, nonlinear advection, diabatic heating, and environmental wind shear. Whereupon, the source function is

$$\mathcal{F} = \underbrace{\nabla_h^2(D_t F_w + F_b) - (D_t F_u)_{xz} - (D_t F_v)_{yz}}_{\text{advection terms}} + \underbrace{\nabla_h^2(\dot{b})}_{\text{heating}} + \underbrace{(U_z F_u)_{xx} + (U_z F_v)_{xy}}_{\text{shear}}.$$

These three terms will be referred to as $\mathcal{F}_a$, $\mathcal{F}_h$, and $\mathcal{F}_s$,

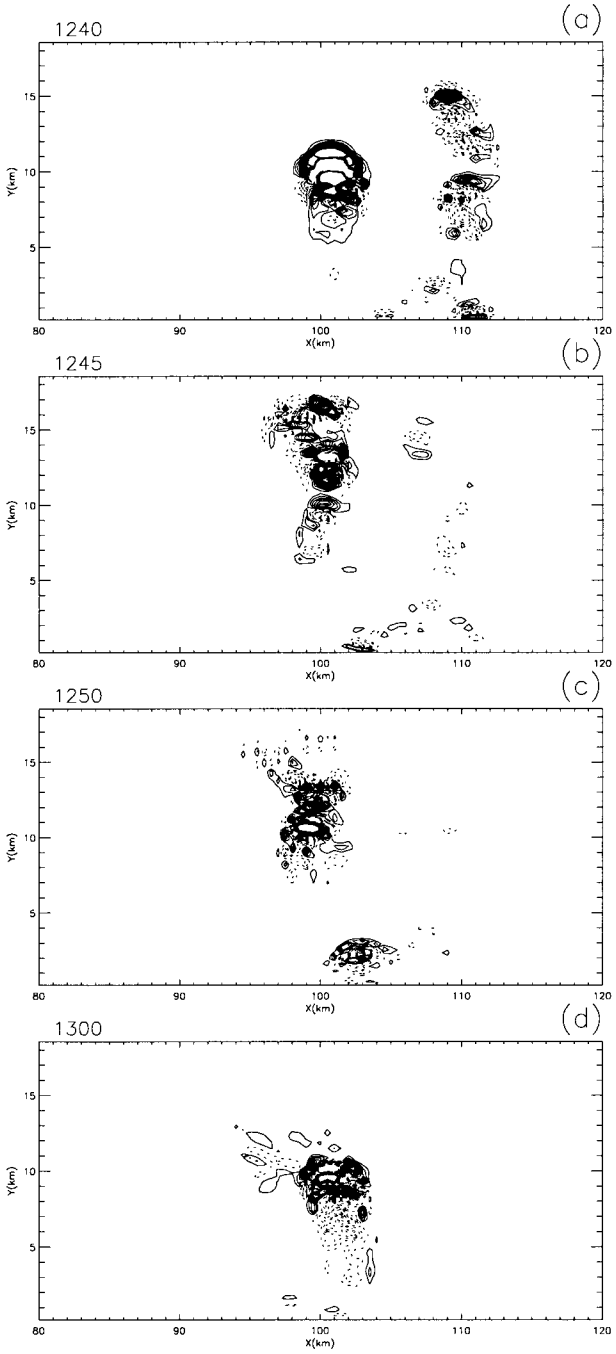

FIG. 18. Zonal cross section through $y = 98$ km of the source function for (a) 1240 LST, (b) 1245 LST, (c) 1250 LST, and (d) 1300 LST. Contour interval is 2×10^{-9} m^{-1} s^{-3}, with negative values dashed, and the zero contour omitted.

respectively. A zonal cross section of these terms through $y = 98$ km at 1245 LST is shown in Figs. 19a–c. Recall that at 1245 LST, the bulk of the updraft is still ascending even though it has overshot its LNB.

Consider the advective source term, $\mathcal{F}_a$, and the diabatic heating source term, $\mathcal{F}_h$ (Figs. 19a and 19b). At this time, the greater contribution to the total forcing (Fig. 18b) comes from the nonlinear advection, with the magnitude of $\mathcal{F}_h$ being approximately one tenth of $\mathcal{F}_a$. Furthermore, $\mathcal{F}_h$ is restricted to the middle troposphere, whereas the maximum of $\mathcal{F}_a$ is in the upper troposphere. This is an important result, as the majority of previous studies dealing with convectively generated waves have assumed a priori that diabatic heating is the dominant wave-producing mechanism (see, e.g., Bretherton 1988; Lin et al. 1998; Chun and Baik 1998). While the cloud ultimately owes its existence to diabatic heating, our results indicate that the production of buoyancy by diabatic heating may not be the main process generating the gravity waves in the numerical model.

One needs to be cautious when making deductions about the relative importance of the forcing terms without explicitly solving the forced wave equation [Eq. (6)]. Even though $\mathcal{F}_h$ is much smaller in amplitude than $\mathcal{F}_a$, it has a more coherent structure and may be an efficient wave generator. Nonetheless, the relative size of $\mathcal{F}_a$ strongly suggests that it cannot be neglected.

Consider now the contribution of the environmental wind shear terms, $\mathcal{F}_s$ (Fig. 19c), to the total source function. The contribution from shear is negligible in this case, with $\mathcal{F}_s$ being at least an order of magnitude smaller than all other terms. Although $\mathcal{F}_s$ is nonzero in Fig. 19c, the contour interval is one fifth of that used for Figs. 19a and 19b. While the convective updraft penetrates the shear layer, the contribution of this mechanism to the source function is negligible. Upon neglecting the effects of shear, the source tensor reduces to

$$T_{ij} = \begin{bmatrix} (D_t F_w + F_B) & 0 & -\frac{1}{2} D_t F_u \\ 0 & (D_t F_w + F_B) & -\frac{1}{2} D_t F_v \\ -\frac{1}{2} D_t F_u & -\frac{1}{2} D_t F_v & 0 \end{bmatrix}. \quad (11)$$

The minor role played by the background wind shear in generating the waves is consistent with the fields in Figs. 7–9. In particular, the horizontal wavelength is the same in both the zonal and meridional cross sections even though there is a shear layer only in the background zonal wind. Nevertheless, it will be shown in the next section that the wind shear plays an important role in changing the propagation characteristics of the waves.

5. Stratospheric wave response to tropospheric oscillations

Section 4 examined the *source* of the gravity waves in the model. In particular, analysis of the source tensor suggested that the waves are probably generated as air parcels in the cloud updraft oscillate about their LNB.

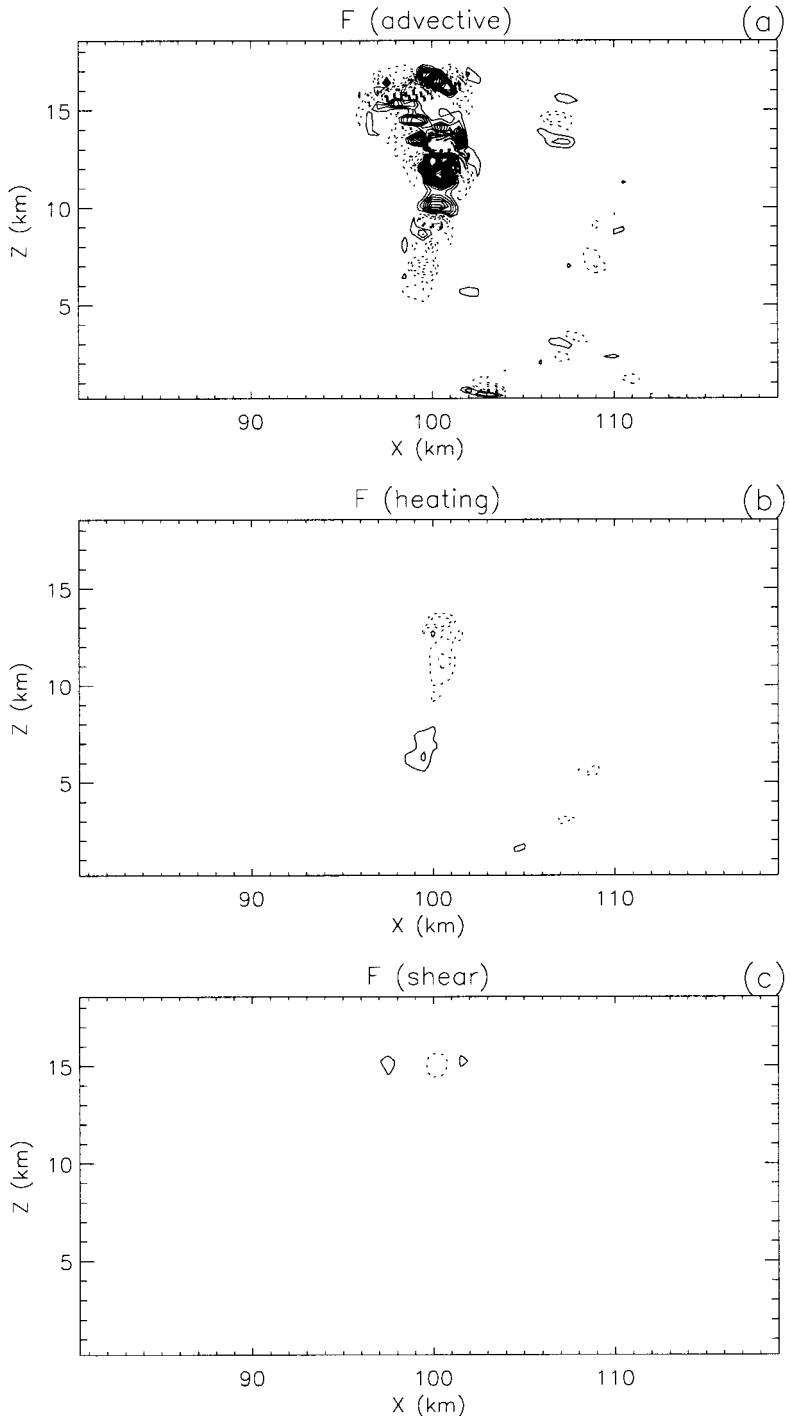

FIG. 19. Zonal cross section through $y = 98$ km at 1245 LST of (a) $\mathcal{F}_a$, (b) $\mathcal{F}_h$, and (c) $\mathcal{F}_s$. Contour interval is 2×10^{-9} m^{-1} s^{-3} in (a) and (b) and 0.4×10^{-9} m^{-1} s^{-3} in (c). Negative values are dashed, and the zero contour is omitted.

This is essentially the mechanism proposed by Pierce and Coroniti (1966). In this section, we examine the *response* of the atmosphere to this kind of forcing, and we show that the wave field is consistent with the hypothesized forcing.

a. Refraction effects

In the case examined, the gravity waves propagate radially away from the source and therefore have no preferred direction of propagation. This suggests that

vertical wind shear, which is only nonzero in the zonal direction, does not play a significant role in the generation of the gravity waves. The analysis of the source tensor has lent support to this. Also, as the wave fronts are circular, in the zonal plane through the wave source, the local meridional wavenumber l is zero, and therefore the analysis using the dispersion relation can be completed in two dimensions. Likewise, in the meridional plane through the source, the local zonal wavenumber k is zero. With these points in mind, the vertical wind shear is neglected in this section, and the two-dimensional dispersion relation is written as

$$N^2 \cos^2(\alpha) = k^2c^2 = (\omega \pm kU)^2, \qquad (12)$$

where α is the angle of phase lines from the vertical, k is the horizontal wavenumber, U is the background flow speed, c is the horizontal phase speed, and ω is the frequency of the wave in the chosen frame of reference. The parameters k and c are conserved along ray paths providing the background flow, U, is steady and horizontally homogeneous. Note that substituting l for k and $V = 0$ for U into Eq. (12) yields the dispersion relation for the meridional direction.

Let U_{LNB} be the background zonal flow at the LNB, and consider a frame of reference translating at this speed. In this frame of reference, the convective updraft is vertical and stationary, and it oscillates with a frequency equal to the background static stability in the troposphere, N_t. The tropospheric waves generated by the source will be evanescent, and consequently, their phase lines will be vertical ($\alpha = 0$). Hence, the real part of the vertical wavenumber m will be zero.

In the stratosphere, however, the dispersion relation is

$$N_s^2 \cos^2(\alpha) = k^2c^2 = (\omega \pm k\tilde{U})^2,$$

where $\omega = N_t$, $\tilde{U} = U - U_{\mathrm{LNB}}$ is the flow in the stratosphere in the frame of reference moving with the LNB, and N_s is the stratospheric Brunt–Väisälä frequency. This implies that

$$\cos(\alpha) = \frac{N_t \pm \tilde{U}k}{N_s}. \qquad (13)$$

The minus sign represents waves propagating to east, and the plus sign represents waves propagating to the west. In the case of zero LNB relative flow ($\tilde{U} = 0$), Eq. (13) reduces to

$$\cos(\alpha) = \frac{N_t}{N_s}. \qquad (14)$$

Using a two-dimensional numerical model, Fovell et al. (1992) examined the generation of gravity waves by a squall line. They concluded that the individual cells that comprise the squall line were responsible for generating the waves, and they discussed the dynamical process in terms of a horizontally propagating mechanical oscillator. Fovell et al. (1992) related the frequency of the oscillator to the lifetime of the individual convective cells. In all other respects, their analysis is very similar to that described above, the principle differences being that ours is performed in the frame of reference moving with the wind at the LNB, and that the frequency of the oscillation in this frame of reference is set by the tropospheric Brunt–Väisälä frequency. Performing the analysis in the frame of reference of the LNB exposes most clearly the simple process responsible for the pattern of gravity waves produced in the stratosphere by the model. The increased stratification above the tropopause refracts the waves, tilting phase lines away from the source, while the flow relative to the LNB refracts the phase lines in the direction of the background flow.

Equations (13) and (14) can be used to predict the slope in the stratosphere of the lines of constant phase. In the model calculations, the LNB lies between 10 and 14 km, depending on the level from which an air parcel is lifted. This is below the shear layer, and the velocity at the LNB is equal to $(-5, 0)$ m s^{-1}. Above the shear layer the velocity is equal to $(-10, 0)$ m s^{-1}. The upper-tropospheric Brunt–Väisälä frequency, N_t, is equal to 0.007 s^{-1}, and the stratospheric Brunt–Väisälä frequency, N_s, is equal to 0.028 s^{-1}. Note that N_t and N_s correspond to periods of 15.0 min and 3.7 min, respectively. In the absence of rotation, the meridional direction can be treated independently of the zonal direction. As there is no background flow in the meridional direction, the slope of the phase lines in a meridional cross section is given by Eq. (14). In the zonal direction, Eq. (13) describes the slope of the phase lines in the stratosphere. The two branches represent upstream propagating waves (negative branch) and downstream propagating waves (positive branch). Figure 20 shows α as a function of wavelength. In the absence of LNB relative flow, the gravity wave pattern is symmetric about the source, and the angle at which the phase lines slope is independent of wavelength. In the case of nonzero LNB relative flow, the phase lines are rotated in the direction of the flow by an angle that is dependent on the horizontal wavelength of the waves.

Dark lines parallel to the lines of constant phase in the stratosphere are marked in Figs. 9a and 9b. In the case with nonzero LNB relative flow (Fig. 9a), the angle from the vertical of the upstream oriented phase lines is 71° ± 1°, and the angle of downstream oriented phase lines is 81° ± 1°. In the case of zero LNB relative flow (Fig. 9b), the waves are symmetric about the source, and the phase lines make an angle of 76° ± 1° to the vertical. These angles compare very well to the solutions of Eqs. (13) and (14). The angle of the phase lines for zero LNB relative flow is within the uncertainty of measurement. For the case with nonzero LNB relative flow, the gravity waves generated by the model are rotated by 5° in the direction of the relative flow. According to Fig. 20, a rotation of 5° corresponds to a horizontal wavelength of approximately 15 km. Given that the spectral peak in the horizontal wavelength is at ap-

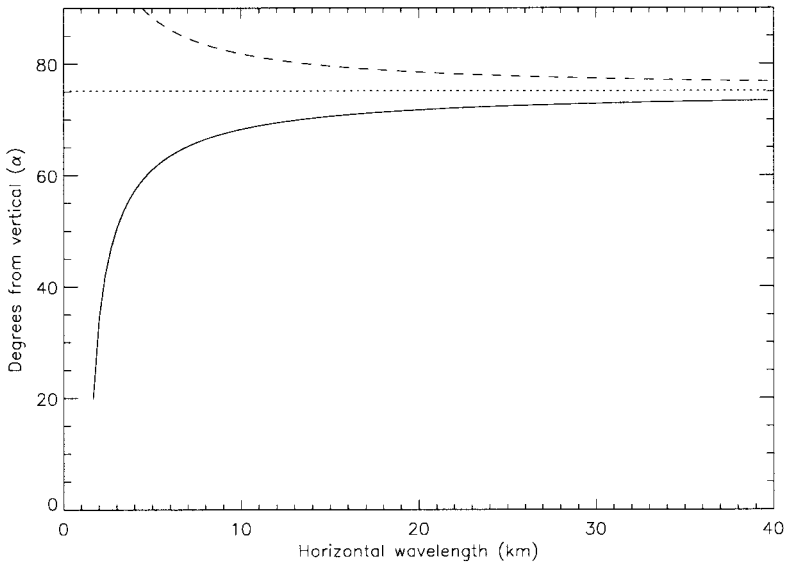

FIG. 20. Angle of the lines of constant phase in the stratosphere from the vertical (α) as a function of horizontal wavelength. The dotted line represents no stratospheric flow with respect to the tropospheric source. Shown also are the upstream (solid) and downstream (dashed) propagating solutions for a stratospheric flow of -5 m s^{-1} relative to the tropospheric source.

proximately 17 km, the theoretically predicted properties of the waves agree well with those of the modeled waves. Such close agreement lends strong support to the hypothesis that the gravity wave source is a vertically oriented oscillator moving at the velocity of the wind at the LNB. Although a spectrum of waves will be generated, the above argument describes the dominant waves.

The phase speed of the gravity waves as seen in the frame of reference of the LNB is $c = \pm N_t/k$ in the zonal direction or $c = \pm N_t/l$ in the meridional direction. Using $N_t = 0.007$ s^{-1} and $k, l = 2\pi/17$ km^{-1}, the phase speed relative to the LNB is 18.9 m s^{-1}. The ground-based phase speed is equal to $c = U_{\text{LNB}} \pm N_t/k$, where the plus sign is for waves propagating in the positive x direction (east), and the minus sign is for waves propagating in the negative x direction (west). It follows that the upstream propagating waves have a ground-based phase speed of 13.9 m s^{-1}, and the downstream propagating waves have a ground-based phase speed of 23.9 m s^{-1}. Moreover, the ground-based frequencies of the upstream and downstream propagating waves are 5.14×10^{-3} s^{-1} and 8.83×10^{-3} s^{-1}, respectively. These frequencies correspond to periods of 20.3 minutes and 11.9 minutes respectively. Of course, in the meridional direction, the ground-based and LNB reference frames are identical, and therefore, the phase speed and frequency remain unchanged.

In the cloud cluster considered here, there are a number of convective clouds with different cloud-top heights. The depth of each cloud, and hence the height of its LNB, depends on a number of factors, including entrainment, intensity, and the initial local forcing. The depth of the convection is essentially irrelevant here because the Brunt–Väisälä frequency and the background wind velocity are constant in the troposphere. Therefore, N_t and U_{LNB} are the same for each cloud, and thus, each cloud contributes to the same part of the ground-based frequency spectrum. However, in an atmosphere with tropospheric wind shear, clouds with different depths would possess different values of U_{LNB}, and each cloud would generate waves with different ground-based frequencies. This would broaden the ground-based frequency spectrum. The effect of tropospheric shear on the gravity wave generation will be considered in a future study.

The momentum flux comprises contributions from upstream propagating waves (positive) and downstream propagating waves (negative). The momentum flux for each branch varies like $\overline{\rho} A_u A_w$, where A_u and A_w are the amplitudes of the perturbation horizontal and vertical velocity, respectively. The size of A_u and A_w changes with the angle of the phase lines. (This is discussed in more detail below.) Therefore, even though shear does not appear to be generating the dominant waves, it changes the slope of upstream and downstream propagating waves. Consequently, the shear produces a zonal asymmetry in the waves and, hence, a nonzero (zonal) momentum flux. However, the downstream propagating waves still make a contribution to the (zonal) momentum flux, although it is smaller than the contribution of the upstream propagating waves. Figure 13a shows that the downstream propagating waves reduce the magnitude of the momentum flux in the lower stratosphere.

Often the wave signatures in vertical velocity or potential temperature are used to analyze gravity waves.

Consider Figs. 9a and 9d. In these figures, the upstream propagating waves appear to dominate the wave field. However, upstream propagating waves are not preferentially excited. As shown earlier, a shear layer refracts the gravity waves. This refraction affects the signature of the waves in vertical velocity, potential temperature, and perturbation horizontal velocity. Using continuity, it can be shown that (in two dimensions) the amplitudes of the horizontal velocity perturbations, A_u, and the vertical velocity, A_w, are related by the expression

$$A_u = -\frac{m}{k}A_w. \tag{15}$$

It follows that when the phase lines of gravity waves tilt to the horizontal (vertical), A_u increases (decreases) with respect to A_w. However, A_w is not conserved following packet trajectories.[3] The wave action, $\tilde{A}$, [first defined by Bretherton (1966)] is conserved along packet trajectories and (in two dimensions) is defined as

$$\tilde{A} = \frac{E_0}{(\omega - Uk)},$$

where E_0 is the wave energy per unit volume defined by

$$E_0 = \frac{1}{2}\overline{\rho}\left(u^2 + w^2 + \frac{b^2}{N^2}\right).$$

It can be shown that the amplitude of w varies as

$$A_w^2 \sim (\omega - Uk)^3\frac{\tilde{A}}{\overline{\rho}N^2},$$

where $\tilde{A}$ depends only on ω and k [see Bretherton (1966) for details]. It is also possible to show that if the background flow is steady and horizontally uniform, then the wave frequency (ω) and horizontal wavenumber (k) are conserved following packet trajectories. Note also that

$$(\omega - Uk)^2 = \frac{N^2k^2}{k^2 + m^2}.$$

Thus in the stratosphere (where k, N, and ω are all constant), the amplitude of the vertical velocity signature will decrease as the magnitude of the vertical wavenumber increases (i.e., as the phase lines are refracted to the horizontal). Therefore, even though the wave action remains constant, a refraction of the phase lines to the horizontal (vertical) will reduce (increase) the vertical velocity signature. Therefore, without taking into account these changes in wave signature due to wave refraction, analyses may be biased toward upstream propagating waves.

[3] A packet trajectory is the trajectory defined by the group velocity of a wave packet.

b. Horizontal wavelength selection

In the previous section, it was shown that the tropospheric gravity waves satisfy the assumptions that $\omega = N_t$ in the frame of reference of the LNB and that $m = 0$. However, under these conditions, the dispersion relation is automatically satisfied for all horizontal wavelengths. This prompts the following question: what determines the horizontal wavelength? The analysis assumes that the frequency, vertical wavenumber, and horizontal wavenumber are all real, which is true for a freely oscillating wave mode with infinite spatial extent. However, the convective updraft, which generates the waves, is damped and has limited spatial extent. In this section, the convective updraft is described as a spatially evanescent damped oscillation, and a simple analysis of the dispersion relation is used to explain how the horizontal wavelength is selected.

Rearranging the dispersion relation [Eq. (12)] for the troposphere, the horizontal wavenumber can be written as a function of the frequency and vertical wavenumber

$$k^2 = m^2 \Bigg/ \left(\frac{N_t^2}{\omega^2} - 1\right), \tag{16}$$

where k, m, and ω may be complex. As before, we assume that the real parts of ω and m are N_t and 0, respectively. Therefore, k, m, and ω have the form

$$k = k_R + ik_I,$$

$$m = 0 + im_I, \quad \text{and}$$

$$\omega = N_t - i\omega_I.$$

Hence, the vertical velocity can be written as

$$w = A(k)\exp(-k_Ix - m_Iz - \omega_It)\exp[i(k_Rx - N_tt)].$$

The horizontal, vertical, and temporal e-folding scales over which the convective updraft decays are $1/k_I$, $1/m_I$, and $1/\omega_I$, respectively. Physically, $1/k_I$ is determined by the width of the convective updraft, $1/m_I$ is related to the distance air parcels overshoot their LNB, while $1/\omega_I$ is presumably related to the turbulent mixing. Of course, the convective system will produce mesoscale variations in the background flow, which will affect the trapping and propagation characteristics of the gravity waves. Such effects are difficult to quantify.

From Fig. 15b, the e-folding decay scale in the vertical is estimated to be approximately 4 km, whereupon k can be calculated as a function of ω_I using Eq. (16). The horizontal wavelength, $2\pi/k_R$, and the horizontal e-folding scale, $1/k_I$, are plotted as a function of ω_I in Fig. 21a. Similarly, the horizontal wavelength can be considered as a function of the e-folding horizontal scale; this is plotted in Fig. 21b. If the convective updraft can be described as a spatially evanescent damped oscillator, then Eq. (16) predicts a single (real) horizontal wavelength, explaining why the stratospheric wave field is almost monochromatic. This mode ''leaks'' from the

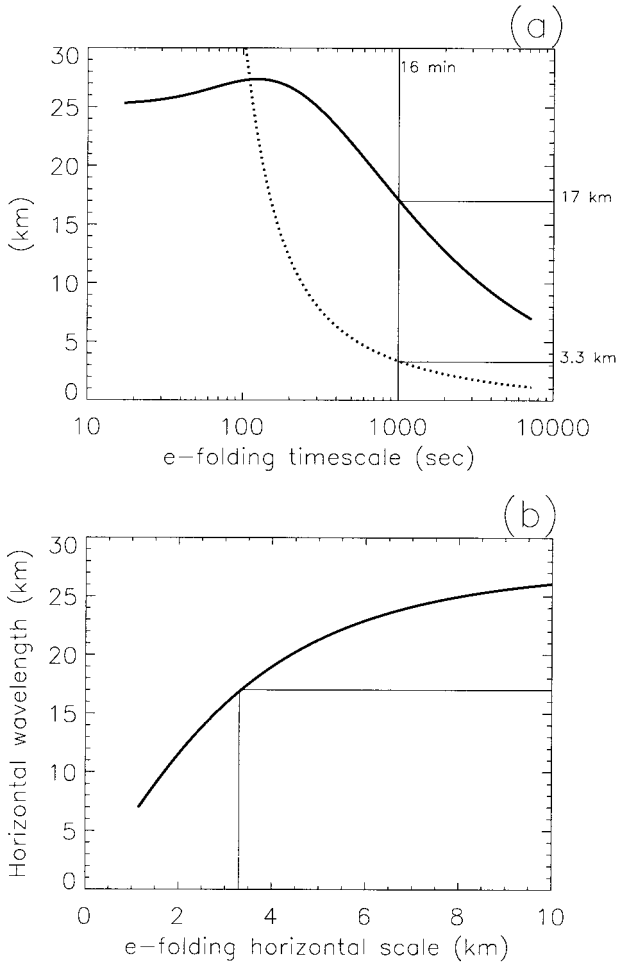

FIG. 21. (a) The horizontal wavelength $2\pi/k_R$ (solid) and *e*-folding horizontal scale $1/k_I$ (dashed) as a function of the *e*-folding timescale $1/\omega_I$. (b) The horizontal wavelength $2\pi/k_R$ as a function of the *e*-folding horizontal scale $1/k_I$. Both plots show the intersection of the curves with the dominant horizontal wavelength from the model calculations (17 km).

troposphere into the stratosphere where it propagates vertically.

In the model calculations, the dominant horizontal wavelength in the stratosphere is approximately 17 km. Assuming that the *e*-folding decay scale in the vertical is 4 km, Fig. 21 shows that the updraft must have horizontal and temporal *e*-folding decay scales of approximately 3.3 km and 16 min, respectively. These values are consistent with those found in the model solution.

6. Summary and conclusions

Convective clouds are known to generate gravity waves. These waves are thought to be important in shaping the mean flow in the middle atmosphere and in modifying the environment of the cloud. The central aim of the present paper has been to clarify how clouds generate such waves.

In this study, a high-resolution numerical model has been used to simulate the evolution and structure of a convective cloud cluster over the Tiwi Islands, and the gravity waves generated by the cluster have been examined in detail. Three numerical runs were presented. The principal differences between each run was the horizontal resolution, which was 2, 1, or 0.5 km. Each run was initialized with an idealization of a particular radiosonde sounding taken over the Tiwi Islands during MCTEX. Island thunderstorms, such as these, are triggered by sea-breeze convergence, and because of their regularity and simple forcing mechanism, they are ideal for studying convectively generated waves.

In the model runs, a cluster of deep convective clouds developed over the western half of the Tiwi Islands. These clouds merged to form a north–south line approximately 40 km long moving westward with the background flow. A number of large convective cells developed in each model run, although in the calculation with coarsest resolution, smaller-scale convective structures were not well resolved. The position of the convective cells was also sensitive to spatial resolution.

As the convection evolved, gravity waves formed part of the numerical solution in both the troposphere and stratosphere. However, the largest amplitude gravity waves developed when the convection deepened and reached the upper troposphere. The gravity wave source was highly localized and highly variable in both space and time. The position of the source was directly related to the position of developing convective cells. The amplitude of the gravity waves in the stratosphere was small. For example, the vertical velocity fluctuations were about 0.3 m s^{-1}. The waves were remarkably monochromatic and had a horizontal wavelength of about 17 km. This wavelength was shown to be set by the width of the convective updraft, the degree of turbulent mixing, and the distance by which rising air parcels overshot their LNB.

The stratospheric momentum flux associated with the vertically propagating waves was greatest shortly after the convective clouds reached the upper troposphere. The waves and their source were highly transient, producing pulses of momentum flux in the stratosphere. Consequently, the momentum flux was sensitive to the area over which it was averaged.

The *source tensor* and *source function* were introduced for the anelastic equations of motion with arbitrary background shear but no background rotation. The source function was used to clarify the source of the gravity waves generated by the modeled convection. Although there was some uncertainty in the conclusions, the results were consistent with the hypothesis that the oscillation of the convective updrafts about their LNB was the dominant mechanism forcing the gravity waves.

Although the production of buoyancy by latent heating is central to the development of convective clouds, it has been shown that in our model, it is not the dominant term forcing the linear wave equation. Rather, non-

linear advection was the dominant term in the source function. This suggests that diabatic heating may not be the primary mechanism forcing the gravity waves. In contrast, most previous work on convectively generated gravity waves has assumed, a priori, that the transient diabatic heating generates the waves (e.g., Bretherton 1988; Lin et al. 1998; Chun and Baik 1998).

Shear was also found to be unimportant in generating gravity waves in our model runs. In particular, the gravity waves showed no preferential direction of propagation, with the dominant horizontal wavelength being the same in all directions from the source. We note that if the waves were generated by the so-called *obstacle effect* (e.g., Clark et al. 1986) or a *moving mountain* effect (e.g., Pfister et al. 1993), upstream propagating gravity waves would have been dominant, and the shear terms in the source tensor would have been important contributors.

It has been shown that treating the wave source as a vertically oriented oscillator moving with the LNB is consistent with the slope of the phase lines in the stratosphere. In the frame of reference moving with wind at the LNB, the frequency of the gravity waves was equal to the Brunt–Väisälä frequency in the troposphere. It was also shown that although shear does not generate the waves, it refracts the phase lines in the direction of the flow relative to the LNB. This refraction creates an asymmetry between the upstream and downstream propagating waves, thereby producing a nonzero momentum flux. The refraction also reduces the wave signature in the vertical velocity of the downstream propagating waves, thereby giving the appearance that upstream waves dominate the stratospheric wave field. Despite this, the downstream propagating waves make an important contribution to the momentum flux in the lower stratosphere.

The results of this paper emphasize that convective clouds generate gravity waves when the convective updraft rapidly decelerates. With this in mind, one might ask the following: how does the role of shear change if a shear layer is centered on the LNB? Collocating the tropopause and the LNB might represent one such case of maximizing shear and buoyancy effects. The analysis presented can also be used to better understand how squall lines, boundary layer thermals, or jet streaks excite gravity waves. These are topics of current and planned research.

Acknowledgments. We would like to thank Andrew Crook for his help in setting up the Tiwi Island simulation. We are grateful to Joan Alexander, Dale Durran, Roger Smith, and two anonymous reviewers whose comments helped improve the manuscript.

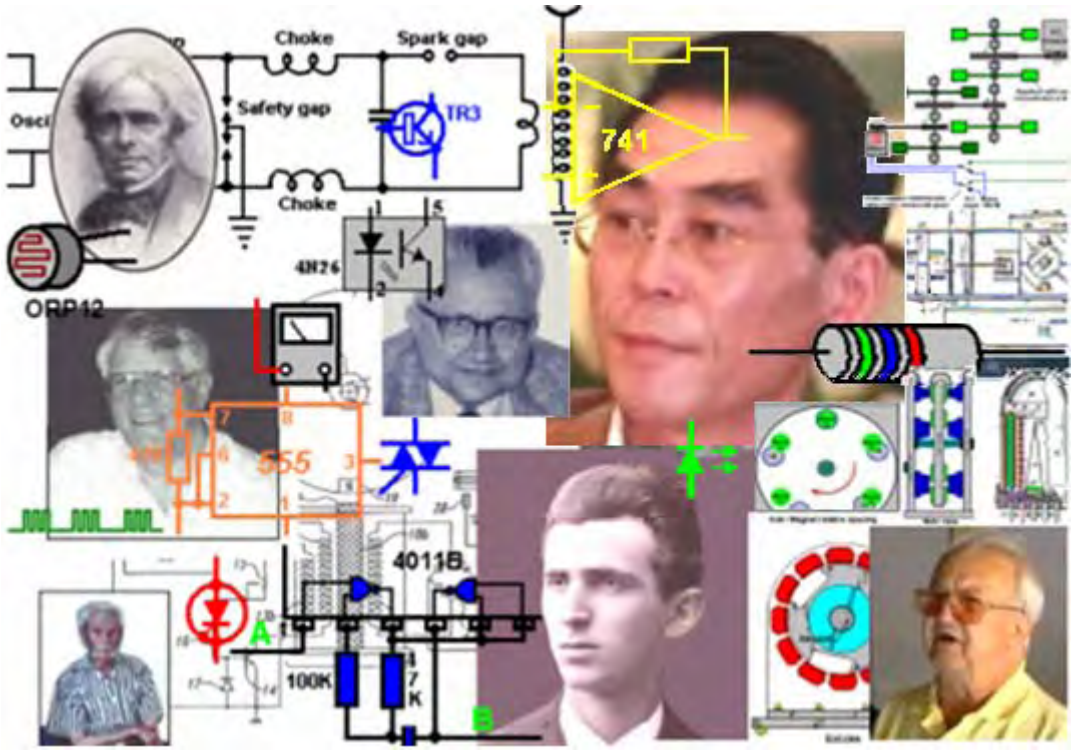
Practical Guide to 'Free-Energy' Devices



Author: Patrick J. Kelly

Version: 26.6 Release date: 5 Nov 2014

This eBook has more than 400 bookmarks to speed up your access to any section of interest. The contents of this eBook is only about 5% of the information on the http:www.free-energy-info.tuks.nl web site

Preface

Here is a small amount of background information in order that you can understand the nature of this "***Practical Guide to Free-Energy Devices***".

I am just an ordinary person who became interested in "free-energy" as a result of a television programme entitled 'It Runs on Water' shown in the 1980s by a UK television company called 'Channel 4'. At the present time that programme can be seen at https://www.youtube.com/watch?v=xHISTsiR9qc. From my point of view, the content of this documentary seemed to be rather unsatisfactory as it suggested quite a number of very interesting things but gave no real hard and fast specifics for the viewer to follow up on to investigate the subject further. However, it had the enormous benefit of making me aware that there was such a thing as "free-energy".

My attempts to find out more were not very successful. I bought paper copies of several of Stan Meyer's HHO gas patents from the Patent Office in 1986 but while they were interesting, they did not provide much in the way of additional information. Searching on the internet at that time did not produce much more in the way of practical information. Things have changed dramatically since then and there has been an enormous increase in available information. But, even today, it is relatively difficult to find much in the way of direct, useful and practical information on free-energy systems and techniques. Much of the information consists of chatty, lightweight articles describing people, events and inventions in vague, broad outline terms which are almost completely lacking in specifics.

These articles have the style of saying "There is a new invention called a 'bus' which is used to carry passengers from place to place. We saw one the other day, it was painted green and blue and looked most attractive. It is driven by Joe Bloggs who wears an engaging smile and a hand-knitted sweater. Joe says that even his children could drive a bus as it is so easy to do. Joe expects to retire in six months time as he is going to take up gold prospecting." While I'm sure that an article like that is interesting, the sort of description which I would want would be: "There is a new invention called a 'bus' which is used to carry passengers from place to place. We saw one the other day, and were very impressed as it has seats for some forty-five people. It has bodywork made of pressed aluminium, a wheel at each corner of its considerable 40' x 10' structure, a five litre diesel engine made by the Bosworth Engineering Company of Newtown, and has power-assisted steering, hydraulic brakes and ……".

There are also many articles, scientific papers and books, some of which, quite frankly, I am not able to understand as the authors think mathematically and express themselves in equations (where they frequently do not define the terms which they use in their equations, making them effectively meaningless). I do not think in mathematical equations, so I do not share in this much higher level of thinking and analysis, though I do have some of these papers on my web site for the benefit of visitors who do have the ability to understand them easily.

After a long period of searching and investigating I was beginning to gather enough information to be fairly confident of what was being done, what had already been achieved, and some of the possible background reasons for the effects which were being observed. Early in 2005 I decided that as I had encountered so much difficulty and had to put in so much effort to find out the basics of "free-energy" that it could be helpful to others if I shared what I had found out. So I wrote the first edition of this presentation and created a simple web site to make it available to others. Of course, this body of information is not static – on the contrary, it is very fast-moving. Consequently, this information digest is updated and refined typically many times each year. The present form of presentation is the third style of layout which has been used as the volume of material has increased.

It should be stressed that this information is what I have discovered as part of my interest in the subject and is mainly a reporting on what is being said by other people. I have not built and proved every device described – to do that would take many lifetimes, so please understand that this is just an attempt to aid your own investigation. While it can be proved that some device works as described, through independent replication and verification, the reverse is not true. If someone were to build a device and fail to get it to work as described, then the most that can honestly be said is that an unsuccessful attempt was made to replicate it. It does not, of course, show that the original device did not operate exactly as described, just that the (possibly inept) attempt at replication, was not successful. In some instances, you will see that I have expressed the opinion that the device is not viable, or, as in the case of the 'Nitro Cell' that I do think that it does work, but as many people have tried to build it and failed

to get the results described, that it can't be recommended as an investigation project. However, as soon as I said that, a local man announced that he had made two Nitro Cells and attached them to his two Ford Transit trucks and that resulted in saving him an estimated £500 over the course of two years.

I do not suggest that this set of information covers every possible device, nor that my description is by any means the complete and definitive statement of everything to be known on the subject. The old saying applies here: "If you think you know all the answers, then you just haven't heard all the questions!" So, this material is just an introduction to the subject and not an encyclopaedia of every known device.

I should like to thank the very large number of people who have most kindly given me their permission to reproduce details of some of their work, providing photographs, checking what I have written, suggesting additions, etc. Also those kind people who have given me permission to reproduce their own works directly on my web sites or in my documents. There seems to be a common thread of concern among many people that shows as a desire to share this information freely rather than to try to make money from selling it, and I thank these people for their generosity.

Many people hold "conspiracy theory" views and believe that there is a concerted effort to suppress this information, and more especially, to prevent free-energy devices reaching the market. Personally, I think that while that is certainly true, much of this opposition may be just the normal reaction of vested commercial interests. If you were making a profit of literally millions per hour, would you welcome the introduction of a system which would eventually cut your income to zero? If not, then how much would you be willing to pay someone to make sure that the present system is never changed – a million? A billion? While this opposition is definitely there and people who stand to lose money and/or power through change will continue to oppose this knowledge, and to a much greater extent, the introduction of any commercial free-energy device, almost the entire focus of the information is on devices – what they do, how they are made and how they may operate when they draw additional energy from the local environment.

Let me stress again, that this set of information is not by any means the final word on the subject, but just an introduction to the subject by a single person who makes no claims to knowing all the answers. Enjoy your research – I hope you are successful in every respect.

Patrick Kelly

April 2008

A Practical Guide to 'Free-Energy' Devices

Contents

Index 1

Introduction . . . . . I -1

Chapter 1: Magnet Power
The ShenHe Wang permanent magnet motor-generator . . . . . 1 - 1
The Ecklin-Brown generator . . . . . 1 - 4
The Howard Johnson magnet motor . . . . . 1 - 6
The 'Carousel' permanent magnet motor . . . . . 1 - 7
The Robert Tracy permanent magnet motor . . . . . 1 - 9
The Ben Teal electromagnet motor . . . . . 1 - 9
The Jines permanent magnet motor . . . . . 1 - 11
The Stephen Kundel permanent magnet motor . . . . . 1 - 12
Charles Flynn's permanent magnet motor . . . . . 1 - 15
Steorn's Magnet Motor . . . . . 1 - 24
George Soukup's Magnet Motor . . . . . 1 - 26
Dietmar Hohl's V-Magnet Motor and Jes Ascanius' implementation of it . . . . . 1 - 29
Constructing a simple permanent magnet motor . . . . . 1 - 30
Muammer Yildiz's Magnet Motor . . . . . 1 - 35
Donald Kelly's Magnet Motor . . . . . 1 - 54
Mike Brady's Perendev Magnet Motor . . . . . 1 - 55
Magnetic shielding from Pasi Mäkilä . . . . . 1 - 55
The Permanent Magnet Motor of Victor Diduck . . . . . 1 - 56

Chapter 2: Moving Pulsed Systems
The Adams Motor/Generator . . . . . 2 - 1
Lidmotor's Low-voltage Rotor . . . . . 2 - 12
The Phemax Self-Powered motor/generator . . . . . 2 - 13
The Kromrey No-Drag Electrical Generator . . . . . 2 - 16
The Teruo Kawai Motor . . . . . 2 - 25
James Hardy's Water-jet Generator . . . . . 2 - 27
Georges Mourier's COP=10,000 Motor/Generator Patent . . . . . 2 - 29
The RotoVerter . . . . . 2 - 39
Coil-shorting techniques . . . . . 2 - 44
Raoul Hatem's Energy System . . . . . 2 - 48
Lawrence Tseung's COP = 3.3 Pulsed Rotor . . . . . 2 - 50
Art Porter's Electromagnetic Motor System . . . . . 2 - 56
Raising DC Motor Efficiency . . . . . 2 - 57
Direct Coupled Motors . . . . . 2 - 67

Chapter 3: Motionless Pulsed Systems
Charles Flynn's devices . . . . . 3 - 1
Lawrence Tseung's magnetic frame . . . . . 3 - 1
Thane Heins' dual toroidal magnetic frame . . . . . 3 - 3
The High-power Motionless Generator of Clemente Figuera . . . . . 3 - 6
The Zero back-EMF Coils of Alexkor . . . . . 3 - 26
The Self-Powered Generators of Barbosa and Leal . . . . . 3 - 27
The Ultra-simple Device of Lorrie Matchett . . . . . 3 - 60
The Motionless Generator of Theodore Annis and Patrick Eberly . . . . . 3 - 66
The Richard Willis COP>1 Motionless Electrical Generator . . . . . 3 -75
The 'silverhealtheu' bar generator . . . . . 3 - 77
The 1982 patent of Heinrich Kunel . . . . . 3 - 77
Valeri Ivanov's Motionless Generator . . . . . 3 - 84
The Motionless Generators of Kelichiro Asaoka . . . . . 3 - 85
Stephan W. Leben's device . . . . . 3 - 99
Floyd Sweet's VTA . . . . . 3 - 101

The magnetic generator of Ashley Gray . . . 3 - 102
Pavel Imris' Optical Generator . . . 3 - 106
The Michel Meyer and Yves Mace Isotopic Generator . . . 3 - 109
The Colman / Seddon-Gilliespie Generator . . . 3 - 110
Don Smith's Magnetic Resonance System . . . 3 - 112
Belkired Mohamed's Don Smith analysis . . . 3 - 112
Ming Cao's Developments . . . 3 - 140
Russian Developments . . . 3 - 145
Chinese Developer 'Salty Citrus' . . . 3 - 148
Another Russian Development . . . 3 - 157
Using two Tesla Coils back-to-back . . . 3 - 157
Joseph Boyd's power transformer . . . 3 - 160
The 'Gegene' Magnetic Plate Arrangement . . . 3 - 173
Tariel Kapanadze's Self-powered Devices . . . 3 - 176
An analysis of the Kapanadze devices . . . 3 - 181
The Cold Electricity Coil of 'UFOpolitics' . . . 3 - 182
Stanley Meyer's Magnetic Particles Power Generator . . . 3 - 191
The E-Stress Power Generator . . . 3 - 203

Chapter 4: Gravity-Powered Systems

Lawrence Tseung's Gravity Impact wheel . . . 4 - 1
The Chas Campbell System . . . 4 - 4
Jacob Bitsadze's Pulley Ratio Information . . . 4 - 6
The self-powered generator of José Luis García del Castillo . . . 4 - 7
The Wilson self-powered DC generator . . . 4 - 11
The Bedini Pulsed Flywheel . . . 4 - 12
James Hardy's Water-jet Generator . . . 4 - 13
The Two-year magnetic Pendulum . . . 4 - 14
Jerzy Zbikowski's Chain Drive system . . . 4 - 17
Gravitational Effects . . . 4 - 18
Mikhail Dmitriev's nudged weights gravity wheel . . . 4 - 20
The Dale Simpson Gravity Wheel . . . 4 - 22
The Veljko Milkovic Pendulum / Lever system . . . 4 - 25
Amr Al-Hossary's Hinged-PlateDesign . . . 4 - 25
The Murilo Luciano Gravity Chain . . . 4 - 27
Other Gravity Designs . . . 4 - 35
James Kwok's "Hidro" Self-Powered Generator . . . 4 - 35
The Ribero Buoyancy Patent . . . 4 - 48
The 30-kilowatt Gravity-Powered Motor . . . 4 - 50
Bhaskara's Gravity Wheel . . . 4 - 51
William Skinners' torque multiplier . . . 4 - 53

Chapter 5: Energy-Tapping Pulsed Systems

Frank Prentice's horizontal wire system . . . 5 - 1
Dave Lawton's Water Fuel Cell . . . 5 - 3
John Bedini's Battery Pulse-Charger . . . 5 - 4
The Tesla Switch . . . 5 - 5
A 3-Battery Switching Circuit . . . 5 - 11
The Self-powered Free-Energy Generators of Carlos Benitez . . . 5 - 20
Bozidar Lisac's 1-battery charger patent . . . 5 - 37
Bob Boyce's Toroid . . . 5 - 46
Don Smith's devices . . . 5 - 52
Tariel Kapanadze's system . . . 5 - 53
The insights of Vladimir Utkin . . . 5 - 53
Walter Ford's high-powered crystal set . . . 5 - 54
Lawrence Tseung's "FLEET" toroid . . . 5 – 56
The LED and CFL lighting circuits of Jeanna and Lidmotor . . . 5 – 58
Advanced Joule Thief circuits . . . 5 - 66
LaserSaber's Joule Thief lighting circuits . . . 5 - 80
The Ed Gray / Marvin Cole Power System . . . 5 - 83
Tesla's Experiments . . . 5 - 85
The Alberto Molina-Martinez Generator . . . 5 - 91
The Hubbard Self-powered Generator . . . 5 - 92
The Joseph Cater Self-powered Generator . . . 5 - 94

Floyd Sweet's VTA . . . . . 5 - 102
Rosemary Ainslie's COP=17 heater . . . . . 5 - 104
Joseph H Cater's Self-sustaining generator . . . . . 5 - 105
Dr Oleg Gritskevitch's COP=100 1.5 MW generator . . . . . 5 - 106

Chapter 6: Battery-Charging Pulsed Systems

Bedini Pulsing . . . . . 6 - 2
Roger Andrews' switching system . . . . . 6 - 2
Ron Knight's professional battery advice . . . . . 6 - 5
Ron Pugh's Charger. . . . . 6 - 5
Ossie Callanan's charging system . . . . . 6 - 18
The Self-charging system . . . . . 6 - 24
The Relay Coil Battery Charger. . . . . 6 - 25
The Re-wired Fan Charger . . . . . 6 - 26
The Automotive Coil Charger . . . . . 6 - 28
The Self-charging Motor . . . . . 6 - 30
The Alexkor multiple battery charger. . . . . 6 - 31
Howerd Halay's cold electricity conditioning . . . . . 6 - 39
The Ron Cole One-Battery Charger . . . . . 6 - 40
The Tesla Switch. . . . . 6 - 42
The self-charging motor . . . . . 6 - 43
The 'UFOpolitics' motor . . . . . 6 - 46
Some battery charging suggestions . . . . . 6 - 46

Chapter 7: Aerial Systems and Electrostatic Generators

Nikola Tesla's Aerial Plate Power System . . . . . 7 - 1
The Jes Ascanius replication of Tesla's Aerial Plate System . . . . . 7 - 8
The printed circuit board of Dragan Kljajic . . . . . 7 - 12
Thomas Henry Moray's System. . . . . 7 - 14
Herman Plauson's System. . . . . 7 - 31
Roy Meyer's System . . . . . 7 - 33
Raymond Phillips' RF System. . . . . 7 - 34
The 'Alexkor' Aerial System . . . . . 7 - 38
The 'TREC' Aerial System of Lawrence Rayburn . . . . . 7 - 39
The Patent Application of Harold Deyo . . . . . 7 - 41
The Electrostatic Generator of Charles Goldie . . . . . 7 - 51
The Electrostatic Generator of D. Le May. . . . . 7 - 55
The Electrostatic Generator of Onezime Breaux . . . . . 7 - 68

Chapter 8: Fuel-less Motors

The Bob Neal Motor. . . . . 8 - 1
The Scott Robertson air compressor. . . . . 8 - 4
The Leroy Rogers Motor . . . . . 8 - 6
The Vortex Tube . . . . . 8 - 21
The Eber Van Valkinburg Motor . . . . . 8 - 23
The Clem Motor . . . . . 8 - 23
The Papp Motor . . . . . 8 - 25
The Robert Britt Motor . . . . . 8 - 28
The Michael Eskeli Turbine . . . . . 8 - 28
James Hardy's Water-Jet Generator. . . . . 8 - 47
The Cahill & Scott Generator . . . . . 8 - 48

Chapter 9: Passive Systems

Hans Cohler's device . . . . . 9 - 1
Thomas Trawoeger's pyramid. . . . . 9 - 3
Peter Grandics' pyramid . . . . . 9 - 20
Les Brown's pyramid . . . . . 9 - 22
Joseph H. Cater's explanation of how a pyramid actually works . . . . . 9 - 29
Pier Luigi Ighina's "ERIM" and "Elios" passive devices. . . . . 9 - 31
The Joe Cell . . . . . 9 - 35
Co-axial Cable Electrets . . . . . 9 - 67

Chapter 10: Vehicle Systems

Booster design . . . 10 - 1
Simple DC boosters . . . 10 - 2
The “Smack's” booster . . . 10 - 17
The “Hotsabi” booster . . . 10 - 18
The Zach West booster . . . 10 - 18
Bill Williams’ “DuPlex” booster . . . 10 - 27
The ‘Hogg’ Electrolyser . . . 10 - 28
Advanced Boosters . . . 10 - 34
The Bob Boyce DC electrolyser . . . 10 - 34
Pulsed Water-Splitters . . . 10 - 35
Dave Lawton's Meyer Replication . . . 10 - 35
Dr Cramton's water-splitter . . . 10 - 54
Bob Boyce's Toroidal water-splitter . . . 10 - 60
John Bedini Water-Splitting . . . 10 - 61
Dave Lawton’s Auto-Tune Circuit . . . 10 - 62
Running an Electrical Generator on Water Alone . . . 10 - 63
Running an Unmodified Generator on Water Alone . . . 10 - 88
Stan Meyer's Water Injection System . . . 10 - 92
Peter Lindemann running a lawnmower on water alone . . . 10 - 97
Peter Lowrie’s High-Current Electrolyser System . . . 10 - 98
Water use in engines . . . 10 - 99
Ted Ewert’s Vortex Tube . . . 10 - 102
Cam timing Issues . . . 10 - 107
Robert Krupa’s ‘FireStorm’ Spark Plug . . . 10 - 108
Plasma Ignition . . . 10 - 109
Roger Maynard’s Water Vapour Injection System . . . 10 - 110
“Fuelsavers” streamlining . . . 10 - 112
The Ram Implosion Wing . . . 10 - 112
High mpg Carburettors . . . 10 - 112
Allen Caggiano’s High-mpg carburettor . . . 10 - 114
A Fuel Vapourisation System . . . 10 - 118
Vortex Fuel Reforming (GEET) . . . 10 - 119
Electric Power . . . 10 - 121
The Weird Nature of Water and Advanced Electrolysis . . . 10 - 123
The Electrolyser of Charles Garrett . . . 10 - 129
The Electrolyser of Archie Blue . . . 10 - 130
The HHO cell of Paul Zigouras . . . 10 - 132

Chapter 11: Other Devices and Theories

The Tesla Generators . . . 11 - 1
The Aspden Device . . . 11 - 3
Paulo & Alexandra Correa . . . 11 - 15
Professor Konstantin Meyl . . . 11 - 16
Tesla’s MHD unit . . . 11 - 16
The Unified Field Theory . . . 11 - 18
Maurice Cotterell’s Explanation of Gravity . . . 11 - 22
John R. R. Searle . . . 11 - 32
The Gravity Wave Detector . . . 11 - 33
The Butch Lafonte Motor / Generator . . . 11 - 35
The Joseph Newman’s COP = 8 Device . . . 11 - 40
Daniel Cook’s Induction Coil . . . 11 - 51
Michael Eskeli’s Fuel-less Heater . . . 11 - 53
Karl Schappeller’s Free-energy Device . . . 11 - 60
Condensation-Induced Water Hammer . . . 11 - 75
William Hyde's COP = 10 Electrostatic Power Generator . . . 11 - 76
The Suppression of Knowledge . . . 11 - 85

Chapter 12: Electronics Tutorial

Voltage . . . 12 - 1
Resistance . . . 12 - 2
Semiconductors – Transistors . . . 12 - 10
Diodes . . . 12 - 19
Alternating Current . . . 12 - 21
Coils (Inductors) . . . 12 - 21
The Ben Teal Motor . . . 12 - 23

Transformers . . . 12 - 21
Rectification and Power Supplies . . . 12 - 26
Multivibrators . . . 12 - 29
The Bistable . . . 12 - 29
The Monostable . . . 12 - 30
The Astable . . . 12 - 31
Inverters . . . 12 - 32
Digital Logic and Truth Tables . . . 12 - 32
The NAND gate and Gating . . . 12 - 34
The Latch . . . 12 - 37
The NE555 Timer Chip . . . 12 - 41
The 741 Op-amp Chip . . . 12 - 56
The SCR (Thyristor) . . . 12 - 59
The Triac . . . 12 - 59
A simple, versatile, Schmitt inverter signal generator . . . 12 - 62
The CD4022BC Divide-By-Eight Chip . . . 12 - 62
The cascaded CD4017B Divide-By-N circuitry . . . 12 - 64
The PIC chip . . . 12 - 66
Capacitors . . . 12 - 71
AC Circuitry, inductors and resonance . . . 12 - 73
Choosing unspecified component values . . . 12 - 78
Prototype Construction . . . 12 - 81
Test Equipment . . . 12 - 85
Power Supply Unit . . . 12 - 88
The Oscilloscope . . . 12 - 90
Measuring magnetic field strength . . . 12 - 91
The Weird Stuff . . . 12 - 92

Chapter 13: Doubtful Devices
Paul Baumann's "Thestakia" . . . 13 - 1
The Homopolar or "N-Machine" . . . 13 - 4
The Borderland Science Homopolar AC Generator . . . 13 - 5
Tesla's Homopolar Generator . . . 13 - 7
The "Romag" and "Mini-Romag" Generators . . . 13 - 8
Cold Fusion . . . 13 - 11
Moller's Atomic Hydrogen Generator . . . 13 - 11
Muammer Yildiz's "Ocean Star" Electrical Generator . . . 13 - 13
Jesse McQueen . . . 13 - 20
The Nitro Cell ("D18") . . . 13 - 23
The HydroStar and HydroGen . . . 13 - 42
Hydrogen from Aluminium . . . 13 - 46
Francois Cornish . . . 13 - 47
Ultrasonic water-splitting . . . 13 - 48
The MEG . . . 13 - 49
Dave Lawton's assymetric MEG variation . . . 13 - 51
The Hitch-Hiker's MEG description . . . 13 - 52
The Devices of Hans Coler . . . 13 - 62

Chapter 14: Renewable Energy Devices
Heaters . . . 14 - 1
The Wood-gas Stove . . . 14 - 1
Mr Teslonian's wood-gas stove / electrical generator / fuel producer . . . 14 - 4
The solid-fuel electricity stove . . . 14 - 5
Henry Paine's HHO patent . . . 14 - 7
Sang Nam Kim's HHO heaters . . . 14 - 7
The H-Cat HHO heater from Justin Church . . . 14 - 10
Eugene Frenette . . . 14 - 11
Eugene Perkins . . . 14 - 12
The Peter Davey Heater . . . 14 - 15
The Jean-Christophe Dumas Heater . . . 14 - 17
The re-wired halogen heater . . . 14 - 20
Home-build Wind Generator . . . 14 - 21
William McDavid's Wind-Power or Water-Power Generator . . . 14 - 22
Frank Herbert's Wind Generator . . . 14 - 23
Mead and Holmes Power System . . . 14 - 25

Solar Ovens . . . . . 14 - 26
Solar Water Pasteurisation. . . . . 14 - 34
Solar Water Stills. . . . . 14 - 52
Sonic Water Pumps . . . . . 14 - 60
The Ram Pump . . . . . 14 - 62
Discouraging mosquitoes and small flies.. . . . . 14 - 64
Wave Power . . . . . 14 - 65
Cooling Using Heat . . . . . 14 - 69
Solar Panels . . . . . 14 - 71
Low-cost Cooling Systems. . . . . 14 - 100

Chapter 15: The Present Situation
Why free-energy devices are not in your local shop . . . . . 15 - 1

Chapter 16: Questions and Answers
What to Build . . . . . 16 - 1
Questions on Electrolysis . . . . . 16 - 7
Questions on Magnet Motors . . . . . 16 - 17
Questions on Don Smith's Devices. . . . . 16 - 19
Questions on General Topics . . . . . 16 - 22

Appendix
US and UK Wire sizes and capacities . . . . . A -1
Frank Fecera's permanent magnet motor patent . . . . . A - 2
Howard Johnson's permanent magnet motor patent . . . . . A - 46
Harold Ewing's Carousel permanent magnet-generator patent. . . . . A - 56
The Pavel Imris minimal power lighting system patent . . . . . A - 74
The Colman/Seddon-Gillespie 70-year battery patent . . . . . A - 83
The Jon Sok An Lenz-less electrical generator patent . . . . . A - 87
The Molina Martinez self-powered electrical generator patent . . . . . A - 100
Michael Ognyanov's solid-state electrical generator patent . . . . . A - 113
Edwin Gray's electric motor patent . . . . . A - 119
Edwin Gray's electric power supply patent . . . . . A - 142
The Adams-Aspden electrical motor-generator patent . . . . . A - 148
William Barbat's self-powered electrical generator patent . . . . . A - 164
John Reardon's AC generator patent . . . . . A - 196
Geoffrey Spence's self-powered electrical generator patent . . . . . A - 213
Robert Alexander's COP = 2.93 electrical generator patent. . . . . A - 228
Shigeaki Hayasaka's electrical generator patent . . . . . A - 236
Larry Jamison's electrical generator patent application . . . . . A - 252
Teruo Kawai's COP>1 electric motor patent . . . . . A - 259
Joseph Newman's Energy Generator patent. . . . . A - 280
Philip Brody's very high output ceramic solar devices patent . . . . . A - 298
Charles Flynn's controlled magnetic devices patent . . . . . A - 338
The **M**otionless **E**lectromagnetic **G**enerator patent . . . . . A - 411
Dan Davidson's acoustic-magnetic electrical generator patent. . . . . A - 427
John Bedini's battery-charging patent . . . . . A - 434
John Bedini's motor-generator patent . . . . . A - 445
John Bedini's pulse-charging system patent . . . . . A - 456
Richard Weir and Carl Nelson's battery replacement patent . . . . . A - 470
Hermann Plauson's aerial power systems patent . . . . . A - 485
Roy Meyers' Electricity-producing device patent . . . . . A - 524
Paulo and Alexandra Correa's free-electricity patent . . . . . A - 532
Paulo and Alexandra Correa's energy conversion patent . . . . . A - 561
The Mead-Nachamkin ZPE to electricity conversion patent . . . . . A - 603
Stanley Meyer's Water Fuel patent 4,936,961 . . . . . A - 620
Stanley Meyer's hydrogen injection system for vehicles patent 4,389,981 . . . . . A - 627
Stanley Meyer's hydrogen gas burner patent 4,421,474. . . . . A - 637
Stanley Meyer's hydrogen generation and enhancement patent 5,149,407 . . . . . A - 642
Stanley Meyer's water fuel generator patent CA 2,067,735 . . . . . A - 659
Stanley Meyer's WFC control circuitry patent WO 92/07861 . . . . . A - 670

Stephen Meyer’s water-splitting patent application 2005/0246059 . . . . . A - 680
Henry Puharich’s water-splitting patent 4,392,230 . . . . . A - 689
Shigeta Hasebe’s spiral electrolyser patent . . . . . A - 719
Stephen Chambers’ hydroxy generator patent (Xogen Power Inc.) . . . . . A - 725
Charles Garrett’s water carburettor patent . . . . . A - 740
Archie Blue’s electrolyser patent . . . . . A - 748
Ruggero Santilli’s plasma arc electrolysis patent . . . . . A - 754
Chak Chang’s low-voltage low-temperature plasma patent application. . . . . A - 764
Juan Aguero’s water-engine patent application . . . . . A - 823
Stephen Horvath’s water-powered car patent . . . . . A - 830
Christopher Eccles’ water-splitting cell patent . . . . . A - 857
Spiro Spiros’ COP>1 electrolyser patent . . . . . A - 864
Henry Paine’s hydroxy gas conversion patent . . . . . A - 901
Boris Volfson’s gravity drive patent. . . . . A - 904
Charles Pogue’s first high-mpg carburettor patent . . . . . A - 919
Charles Pogue’s second high-mpg carburettor patent . . . . . A - 927
Charles Pogue’s third high-mpg carburettor patent . . . . . A - 932
Ivor Newberry’s high-mpg carburettor patent. . . . . A - 940
Robert Shelton’s high-mpg carburettor patent . . . . . A - 945
Harold Schwartz’s high-mpg carburettor patent . . . . . A - 949
Oliver Tucker’s high-mpg carburettor patent . . . . . A - 952
Thomas Ogle’s high-mpg carburettor patent . . . . . A - 955
Stephen Kundel’s permanent magnet motor . . . . . A - 968
Charles Flynn’s permanent magnet motor . . . . . A - 992
Claude Mead and William Holmes’ wind power storage system . . . . . A - 1021
The Richard Willis COP>>1 electrical generator . . . . . A - 1028
Graham Gunderson's pulsed toroid generator . . . . . A - 1038
Mark McKay's investigation into Edwin Gray's technology . . . . . A - 1046
Mike Brady’s “Perendev” magnet motor patent . . . . . A - 1107
Donald Kelly’s magnet motor patent . . . . . A - 1117
Bob Neal’s compressor patent . . . . . A - 1125
Leroy Rogers’ compressed air engine patent . . . . . A - 1132
Eber Van Valkinburg’s compressed air/oil engine patent . . . . . A - 1148
Josef Papp’s inert-gas engine patent . . . . . A - 1153
Robert Britt’s Inert-gas engine patent . . . . . A - 1186
Floyd Sweet’s “VTA” Electrical Generator . . . . . A - 1196
Meguer Kalfaian’s Electrical Generator . . . . . A - 1210
Theodore Annis and Patrick Eberly’s Motionless Generator . . . . . A - 1220
William McDavid’s Wind-Power or Water-power Generator. . . . . A - 1232
The Self-powered Generators of Barbosa and Leal . . . . . A - 1252
Web links to Scientific Papers and Videos . . . . . A - 1283

Alphabetical Index of Devices

AC generator patent, John Reardon . . . A - 196
Acoustic water pumps: Bellocq, Dickinson and Benson . . . 14 - 61
Advanced Electrolysis, Moray B. King . . . 10 - 120
Aerial power systems patent, Hermann Plauson . . . A - 485
Aerial system, Frank Prentice . . . 5 - 1
Aerial system, Jes Ascanius . . . 7 - 9
Aerial system, Lawrence Rayburn . . . 7 - 39
Aerial system, Nikola Tesla . . . 7 - 1
Aerial system, Raymond Phillips . . . 7 - 34
Aerial system, Thomas Henry Moray . . . 7 - 14
Air Vortex Turbine, Ted Ewert . . . 10 - 89
Aspden Effect, Harold Aspden . . . 5 - 66
Asymmetrical Motionless Generator, Dave Lawton . . . 13 - 51
Atomic Hydrogen generator, William Lyne . . . 13 - 11
Automotive Relay battery pulser, Imhotep . . . 6 - 28
Battery-charging patent, John Bedini . . . A - 434
Battery-pulser, Alexkor . . . 6 - 31
Battery-pulser, Bozidar Lisac . . . 5 - 37
Battery-pulser, John Bedini . . . 6 - 2
Battery-pulser, Ossie Callanan . . . 6 - 18
Battery-pulser, Ron Pugh . . . 6 - 5
Battery replacement patent, Richard Weir and Carl Nelson . . . A - 470
Battery technology, Ronald Knight . . . 6 - 5
Blood electrifier, Bob Beck . . . 11 - 88
Boosters, Various . . . 10 - 1
Britt Engine . . . 8 - 28
Buoyancy patent, Renato Ribera . . . 4 - 48
Capacitor Battery Pulser, Ron Cole . . . 6 - 40
Caravan Power System, Claude Mead and William Holmes . . . 14 - 21
Car relay pulse charger, Imhotep . . . 6 - 28
Chain Drive, Jerzy Zbikowski . . . 4 - 17
Clem engine, Richard Clem . . . 8 - 23
Co-axial Cable Electrets . . . 9 - 67
Cold Electricity Coil of ‘UFOpolitics’ . . . 3 - 182
Colloidal Silver, Bob Beck . . . 11 - 88
Compressed-air engine, Bob Neal . . . 8 - 1
Compressed-air engine, Leroy Rogers . . . 8 - 6
Compressed-air tank, Scott Robertson . . . 8 - 4
Compressed-air/oil engine, Eber Van Valkenburg . . . 8 - 23
Controlled magnetic devices patent, Charles Flynn . . . A - 338
Cooling systems for low-power use . . . 14 - 96
COP = 2.93 electrical generator patent, Robert Alexander . . . A - 228
COP>1 electric motor patent, Teruo Kawai . . . A - 259
COP>1 electrolyser patent, Spiro Spiros . . . A - 864
Davey water heater, Peter Davey . . . 14 - 15
Direct Coupled Motors . . . 2 - 67
Drinking Water Systems . . . 14 - 48
Electrets . . . 9 - 68
Electrical energy from air, Nikola Tesla . . . 11 - 1
Electrical free-energy generation, Harold Aspden . . . 11 - 3
Electrical generator, Alfred Hubbard . . . 5 - 90
Electrical generator, Arthur Cahill & John Scott . . . 8 - 48
Electrical generator, Joseph Cater . . . 5 - 103
Electrical generator, Alberto Molina-Martinez . . . 5 - 89
Electrical generator, Clemente Figuera . . . 3 - 6
Electrical generator, Borderland Science . . . 13 - 8
Electrical generator, Ecklin-Brown . . . 1 - 4
Electrical generator, Dr Oleg Gritskevitch . . . 5 - 104
Electrical generator patent application, Larry Jamison . . . A - 252
Electrical generator, Meyer-Mace . . . 3 - 103
Electrical generator, Raoul Hatem . . . 2 - 48
Electrical generator, Raymond Kromrey . . . 2 - 16
Electrical generator, Richard Willis . . . 3 - 75

Electrical generator, self-powered, Mr Wilson . . . . . 4 - 7
Electrical Generator, ‘silverhealtheu’. . . . . 3 - 77
Electrical generator patent, Shigeaki Hayasaka . . . . . A - 236
Electrical Generator, Stan Meyer . . . . . 3 - 191
Electrical Generator, Tariel Kapanadze . . . . . 3 - 176
Electrical motor-generator patent, Adams-Aspden . . . . . A - 148
Electricity-producing device patent, Roy Meyers . . . . . A - 524
Electricity-producing solid-fuel stove . . . . . 14 - 5
Electric motor, Ben Teal . . . . . 1 - 9
Electric motor patent, Edwin Gray . . . . . A - 119
Electrical motor, Georges Mourier . . . . . 2 - 29
Electrical motor, Edwin Gray . . . . . 5 - 81
Electric motor, Robert Adams . . . . . 2 - 1
Electric motor, Teruo Kawai . . . . . 2 - 25
Electric power supply patent, Edwin Gray . . . . . A - 142
Electrolyser, Archie Blue . . . . . 10 - 128
Electrolyser, Bob Boyce . . . . . 5 - 46
Electrolyser, Bob Boyce . . . . . 10 - 33
Electrolyser, Bob Boyce . . . . . 10 - 59
Electrolyser, Charles Garrett . . . . . 10 - 126
Electrolyser, Paul Zigouras . . . . . 10 - 129
Electrolyser, Peter Lowrie . . . . . 10 - 95
Electrolyser, Selwyn Hughes . . . . . 10 - 95
Electrolyser, Zach West . . . . . 10 - 18
Electrolyser patent, Archie Blue. . . . . A - 748
Electrostatic Power Generator, Onezime Breaux . . . . . 7 - 68
Electrostatic Power Generator, Charles Goldie . . . . . 7 - 51
Electrostatic Power Generator, William Hyde . . . . . 11 - 76
Electrostatic Power Generator, D. Le May . . . . . 7 - 55
Elios device, Pier Luigi Ighina . . . . . 9 - 34
Energy-conversion patent, Paulo and Alexandra Correa . . . . . A - 561
Energy Generator patent, Joseph Newman . . . . . A - 280
ERIM device, Pier Luigi Ighina . . . . . 9 - 31
E-Stress Power Generator, harisingh. . . . . 3 - 203
Fan Battery Pulser, Imhotep . . . . . 6 - 26
FLEET power toroid . . . . . 5 - 56
Francois Cornish hydrogen generator . . . . . 13 - 47
Free-electricity patent, Paulo and Alexandra Correa . . . . . A - 532
Free-energy device, Karl Schappeller . . . . . 11 - 60
Fuelsavers . . . . . 10 - 109
Fuji camera circuit adaption . . . . . 5 - 62
GEET fuel re-former system, Paul Pantone . . . . . 10 - 107
Generator running on water alone . . . . . 10 - 63
Gravity-chain device, Murilo Luciano . . . . . 4 - 27
Gravity device, Amr Al-Hossary. . . . . 4 - 26
Gravity drive patent, Boris Volfson . . . . . A - 904
Gravity-tapping generator, Chas Campbell . . . . . 4 - 4
Gravity Wave Detector, Dave Lawton . . . . . 11 - 33
Gravity wheel, Bhaskara. . . . . 4 - 51
Gravity wheel, Dale Simpson . . . . . 4 - 22
Gravity wheel, Lawrence Tseung . . . . . 4 - 1
Gravity wheel, Mikhail Dmitriev . . . . . 4 - 20
Heater, Fuel-less, Michael Eskeli . . . . . 11 - 53
Heater, COP=17 by Rosemary Ainslie . . . . . 5 - 102
Heaters . . . . . 14 - 1
Heater, Magnetic. . . . . 16 - 39
H-Cat HHO heater, Justin Church . . . . . 14 - 10
Hidro Generator, James Kwok . . . . . 4 - 35
High-mpg carburettor patent, Charles Pogue . . . . . A - 919
High-mpg carburettor patent, Charles Pogue . . . . . A - 927
High-mpg carburettor patent, Charles Pogue . . . . . A - 932
High-mpg carburettor patent, Harold Schwartz . . . . . A - 949
High-mpg carburettor patent, Ivor Newberry . . . . . A - 940
High-mpg carburettor patent, Oliver Tucker . . . . . A - 952
High-mpg carburettor patent, Robert Shelton . . . . . A - 945

High-mpg carburettor patent, Thomas Ogle . . . . . A - 955
Hinged-Plate Gravity Device, Amr Al-Hossary . . . . . 4 - 25
Hogg electrolyser . . . . . 10 - 28
Homopolar generator, Michael Faraday . . . . . 13 - 4
Hotsabi booster, "Hotsabi" . . . . . 10 - 18
Hydraulic Ram Pump . . . . . 14 - 58
Hydrogen from Aluminium . . . . . 13 - 46
Hydrogen gas burner patent 4,421,474, Stanley Meyer . . . . . A - 637
Hydrogen generation and enhancement patent 5,149,407, Stanley Meyer . . . . . A - 642
Hydrogen injection system for vehicles patent 4,389,981, Stanley Meyer . . . . . A - 627
HydroStar and HydroGen devices . . . . . 13 - 42
Hydroxy gas conversion patent, Henry Paine . . . . . A - 901
Hydroxy generator patent, Stephen Chambers . . . . . A - 725
Hydroxy-burning heaters . . . . . 14 - 7
Induction Coil generator, Daniel Cook . . . . . 11 - 51
Inert-gas engine, Josef Papp . . . . . 8 - 25
Inert-gas engine, Robert Britt . . . . . 8 - 28
Inverter system, Jesse McQueen . . . . . 13 - 20
Joe Cell, Joe Nobel . . . . . 9 - 35
Joseph Newman Motor, Joseph Newman . . . . . 11 - 40
Joule Ringer circuits, Lasersaber . . . . . 5 - 80
Joule Thief advanced circuits . . . . . 5 - 66
Joule Thief lighting circuits . . . . . 5 - 56
Lead-out energy, Lawrence Tseung . . . . . 4 - 1
Lawnmower running on water alone . . . . . 10 - 94
Lenz-less electrical generator patent, Jon Sok An . . . . . A - 87
Long-life battery, Colman / Seddon-Gillespie . . . . . 3 - 110
Low-voltage low-temperature plasma patent application, Chak Chang . . . . . A - 764
Magnetic shielding from Pasi Mäkilä . . . . . 1 - 55
Magnet motor-generator, permanent 5kW, Shen He Wang . . . . . 1 - 1
Magnet Motor, Art Porter . . . . . 2 - 57
Magnet motor, Carousel . . . . . 1 - 7
Magnet-generator patent, Carousel . . . . . A - 56
Magnet motor patent, Charles Flynn . . . . . 1 - 15
Magnet Motor, Dietmar Hohl . . . . . 1 - 29
Magnet Motor, Jes Ascanius . . . . . 1 - 29
Magnet motor patent, Frank Fecera . . . . . A - 2
Magnet Motor, George Soukup . . . . . 1 - 26
Magnet motor, Howard Johnson . . . . . 1 - 6
Magnet motor patent, Howard Johnson . . . . . A - 46
Magnet motor, John Jines . . . . . 1 - 11
Magnet motor, Donald Kelly . . . . . 1 - 54
Magnet motor, Perendev (Mike Brady) . . . . . 1 - 55
Magnet motor, Robert Tracy . . . . . 1 - 9
Magnet motor, simple . . . . . 1 - 30
Magnet motor, Steorn . . . . . 1 - 24
Magnet motor, Stephen Kundel . . . . . 1 - 12
Magnet motor, Victor Diduck . . . . . 1 - 56
Magnetic Conversion, Don Smith . . . . . 3 - 112
Magnetic Conversion, Don Smith . . . . . 5 - 52
Magnetic flux, Charles Flynn . . . . . 3 - 1
Magnetic frame, Lawrence Tseung . . . . . 3 - 1
Magnetic frame, Thane Heins . . . . . 3 - 3
Magnetic Plate, The ‘Gegene’ . . . . . 3 - 173
Magnetohydrodynamic drive, Nikola Tesla . . . . . 11 - 17
MEG, Tom Beardon et al. . . . . 13 - 49
Minimal power lighting system patent, Pavel Imris . . . . . A - 74
Motionless Generators of Kelichiro Asaoka . . . . . 3 - 84
Motionless Generator of Dietmar Kunel . . . . . 3 - 77
Motionless Generator of Valeri Ivanov . . . . . 3 - 84
Motionless **E**lectromagnetic **G**enerator patent . . . . . A - 411
Motor-generator, Butch Lafonte . . . . . 11 - 35
Motor-generator patent, John Bedini . . . . . A - 445
Motor-generator patent, Georges Mourier . . . . . 2 - 29
N-machine generator, Michael Faraday . . . . . 13 - 2

Neal Compressed-air Engine . . . . . 8 - 1
Nitro Cell . . . . . 13 - 22
Ocean-Star generator, Muammer Yaldiz . . . . . 13 - 13
One-battery switch, Ron Cole . . . . . 6 - 40
Optical Amplifier, Pavel Imris . . . . . 3 - 106
Pancake Coil, Nikola Tesla . . . . . 5 - 66
Pendulum/lever device, Veljko Milkovic . . . . . 4 - 25
Phase-Lock-Loop water-splitting circuit . . . . . 10 - 62
Plasma arc electrolysis patent, Ruggero Santilli . . . . . A - 754
Power System for Caravans, Mead and Holmes . . . . . 14 - 21
Power tube, Edwin Gray . . . . . 5 - 81
Pulse-charging system patent, John Bedini . . . . . A - 456
Pulsed flywheel generator, Jacob Bitsadze . . . . . 4 - 6
Pulsed flywheel generator, Chas Campbell . . . . . 4 - 4
Pulsed flywheel generator, John Bedini . . . . . 4 - 12
Pulsed flywheel generator, Jim Watson . . . . . 4 - 11
Pulsed flywheel generator, Lawrence Tseung . . . . . 2 - 50
Pyramid, James Brock . . . . . 9 - 15
Pyramid, Joseph H. Cater . . . . . 9 - 29
Pyramid, Les Brown . . . . . 9 - 22
Pyramid, Paulo and Alexandra Correa . . . . . 11 - 15
Pyramid, Peter Grandics . . . . . 9 - 21
Pyramid, Thomas Trawoeger . . . . . 9 - 3
Radium power generation, Nikola Tesla . . . . . 11 - 2
RF aerial to DC power, Raymond Phillips . . . . . 7 - 34
Raising DC motor efficiency . . . . . 2 - 57
Ram Implosion Wing, Robert Patterson . . . . . 10 - 109
Ram Pump . . . . . 14 - 58
Refrigeration through heating, Albert Einstein . . . . . 14 - 66
Romag generator, Magnetic Energy . . . . . 13 - 8
RotoVerter, Hector Torres . . . . . 2 - 39
Screened transformer, Joseph Boyd . . . . . 3 - 160
Searle Effect Device, John R. R. Searle . . . . . 11 - 32
Self-powered water-jet electrical generator, James Hardy . . . . . 2 - 27
Self-powered water-jet electrical generator, James Hardy . . . . . 4 - 13
Self-powered water-jet electrical generator, James Hardy . . . . . 8 - 47
Self-powered water-jet electrical generator, James Hardy . . . . . 2 - 27
Self-powered electrical generator, Nilson Barbosa and Cleriston Leal . . . . . 3 - 27
Self-powered electrical generator, Carlos Benitez . . . . . 5 - 20
Self-powered electrical generator, Joseph H Cater . . . . . 5 - 103
Self-powered electrical generator, José Luis García del Castillo . . . . . 4 - 7
Self-powered electrical generator patent, Molina Martinez . . . . . A - 100
Self-powered electrical generator patent, Tariel Kapanadze . . . . . 3 - 176
Self-powered electrical generator, Stephan W. Leben . . . . . 3 - 99
Self-powered electrical generator patent, William Barbat . . . . . A - 164
Seventy-year battery patent, Colman/Seddon-Gillespie . . . . . A - 83
Smack's Booster, Eletrik . . . . . 10 - 17
Solar ovens, BYU . . . . . 14 - 22
Solar panels . . . . . 14 - 67
Solar Still Water-makers . . . . . 14 - 48
Spiral electrolyser patent, Shigeta Hasebe . . . . . A - 719
Static electricity, Lorrie Matchett . . . . . 3 - 61
Stromerzeuger, Hans Coler . . . . . 13 - 62
Stromerzeuger, Hans Coler . . . . . 9 - 1
Tesla Coil, Correas . . . . . 11 - 15
Tesla Coils back-to-back, Nick Giannopoulous . . . . . 3 - 157
Tesla Switch, Nikola Tesla . . . . . 5 - 6
Tesla Switch, Nikola Tesla . . . . . 6 - 42
Testatika, Paul Baumann . . . . . 13 - 1
The Thirty Kilowatt Gravity-Powered Motor . . . . . 4 - 50
Toroidal Power Unit, Bob Boyce . . . . . 5 - 46
Torque multiplier, William Skinner . . . . . 4 - 53
Turbine, Michael Eskeli . . . . . 8 - 28
Ultrasonic hydrogen generator . . . . . 13 - 48
Very high output ceramic solar devices patent, Philip Brody . . . . . A - 298

Vortex Fuel Reformers . . . . . 10 - 116
Vortex tube . . . . . 8 - 21
VTA, Floyd Sweet . . . . . 3 - 102
VTA, Floyd Sweet . . . . . 5 - 102
VTA, Floyd Sweet . . . . . A - 1196
Waste spark handling . . . . . 10 - 70
Water Acoustic Pump, Toribio Bellocq . . . . . 14 - 55
Water Acoustic Pump, Richard Dickinson . . . . . 14 - 57
Water Acoustic Pump, Arthur Bentley . . . . . 14 - 57
Water carburettor patent, Charles Garrett . . . . . A - 740
Water clusters, Moray B. King . . . . . A - 740
Water-engine patent application, Juan Aguero . . . . . A - 823
Water Fuel Cell, Dr Scott Cramton . . . . . 10 - 53
Water Fuel Cell, Dave Lawton . . . . . 5 - 4
Water Fuel Cell, Dave Lawton . . . . . 10 - 34
Water fuel generator patent CA 2,067,735, Stanley Meyer . . . . . A - 659
Water Fuel patent 4,936,961, Stanley Meyer . . . . . A - 620
Water-jet self-powered generator, James Hardy . . . . . 2 - 27
Water-jet self-powered generator, James Hardy . . . . . 8 - 47
Water-maker, Calice Courneya . . . . . 14 - 56
Water-maker, Elmer Grimes . . . . . 14 - 56
Water-makers . . . . . 14 - 48
Water Heater, Peter Davey . . . . . 14 - 15
Water-powered car patent, Stephen Horvath . . . . . A - 830
Water-Powered Generator, William McDavid . . . . . 14 - 18
Water-Powered Generator, William McDavid . . . . . A - 1233
Water-splitting cell patent, Christopher Eccles . . . . . A - 857
Water-splitting patent application 2005/0246059, Stephen Meyer . . . . . A - 680
Water-splitting patent 4,392,230, Henry Puharich . . . . . A - 689
Water vapour injection systems . . . . . 10 - 107
Water injection systems, Stan Meyer . . . . . 10 - 89
WFC control circuitry patent WO 92/07861, Stanley Meyer . . . . . A - 670
Wind Generator, Dan Bartmann and Dan Fink . . . . . 14 - 17
Wind Generator, Frank Herbert . . . . . 14 - 19
Wind-Powered Generator, William McDavid . . . . . 14 - 18
Wind-Powered Generator, William McDavid . . . . . A - 1233
Wind Power Storage System, Claude Mead and William Holmes . . . . . A - 1021
Wire sizes and capacities . . . . . A -1
ZPE to electricity conversion patent, Mead-Nachamkin . . . . . A - 603

Alphabetical Index of People

Adams, Robert . . . . . 2 - 1
Adams, Robert . . . . . A – 148
Aguero, Juan . . . . . A - 823

A Practical Guide to 'Free-Energy' Devices

Overview

This eBook contains most of what I have learned about this subject after researching it for a number of years. I am not trying to sell you anything, nor am I trying to convince you of anything. When I started looking into this subject, there was very little useful information and any that was around was buried deep in incomprehensible patents and documents. My purpose here is to make it easier for you to locate and understand some of the relevant material now available. What you believe is up to yourself and is none of my business. Let me stress that almost all of the devices discussed in the following pages, are devices which I have not personally built and tested. It would take several lifetimes to do that and it would not be in any way a practical option. Consequently, although I believe everything said is fully accurate and correct, you should treat everything as being "hearsay" or opinion.

Some time ago, it was commonly believed that the world was flat and rested on the backs of four elephants and that when earthquakes shook the ground, it was the elephants getting restless. If you want to believe that, you are fully at liberty to do so, however, you can count me out as I don't believe that.

The Wright brothers were told that it was impossible for aeroplanes to fly because they were heavier than air. That was a commonly believed view. The Wright brothers watched birds flying and since, without question, birds are considerably heavier than air, it was clear that the commonly held view was plain wrong. Working from that realisation, they developed aeroplanes which flew perfectly well.

The years passed, and the technology started by the Wright brothers and their careful scientific measurements and well-reasoned theory, advanced to become the "science" of aeronautics. This science was used extensively to design and build very successful aircraft and "aeronautics" gained the aura of being a "law".

Unfortunately, somebody applied aeronautic calculations to the flight of bumblebees and discovered that according to aeronautics, bumblebees couldn't possibly fly as their wings could not generate enough lift to get them off the ground. This was a problem, as it was perfectly possible to watch bees flying in a very competent manner. So, the "laws" of aeronautics said that bees can't fly, but bees actually **do** fly.

Does that mean that the laws of aeronautics were no use? Certainly not - those "laws" had been used for years and proved their worth by producing excellent aircraft. What it did show was that the "laws" of aeronautics did not yet cover every case and needed to be extended to cover the way that bees fly, which is through lift generated by turbulent airflow.

It is **very** important to realise that what are described as scientific "laws" are just the best working theories at the present time and it is virtually certain that those "laws" will have to be upgraded and extended as further scientific observations are made and further facts discovered. Let's hope those four elephants don't get restless before we have a chance to learn a bit more!

Introduction

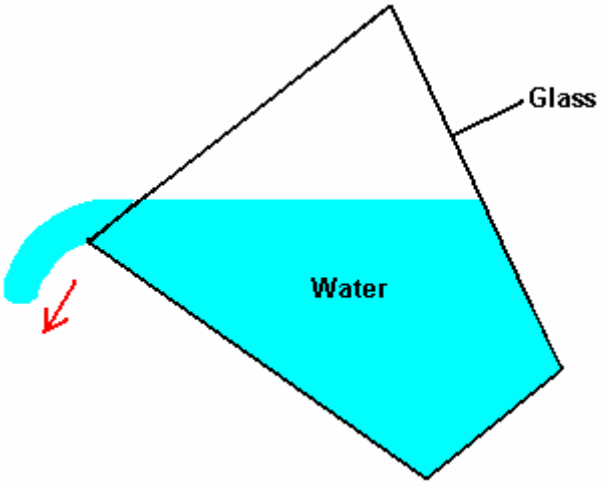
It should be stressed at this point, that this material is intended to provide you with information and only that. If you should decide, on the basis of what you read here, to build some device or other, you do so solely and entirely at your own risk and on your own responsibility. For example, if you build something in a heavy box and then drop it on your toe, then that is completely your own responsibility (you should learn to be more careful) and nobody other than yourself is in any way liable for your injury, or any loss of income caused while your toe is recovering. Let me amplify that by stating that I do not warrant that any device or system described in this document works as described, or in any other way, nor do I claim that any of the following information is useful in any way or that any device described is useful in any way or for any purpose whatsoever. Also, let me stress that I am not encouraging you to actually construct any device described here, and the fact that very detailed construction details are provided, must not be interpreted as my encouraging you to physically construct any device described in this document. You are welcome to consider this a work of fiction if you choose to do so.

I apologise if this presentation seems very elementary, but the intention is to make each description as simple as possible so that everybody can understand it, including people whose native language is not English. If you are not familiar with the basic principles of electronics, then please read the simple step-by-step electronics tutorial in Chapter 12 which is intended to help complete beginners in the subject.

At this point in time - the early years of the twenty-first century - we have reached the point where we need to realise that some of the “laws” of science do not cover every case, and while they have been very useful in the past, they do need to be extended to cover some cases which have been left out until now.

For example, suppose a bank robber broke into a bank and stole all of the cash there. How much could he take? Answer: “every coin and every note”. The limit is the sum total of all cash in the building. This is what the “Law” of Conservation of Energy is all about. What it says is very simple – you can’t take out any more than there is there in the beginning. That seems pretty straightforward, doesn’t it?

As another example, consider a glass tumbler filled completely with water. Using common sense, tell me, how much water can be poured out of the glass? For the purposes of this illustration, please take it that temperature, pressure, gravity, etc. all remain constant for the duration of the experiment.

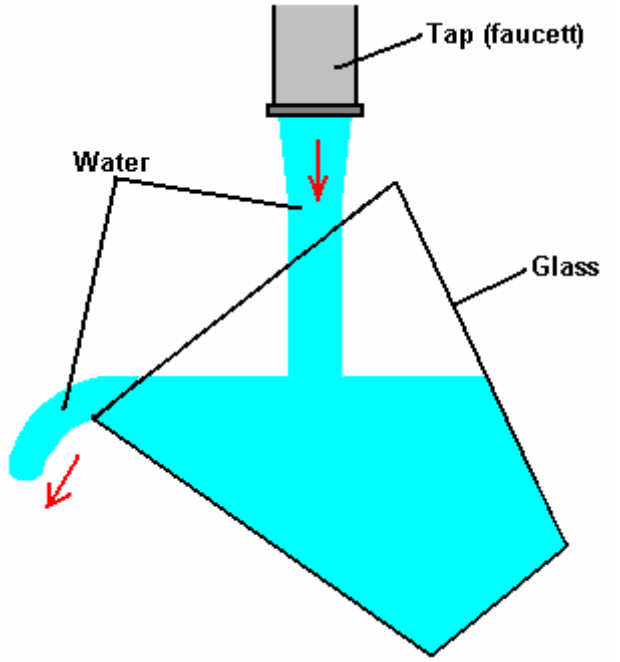


The answer is: “the exact volume contained inside the tumbler”. Agreed. This is what present day science says. To be strictly accurate, you will never be able to pour all of the water out as a small amount will remain, wetting the inside of the glass. Another way of putting this is to say that the “efficiency” of the pouring operation is not 100%. This is typical of life in general, where very few, if any, actions are 100% efficient.

So, are we agreed with current scientific thinking then – the maximum amount of water which can pour out of the tumbler is the total volume inside the tumbler? This seems simple and straightforward, doesn’t it? Science thinks so, and insists that this is the end of the story, and nothing else is possible. This arrangement is called a “closed system” as the only things being considered are the glass, the water and gravity.

Well, unfortunately for current scientific thinking, this is not the only possible situation and “closed systems” are almost unknown in the real world. Mostly, assumptions are made that the effects of anything else around will cancel out and add up to a net zero effect. This is a very convenient theory, but unfortunately it has no basis in reality.

Let’s fill our glass with water again and begin to pour it out again, but this time we position it underneath a source of flowing water:



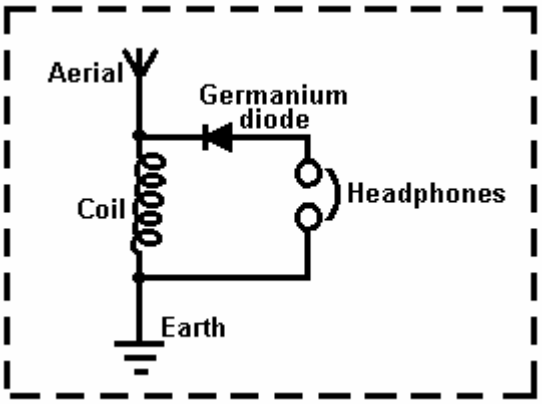
So, now, how much water can be poured out of the tumbler? Answer: “millions of times the volume of the tumbler”. But hang on a moment, haven’t we just said that the absolute limit of water poured from the tumbler has to be the volume inside the tumbler? Yes, that’s exactly what we said, and that is what current science teaching says. The bottom line here is that what current science says does in fact hold true for most of the time, but there are cases where the basic assumption of it being a “closed system” is just not true.

One popular misconception is that you can’t get more energy out of a system than you put into it. That is wrong, because the sentence was worded carefully. Let me say it again and this time, emphasise the key words: “**you** can’t get more energy out of a system than **you** put into it”. If that were true, then it would be impossible to sail a yacht all the way around the world without burning any fuel, and that has been done many times and none of the driving energy came from the crews. If it were true, then a grain mill driven by a waterwheel would not be able to produce flour as the miller certainly does not push the millstones around himself. If that were true, then nobody would build windmills, or construct solar panels, or tidal power stations.

What the statement should say is “more energy can’t be taken out of a system than is put into it or is already in it” and that is a very different statement. When sailing a yacht, the wind provides the driving force which makes the trip possible. Notice that, it is the environment providing the power and not the sailors. The wind arrived without them having to do anything about it, and a lot less than 100% of the wind energy reaching the yacht actually becomes forward thrust, contributing to the voyage. A good deal of the energy arriving at the yacht ends up stretching the rigging, creating a wake, producing noise, pushing the helmsman, etc. etc. This idea of no more energy coming out of a system than goes into it, is called “The Law of Conservation of Energy” and it is perfectly right, in spite of the fact that it gets people confused.

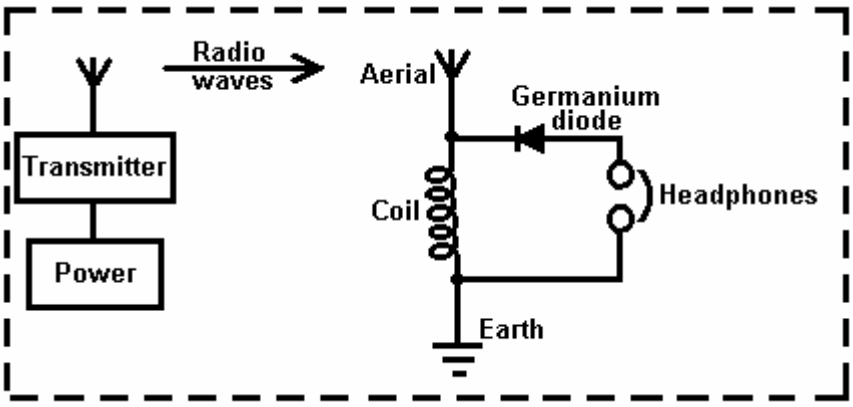
“Free-Energy Devices” or “Zero-Point Energy Devices” are the names applied to systems which appear to produce a higher output power than their input power. There is a strong tendency for people to state that such a system is not possible since it contravenes the Law of Conservation of Energy. It doesn’t. If it did, and any such system was shown to work, then the “Law” would have to be modified to include the newly observed fact. No such change is necessary, it merely depends on your point of view.

For example, consider a crystal set radio receiver:



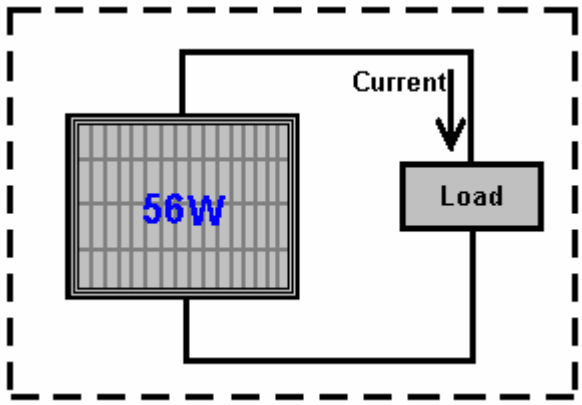
Looking at this in isolation, we appear to have a free-energy system which contradicts the Law of Conservation of Energy. It doesn't, of course, but if you do not view the whole picture, you see a device which has only passive components and yet which (when the coil is of the correct size) causes the headphones to generate vibrations which reproduce recognisable speech and music. This looks like a system which has no energy input and yet which produces an energy output. Considered in isolation, this would be a serious problem for the Law of Conservation of Energy, but when examined from a common sense point of view, it is no problem at all.

The whole picture is:

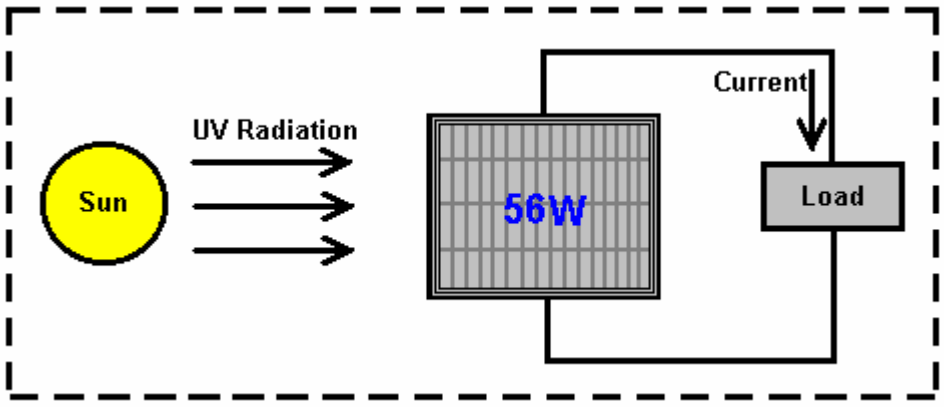


Power is supplied to a nearby transmitter which generates radio waves which in turn, induce a small voltage in the aerial of the crystal set, which in turn, powers the headphones. The power in the headphones is far, far less than the power taken to drive the transmitter. There is most definitely, no conflict with the Law of Conservation of Energy. However, there is a quantity called the "**C**oefficient **O**f **P**erformance" or "**COP**" for short. This is defined as the amount of power coming out of a system, divided by the amount of power that **the operator** has to put into that system to make it work. In the example above, while the **efficiency** of the crystal set radio is well below 100%, the **COP** is greater than 1. This is because the owner of the crystal radio set does not have to supply any power at all to make it work, and yet it outputs power in the form of sound. As the input power from the user, needed to make it work is zero, and the COP value is calculated by dividing the output power by this zero input power, the COP is actually infinity. **Efficiency** and **COP** are two different things. Efficiency can never exceed 100% and almost never gets anywhere near 100% due to the losses suffered by any practical system.

As another example, consider an electrical solar panel:



Again, viewed in isolation, this looks like (and actually **is**) a Free-Energy device if it is set up out of doors in daylight, as current is supplied to the load (radio, battery, fan, pump, or whatever) without the user providing any input power. Again, Power Out with no Power In. Try it in darkness and you find a different result because the whole picture is:



The energy which powers the solar panel comes from the sun.. Only some 17% of the energy reaching the solar panel is converted to electrical current. This is most definitely not a contravention of the Law of Conservation of Energy. This needs to be explained in greater detail. The Law of Conservation of Energy applies to closed systems, and only to closed systems. If there is energy coming in from the environment, then the Law of Conservation of Energy just does not apply, unless you take into account the energy entering the system from outside.

People sometimes speak of “over-unity” when talking about the efficiency of a system. From the point of efficiency, there is no such thing as “over-unity” as that would mean that more power was coming out of the system than the amount of power entering the system. Our trusty bank robber mentioned above would have to take out of the bank vault, more money than was actually in it, and that is a physical impossibility. There are always some losses in all practical systems, so the efficiency is always less than 100% of the power entering the system. In other words, the efficiency of any practical system is always under unity.

However, it is perfectly possible to have a system which has a greater power output than the power input which **we** have to put into it to make it work. Take the solar panel mentioned above. It has a terribly low efficiency of about 17%, **but**, we don’t have to supply it with any power to make it work. Consequently, when it is in sunlight, it’s Coefficient Of Performance (“COP”) is it’s output power (say, 50 watts) divided by the input power needed to make it work (zero watts) which is infinity. So, our humble, well-known solar panel has terrible efficiency of 17% but at the same time it has a COP of infinity.

It is now generally accepted that “Dark Matter” and “Dark Energy” form more than 80% of our universe. There is nothing sinister about the adjective “Dark” as in this context, it merely means that we cannot see it. There are many useful things which we utilise, which we can’t see, for example, radio waves, TV signals, magnetism, gravity, x-rays, etc. etc.

The actual situation is, that we are sitting in a vast field of energy which we can't see. This is the equivalent of the situation for the crystal set shown above, except that the energy field we are in is very, very much more powerful than the radio waves from a radio transmitter. The problem is, how to tap the energy which is freely available all around us, and get it to do useful work for us. It can definitely be done, but it is not easy to do.

Some people think that we will never be able to access this energy. Not very long ago, it was widely believed that nobody could ride a bicycle faster than 15 miles per hour because the wind pressure on the face of the rider would suffocate him. Today, many people cycle much faster than this without suffocating - why? - because the original negative opinion was wrong.

Not very long ago, it was thought that metal aircraft would never be able to fly because metal is so much heavier than air. Today, aircraft weighing hundreds of tons fly on a daily basis. Why? - because the original negative opinion was not correct.

It is probably worth while, at this point, to explain the basics of Zero-Point Energy. The experts in Quantum Mechanics refer to how the universe operates as "Quantum Foam". Every cubic centimetre of "empty" space is seething with energy, so much in fact, that if it were converted using Oliver Heaviside's equation (made famous by Albert Einstein) $E = mC^2$ (that is Energy = Mass multiplied by a very big number), then it would produce as much matter as can be seen by the most powerful telescope. There is actually nothing "empty" about space. So why can't we see anything there? Well, you can't actually see energy. All right then, why can't you measure the energy there? Well, two reasons actually, firstly, we have never managed to design an instrument which can measure this energy, and secondly, the energy is changing direction incredibly rapidly, billions and billions and billions of times each second.

There is so much energy there, that particles of matter just pop into existence and then pop back out again. Half of these particles have a positive charge and half of them have a negative charge, and as they are evenly spread out in three-dimensional space, the overall average voltage is zero. So, if the voltage is zero, what use is that as a source of energy? The answer to that is "none" if you leave it in it's natural state. However, it is possible to change the random nature of this energy and convert it into a source of unlimited, everlasting power which can be used for all of the things we use mains electricity for today - powering motors, lights, heaters, fans, pumps, ... you name it, the power is there for the taking.

So, how do you alter the natural state of the energy in our environment? Actually, quite easily. All that is needed is a positive charge and a negative charge, reasonably near each other. A battery will do the trick, as will a generator, as will an aerial and earth, as will an electrostatic device like a Wimshurst machine. When you generate a **Plus** and a **Minus**, the quantum foam is affected. Now, instead of entirely random plus and minus charged particles appearing everywhere, the **Plus** which you created gets surrounded by a sphere of minus charge particles popping into existence all around it. Also, the **Minus** which you created, gets surrounded by a spherical-shaped cloud of plus-charge particles popping into existence all around it. The technical term for this situation is "**broken symmetry**" which is just a fancy way of saying that the charge distribution of the quantum foam is no longer evenly distributed or "symmetrical". In passing, the fancy technical name for your **Plus** and **Minus** near each other, is a "**dipole**" which is just a techno-babble way of saying "two poles: a plus and a minus" - isn't jargon wonderful?

So, just to get it straight in your mind, when you make a battery, the chemical action inside the battery creates a Plus terminal and a Minus terminal. Those poles actually distort the universe around your battery, and causes vast streams of energy to radiate out in every direction from each pole of the battery. Why doesn't the battery run down? Because the energy is flowing from the environment and not from the battery. If you were taught basic physics or electrical theory, you will probably have been told that the battery used to power any circuit, supplies a stream of electrons which flows around the circuit. Sorry Chief - it just ain't like that at all. What really happens is that the battery forms a "dipole" which nudges the local environment into an unbalanced state which pours out energy in every direction, and some of that energy from the environment flows around the circuit attached to the battery. The energy does **not** come from the battery.

Well then, why does the battery run down, if no energy is being drawn from it to power the circuit? Ah, that is the really silly thing that we do. We create a closed-loop circuit (because that's what we have always done) where the current flows around the circuit, reaches the other battery terminal and immediately destroys the battery's "dipole". Everything stops dead in it's tracks. The environment becomes symmetrical again, the massive amount of readily available free-energy just disappears and you are back to where you started from. **But**, do not despair, our trusty battery immediately creates the Plus and Minus terminals again and the process starts all over again. This happens so rapidly that we don't see the breaks in the operation of the circuit and it is the continual recreation of the dipole which causes the battery to run down and lose it's power. Let me say it again, the battery

does **not** supply the current that powers the circuit, it never has and it never will - the current flows into the circuit from the surrounding environment.

What we really need, is a method of pulling off the power flowing in from the environment, without continually destroying the dipole which pushes the environment into supplying the power. That is the tricky bit, but it has been done. If you can do that, then you tap into an unlimited stream of inexhaustible energy, with no need to provide any input energy to keep the flow of energy going. In passing, if you want to check out the details of all of this, Lee and Yang were awarded the Nobel Prize for Physics in 1957 for this theory which was proved by experiment in that same year. This eBook includes circuits and devices which manage to tap this energy successfully.

Today, many people have managed to tap this energy but very few commercial devices are readily available for home use. The reason for this is human rather than technical. More than 10,000 Americans have produced devices or ideas for devices but none have reached commercial production due to opposition from influential people who do not want such devices freely available. One technique is to classify a device as "essential to US National Security". If that is done, then the developer is prevented from speaking to anyone about the device, even if he has a patent. He cannot produce or sell the device even though he invented it. Consequently, you will find many patents for perfectly workable devices if you were to put in the time and effort to locate them, though most of these patents never see the light of day, having been taken for their own use, by the people issuing these bogus "National Security" classifications.

If you feel that this opposition to free-energy and related technology is a figment of my imagination and that the people who state that more than 40,000 free-energy device patents have already been suppressed, then please consider this extract from a 2006 reminder to Patent Office staff in America to single out all patents which have to do with free-energy and any related subjects and take those patent applications to their supervisor to be dealt with differently to all other patent applications:

B. Subject matter of special interest in TC 2800

1. Perpetual motion machines; classes 310 and 290
2. Anti-gravity devices
3. Room temperature superconductivity; class 310
4. Free energy – Tachyons, etc.
5. Gain-Assisted Superluminal Light Propagation (faster than the speed of light); class 702, 359
6. Other matters that violate the general laws of physics; classes 73, 290.
7. Applications containing claims to subject matter which, if issued, would generate unfavorable publicity for the USPTO, class 84, 702.
8. Reexamination proceedings involving patents in litigation and:
   The court decision/verdict is subject to review by the Supreme Court
   The court decision includes high monetary awards
   The technology and companies involved would likely generate high publicity

Here "USPTO" is the United States Patent and Trademark Office, which is a privately owned commercial company run to make money for it's owners.

The purpose of this eBook is to present the facts about some of these devices and more importantly, where possible, explain the background details of why and how systems of that type function. As has been said before, it is not the aim of this book to convince you of anything, just to present you with some of the facts which are not that easy to find, so that you can make up your own mind on the subject.

The science taught in schools, colleges and universities at this time, is well out of date and in serious need of being brought up to date. This has not happened for some time now as people who make massive financial profits have made it their business to prevent any significant advance for many years now. However, the internet and free sharing of information through it, is making things very difficult for them. What is it that they don't want you to know? Well, how about the fact that you don't have to burn a fuel to get power? Shocking, isn't it !! Does it sound a bit mad to you? Well, stick around and start doing some thinking.

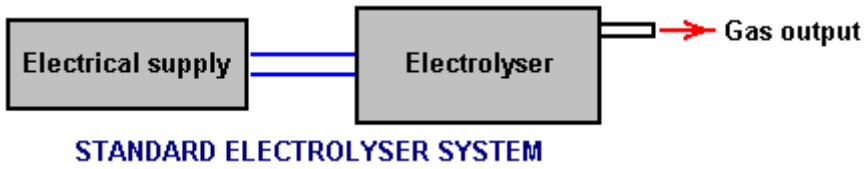
Suppose you were to cover a boat with lots of solar panels which were used to charge a large bank of batteries inside the boat. And if those batteries were used to operate electric motors turning propellers which drive the boat along. If it is sunny weather, how far could you go? As far as the boat can travel while the sun is up and if the battery bank is large, probably most of the night as well. At sun-up on the next day, you can continue your journey. Oceans have been crossed doing this. How much fuel is burned to power the boat? None !! Absolutely none at all. And yet, it is a fixed idea that you have to burn a fuel to get power.

Yes, certainly, you can get power from the chemical reaction of burning a fuel - after all, we pour fuel into the tanks of vehicles "to make them go" and we burn oil in the central heating systems of buildings. But the big question is: "Do we have to?" and the answer is "No". So why do we do it? Because there is no alternative at present. Why is there no alternative at present? Because the people making incredibly large financial profits from selling this fuel, have seen to it that no alternative is available. We have been the suckers in this con trick for decades now, and it is time for us to snap out of it. Let's have a look at some of the basic facts:

Let me start by presenting some of the facts about electrolysis. The electrolysis of water is performed by passing an electric current through the water, causing it to break up into hydrogen gas and oxygen gas. This process was examined in minute detail by Michael Faraday who determined the most energy efficient possible conditions for electrolysis of water. Faraday determined the amount of electric current needed to break the water apart, and his findings are accepted as a scientific standard for the process.

We now bump into a problem which scientists are desperate to ignore or deny, as they have the mistaken idea that it contradicts the Law of Conservation of Energy – which, of course, it doesn't. The problem is an electrolyser design by Bob Boyce of America which appears to have an efficiency twelve times greater than Faraday's maximum possible gas production. This is a terrible heresy in the scientific arena and it gets the average "by the book" scientist very up-tight and flustered. There is no need for this worry. The Law of Conservation of Energy remains intact and Faraday's results are not challenged. However, an explanation is called for.

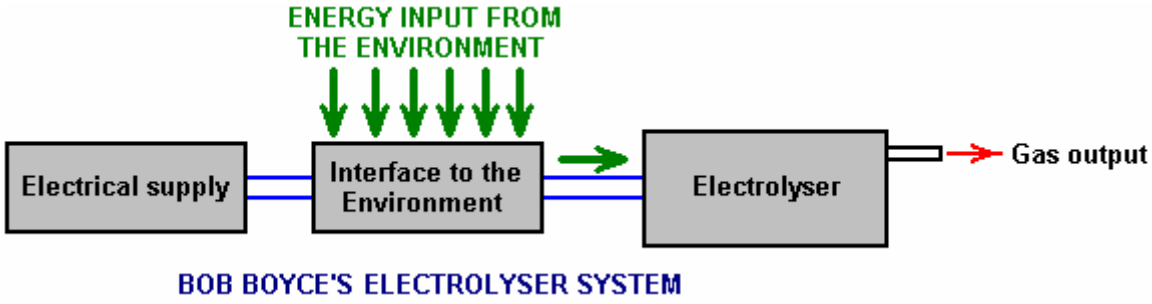
To start with, let me show the arrangement for a standard electrolyser system:



STANDARD ELECTROLYSER SYSTEM

Here, current is supplied to the electrolyser by the electrical supply. The current flow causes breakdown of the water contained in the electrolyser, resulting in the amount of gas predicted by Faraday (or less if the electrolyser is not well designed and accurately built).

Bob Boyce, who is an exceptionally intelligent, perceptive and able man, has developed a system which performs the electrolysis of water using power drawn from the environment. To a quick glance, Bob's design looks pretty much like a high-grade electrolyser (which it is) but it is a good deal more than that. The practical construction and operational details of Bob's design are shown in http://www.free-energy-info.tuks.nl/D9.pdf, but for here, let us just consider the operation of his system in very broad outline:



BOB BOYCE'S ELECTROLYSER SYSTEM

The very important distinction here is that the power flowing into the electrolyser and causing the water to break down and produce the gas output, is coming almost exclusively from the environment and **not** from the electrical supply. The main function of Bob's electrical supply is to power the device which draws energy in from the environment. Consequently, if you assume that the current supplied by the electrical supply is the whole of the power driving the electrolyser, then you have a real problem, because, when properly built and finely tuned, Bob's electrolyser produces up to 1,200% of Faraday's maximum efficiency production rate.

This is an illusion. Yes, the electrical input is exactly as measured. Yes, the gas output is exactly as measured. Yes, the gas output is twelve times the Faraday maximum. But Faraday's work and the Law of Conservation of Energy are not challenged in any way **because** the electrical current measured is used primarily to power the interface to the environment and nearly all of the energy used in the electrolysis process flows in from the local environment and is not measured. What we can reasonably deduce is that the energy inflow from the environment is probably about twelve times the amount of power drawn from the electrical supply.

At this point in time, we do not have any equipment which can measure this environmental energy. We are in the same position as people were with electrical current five hundred years ago – there was just no equipment around which could be used to make the measurement. That, of course, does not means that electrical current did not exist at that time, just that we had not developed any equipment capable of performing measurement of that current. Today, we know that this environmental energy exists because we can see the effects it causes such as running Bob's electrolyser, charging batteries, etc. but we can't measure it directly because it vibrates at right-angles to the direction that electrical current vibrates in. Electrical current is said to vibrate "transversely" while this zero-point energy vibrates "longitudinally", and so has no effect on instruments which respond transversely such as ammeters, voltmeters, etc.

Bob Boyce's 101-plate electrolyser produces anything up to 100 litres of gas per minute, and that rate of production is able to power internal combustion engines of low capacity. The vehicle alternator is perfectly capable of powering Bob's system, so the result is a vehicle which appears to run with water as the only fuel. This is not the case, nor is it correct to say that the engine is powered by the gas produced. Yes, it does utilise that gas when running, but the power running the vehicle is coming directly from the environment as an inexhaustible supply. In the same way, a steam engine does not run on water. Yes, it does utilise water in the process, but the power that runs a steam engine comes from burning the coal and not from the water.

The Basics of "Free-Energy":

This beginner's introduction presumes that you have never heard of free-energy before and would like an outline sketch of what it is all about, so let's begin at the beginning.

We tend to have the impression that people who lived a long time ago were not as clever as we are - after all, we have television, computers, mobile phones, games consoles, aeroplanes, …. But, and it is a big "but", the reason why they did not have those things is because science had not advanced far enough for those things to become possible. That did **not** mean that the people who lived before us were any less clever than we are.

For example, could you, personally, come up with an accurate calculation of the circumference of the Earth? This has to be without prior knowledge, no satellites, no astronomical information, no calculators, no computers and no experts to guide you. Eratosthenes did by observing the shadows in two wells some 800 kilometres apart. When was that? More than two thousand years ago.

You have probably heard of the geometry of Pythagoras who lived hundreds of years before Eratosthenes, and that geometry is still used in remote areas to lay out the foundations for new buildings. You have probably heard of Archimedes who worked out why things float. He lived more than two thousand years ago. So, how do those people stack up against you and me? Were they stupid people?

This is quite an important point because it demonstrates that the body of scientific information enables many things which were not thought possible in earlier times. This effect is not restricted to centuries ago. Take the year 1900. My father was a youngster then, so it is not all that long ago. It would be another three years before Orville and Wilbur Wright made their first 'heavier-than-air' flight, so there no aircraft around in 1900. There were no radio stations and most definitely, no television stations, nor would you have found a telephone inside a house. The only serious forms of information were books and periodicals or teaching establishments which relied on the knowledge of the teachers. There were no cars and the fastest form of transport for the average person was on a galloping horse.

Today, it is difficult to grasp what things were like not all that long ago, but come closer in time and look back just fifty years. Then, people researching in scientific fields had to design and build their own instruments before they ever got to experimenting in their chosen fields of knowledge. They were instrument makers, glass-blowers, metal workers, etc. as well as being scientific researchers. Nowadays there are measuring instruments of all

kinds for sale ready-made. We have silicon semiconductors which they didn't have, integrated circuits, computers, etc. etc.

The important point here is the fact that advances in scientific theory have made possible many things which would have been considered quite ridiculous notions in my father's time. However, we need to stop thinking as if we already know everything there is to know and that nothing which we think of as "impossible !!" could ever happen. Let me try to illustrate this by remarking on just a few things which as recently as the year 1900 would have marked you out as a "lunatic crank", things which we take for granted today because, and only because, we are now familiar with the science behind each of these things.

Certainties in the year 1900

A metal aeroplane weighing 350 tons couldn't possibly fly - everyone knows that !!

You couldn't possibly watch someone who is a thousand miles away - talk sense !!

No ! Of course you can't speak to somebody who lives in a different country unless you visit them !

The fastest way to travel is on a galloping horse.

A machine could never beat a man at chess - be realistic !

Today, we know that these things are not just possible, but we take them for granted. We have a mobile phone in our pocket and could easily use it to talk to friends in other countries almost anywhere in the world. It would seem very strange if we could not do that any more.

We each have a television and can watch, say, a golf tournament taking place at the other side of the world. We watch in real time, seeing the result of each stroke almost as soon as the golfer does himself. Even suggesting that such a thing was possible might have got you burnt at the stake for witchcraft, not all that long ago, but not having television would seem a very strange situation for us today.

If we see a 350 ton metal Boeing 747 aircraft flying past, we would not think it to be strange in any way, let alone think it was "impossible". It is routine, casual travel at 500 mph, a speed which would have been considered to be a fantasy when my father was young. The fact that the aircraft is so heavy, is of no concern to us as we know that it will fly, and does so, routinely, every day of the year.

We take for granted, a computer which can do a million things in one second. Today, we have lost the understanding of how big "a million" is, and we know that most people are likely to lose a game of chess if they play against a computer, even a cheap chess computer.

What we need to understand is that our present scientific knowledge is far from being comprehensive and there is still a very large amount to be learned, and that things which the average person today would consider "impossible" are quite liable to be casually routine day-to-day devices in just a few years time. This is **not** because we are stupid but instead it is because our current science still has a long way to go.

The objective of this website (http://www.free-energy-info.tuks.nl) is to explain some of the things which current science is not teaching at the present time. Ideally, we want a device which will power our homes and cars without the need to burn a fuel of any kind. Before you get the idea that this is some new and wild idea, please remember that windmills have been pumping water, milling grain, lifting heavy loads and generating electricity for a very long time now. Water wheels have been doing similar work for a very long time and both of these devices are fuel-less.

The energy which powers windmills and water wheels comes to us via our Sun which heats air and water, causing wind and rain, feeding power to our devices. The energy flows in from our local environment, costs us nothing and will keep on coming whether we make use of it or not.

Most of the pictures of wind generators and water wheels which you will see, show devices which would take a large amount of money to set up. The title of this eBook is "The Practical Guide to Free-Energy Devices" and the word "practical" is intended to indicate that most of the things spoken about are things which you, personally, have a reasonable chance of constructing for yourself if you decide to do so. However, while in chapter 14 there are instructions for building your own wind-powered electrical generator from scratch, pumping water uphill without using a fuel and utilising wave power at low cost, these things are subject to the weather. So, because of this, the main subject is the next generation of commercial devices, devices which do not need a fuel in order to function and power our homes and vehicles, devices which operate no matter what the weather is doing.

Perhaps I should remark at this point, that the commercial introduction of this new wave of hi-tech devices is being actively opposed by people who will lose a very large stream of revenue when it does eventually happen, as it most certainly will. For example, Shell BP which is a typical oil company, makes about US $3,000,000 profit per hour, every hour of every day of every year, and there are dozens of oil companies. The government makes even more than that out of the operation, with 85% of the sale price of oil in the UK being government tax. No matter what they say, (and they both do like to talk "green" in order to gain popularity), neither would ever for a single moment, consider allowing the introduction of fuel-less power devices, and they have the financial muscle to oppose this new technology at every possible level.

For example, some years ago Cal-Tech in the USA spent millions proving that on board fuel reformers for vehicles would give us all better fuel economy and cleaner air. They did long-term testing on buses and cars to provide proof. They teamed up with the very large auto-parts supplier Arvin Meritor to put these new devices in production vehicles. Then "One Equity Partners" bought out Arvin Meritor's division that did all the final work to get fuel reformers put into all new vehicles. They created a new company, EMCON Technologies, and that company dropped the fuel reformer from their product line, not because it did not work, but because it **did** work. This is not "conspiracy theory" but a matter of public record.

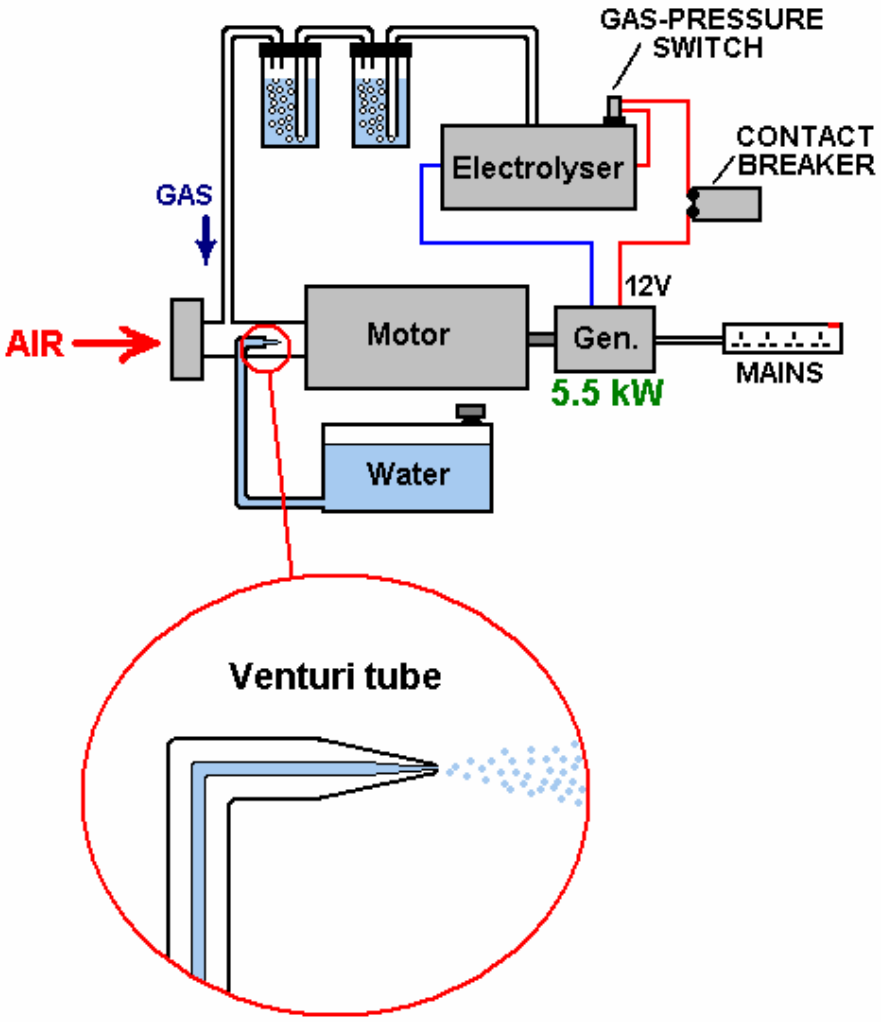
Some years ago, Stanley Meyer, a very talented man living in America, found a very energy-efficient way of breaking water into a mixture of hydrogen gas and oxygen gas. He pushed on further and found that a vehicle engine could be run on quite a small amount of this "HHO" gas if it was mixed with air, water droplets and some of the exhaust gas coming from the engine. He got funding to allow him to start manufacturing retro-fit kits which would allow any car to run on water alone and not use any fossil fuel at all. You can imagine how popular that

would have been with the oil companies and the government. Just after getting his funding, Stan was eating a meal at a restaurant when he jumped up, said "I've been poisoned !", rushed out into the car park and died on the spot. If Stan was mistaken, and he died of 'natural causes', then it was remarkably convenient timing for the oil companies and the government, and his retro-fit kits were never manufactured.

Even though Stan left behind many patents on the subject, until recently nobody managed to replicate his very low-power electrolyser, then Dave Lawton in Wales achieved the feat and many people have since replicated it by following Dave's instructions. More difficult still is getting an engine to run on no fossil fuel as Stan did, but recently, three men in the UK achieved just that by getting a standard petrol-engined electrical generator to run with water as the only fuel. Interestingly, this is not something which they want to pursue as they have other areas which appeal more to them. Consequently, they have no objections to sharing the practical information on what they did and the details are in chapter 10.

In very brief outline, they took a standard 5.5 kilowatt generator and delayed the spark timing, suppressed the 'waste' spark and fed the engine a mix of air, water droplets and just a small amount of HHO gas (which they measured at a flow rate of just three litres per minute). They test-loaded the generator with four kilowatts of electrical equipment to confirm that it worked well under load, and then moved on to a larger engine. This is the general style of generator which they used:

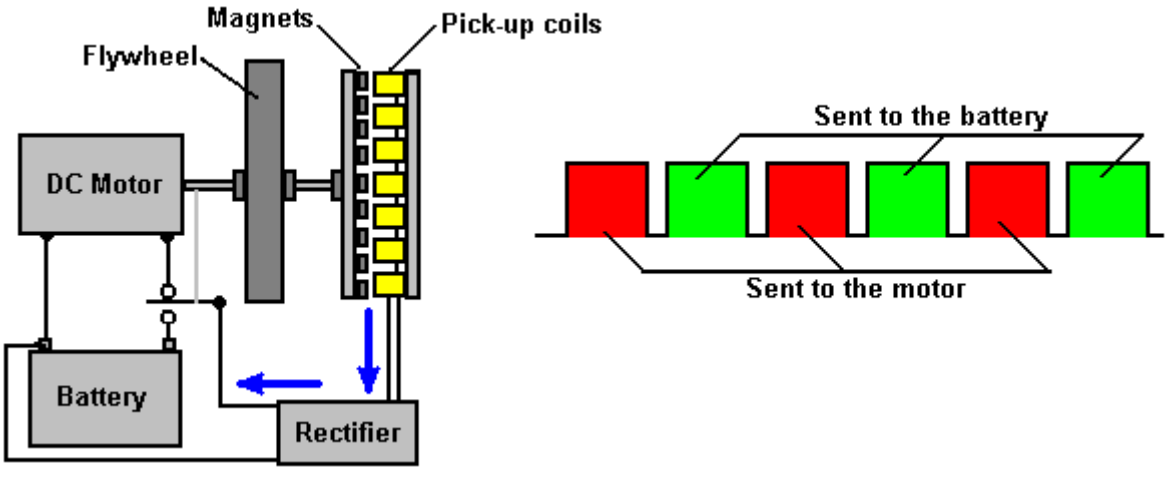
And their arrangement for running it without petrol, is shown in outline here, the full details being in chapter 10, including how to make your own high-performance electrolyser:



Conventional science says that it can prove mathematically that it is quite impossible to do this. However, the calculation is massively flawed in that is not based on what is actually happening and worse still, it makes initial assumptions which are just plain wrong. Even if we were not aware of these calculations, the fact that it has been done is quite enough to show that the current engineering theory is out of date and needs to be upgraded.

In passing, it might be remarked that an isolated, almost self-sufficient commune in Australia has been supplying their electrical needs by running ordinary electrical generators on water as the only (apparent) fuel for many years now.

However, let us now consider a device built by John Bedini, another talented man in America. He built a battery-powered motor with a flywheel on the shaft of the motor. This, of course, does not sound like startling stuff, but the crunch is that this motor ran in his workshop for more than three years, keeping it's battery fully charged during that time - now that **is** startling. The arrangement is like this:

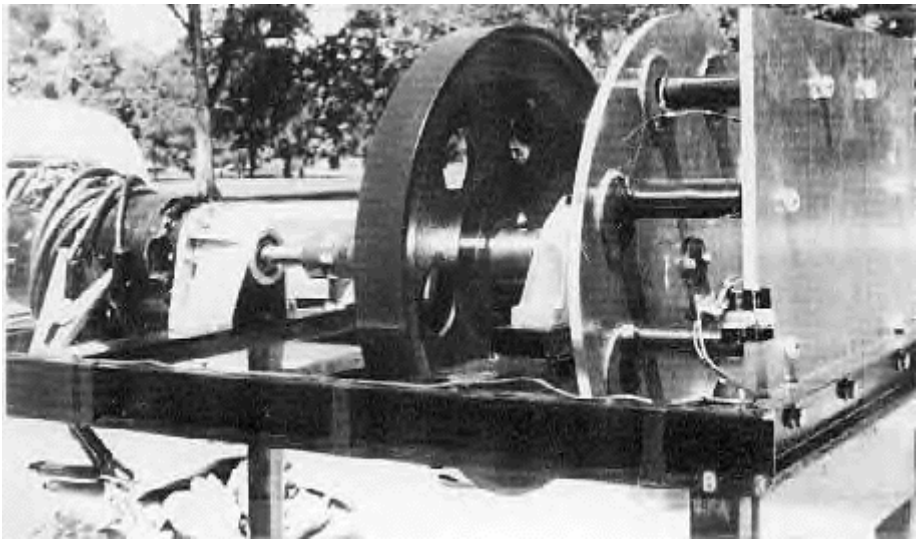


What makes this arrangement different from a standard set-up is that the battery powered motor is not connected directly to the battery but instead is fed with a rapid series of DC pulses. This has two effects. Firstly, that method of driving a motor is very efficient electrically speaking and secondly, when a flywheel is driven with a series of pulses, it picks up additional energy from the local environment.

One other unusual feature is the way that the motor shaft spins a disc with permanent magnets mounted on it. These sweep past a matching set of coils attached to a stationary board, forming an ordinary electrical generator and the resulting electrical power which is generated is converted to DC current and fed back to the driving battery, charging it and maintaining its voltage.

Standard theory says that a system like this has to be less than 100% efficient because the DC motor is less than 100% efficient (true) and the battery is only about 50% efficient (true). Therefore, the conclusion is that the system cannot possibly work (false). What is not understood by conventional science is that the pulsed flywheel draws in additional energy from the local environment, showing that conventional science theory is inadequate and out of date and needs to be upgraded, after all, this is not a ‘closed system’.

An American called Jim Watson built a much larger version of John's system, a version which was twenty feet (6 meters) long. Jim's version not only powered itself, but generated 12 kilowatts of excess electrical power. That extra 12 kilowatts of power must be a considerable embarrassment for conventional science and so they will either ignore it, or deny that it ever existed, in spite of the fact that it was demonstrated at a public seminar. This is what Jim's device looked like:



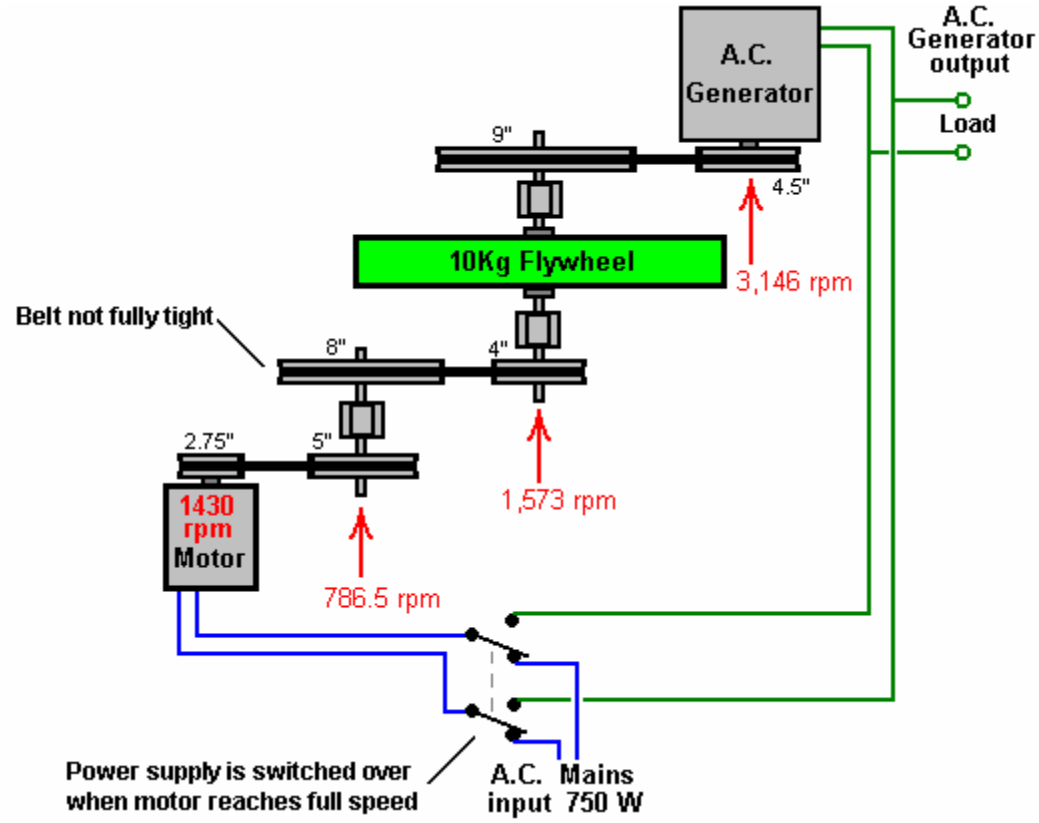
Working quite independently, an Australian called Chas Campbell, discovered the same effect. He found that if he used an AC motor plugged into the mains to drive a flywheel which in turn drove an ordinary generator, that it was possible to get a greater power output from the generator than the amount needed to drive the motor.

Chas used his motor to drive a series of shafts, one of which has a heavy flywheel mounted on it, like this:

The final shaft drives a standard electrical generator and Chas found that he could power electrical equipment from that generator, electrical mains equipment which required greater current that his mains-driven motor did.

Chas then took it one stage further and when the system was running at full speed, he switched his mains motor over from the wall socket to his own generator. The system continued to run, powering itself and driving other equipment as well.

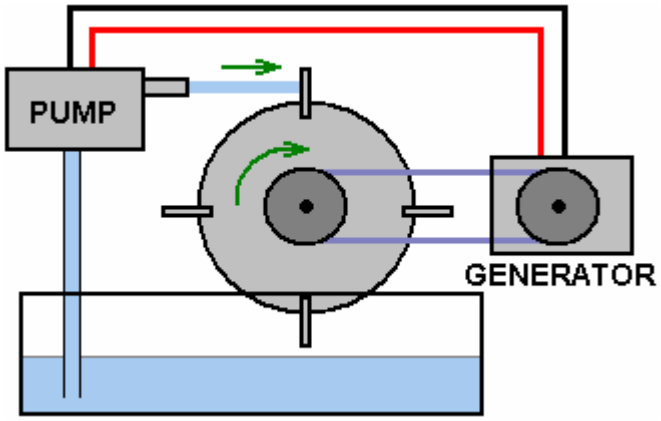
Conventional science says that this is impossible, which just goes to show that conventional science is out of date and needs to be upgraded to cover system like this where excess energy is flowing in from the local environment. Here is a diagram of how Chas Campbell's system is set up:



James Hardy has put a video on the web, showing a variation of this same principle. In his case, the flywheel is very light and has simple paddles attached around the rim of the wheel:

He then aims a powerful jet of water from a high-powered water pump, directly at the paddles, driving the wheel round with a rapid series of pulses. The shaft, on which the wheel is mounted, drives a standard electrical generator which lights an ordinary light bulb:

The really interesting part comes next, because he then unplugs the electrical supply to the water pump and switches it over to the generator which the wheel is driving. The result is that the pump powers itself and provides excess electricity which can be used to power other electrical equipment. The arrangement is like this:



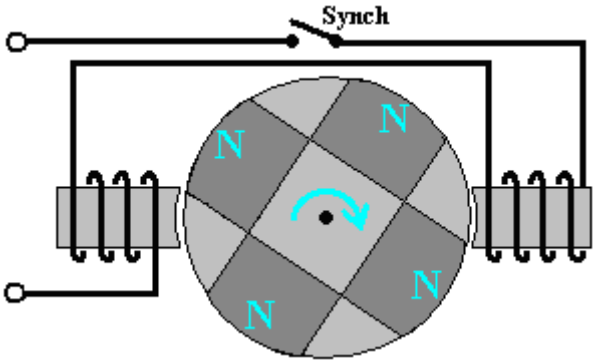
Once again, conventional science says that this is impossible, which in turn, demonstrates that conventional science is out of date and needs to be expanded to include these observed facts.

Permanent Magnets provide continuous power. This is because the poles of the magnet form a dipole, unbalancing the zero-point energy field near the magnet, and causing a continuous flow of energy which we call “lines of magnetic force”. This should be obvious as a magnet can support its own weight on the vertical face of a

refrigerator, for years on end. Conventional science says that permanent magnets can't be used as a source of power. However, the reality is that conventional science just doesn't know the techniques necessary for extracting that power. The lines of magnetic flow around any magnet are symmetrical and in order for a magnet to provide a useful directional force, it is necessary to arrange magnets in such a way that their combined magnetic field is no longer symmetrical. Doing that is not easy, but there are many alternative methods. Magnets are attracted to iron and that principle along with several other techniques have been successfully use by the New Zealander, **Robert Adams** who produced a motor which is, typically, at least 800% efficient. This, of course, is impossible according to conventional science. Robert was told that if he shared the information, he would be killed. He decided that at his age, being killed was not a major thing, so he went ahead and published all the details.

Present day motors driven by electricity are always less than 100% efficient as they are deliberately wound in a symmetrical way in order to make them inefficient. The Adams motor looks like a motor driven by electrical pulses, but it is **not**. The motor power comes from the permanent magnets mounted on the rotor and not from an electrical pulse applied to the electromagnets attached to the stator. The magnets are attracted to the metal cores of the stationary electromagnets. This provides the driving power of the motor. The electromagnets are then powered just enough to overcome the backwards drag of the magnets when they have just passed by the cores of the electromagnets.

The system works like this:



1. The magnets are attracted to the iron cores of the electromagnets, rotating the drive shaft and powering the motor.

2. The moving magnets generate electrical power in the windings of the electromagnets and this power is used to charge the driving battery.

3. When the permanent magnets reach the electromagnets, a small amount of electrical power is fed to the windings of the electromagnets in order to overcome any backward pull hindering the rotation of the drive shaft.

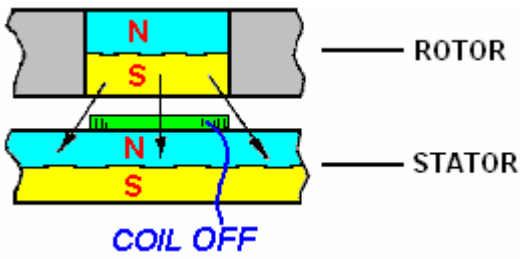
4. When that power supplied to the electromagnets is cut off, the Back EMF pulse is captured and used to charge the driving battery.

5. Although not shown in the diagram above, there are normally additional pick-up coils mounted round the rotor and if they are connected briefly at the right moment, they generate extra current and when they are switched off, their resulting reversed magnetic field also boosts the rotor on it's way, and that can raise the COP over 1000. One replication using this technique has an electrical input of 27 watts and a 32 kilowatt output.

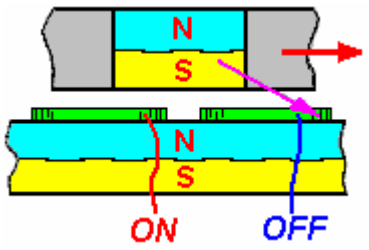
When operated in this way, the Adams Motor has a power output far in excess of the input power needed to make it run. The design confuses conventional science because conventional science refuses to accept the concept of energy flow into the motor, from the local environment. This is all the more strange, considering that windmills, water wheels, hydro-electric schemes, solar panels, wave-power systems, tidal power systems and geothermal energy systems are accepted and considered perfectly normal, in spite of the fact that they all operate on energy flowing in from the local environment. It is difficult to avoid the conclusion that vested interests are working hard to prevent conventional science accepting the fact that free-energy is all around us and there for the taking. Perhaps it is the case that they want us to go on paying for fuel to burn to "make" energy to power our homes and vehicles.

Another example of magnet power being used in the design of a powerful motor comes from **Charles Flynn**. He uses a similar method of electrical screening to prevent magnetic drag hindering the drive shaft rotation. Instead

of using electromagnets, Charles uses permanent magnets on both the rotor and the stator, and a flat coil of wire to create the blocking fields:

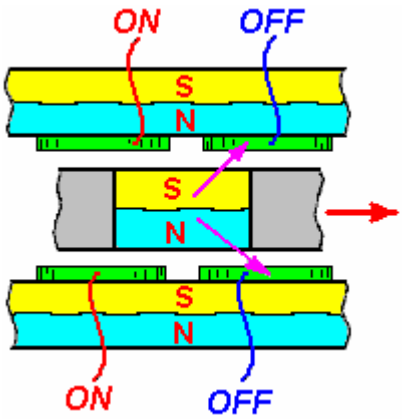


When the coil does not have current flowing through it, it does not produce a magnetic field and the South pole of the rotor magnet is attracted equally forwards and backwards by the North pole of the stator magnet. If there are two coils as shown below, and one is powered and the other is not powered, the backward pull is cancelled out and the forward pull causes the rotor to move forwards:

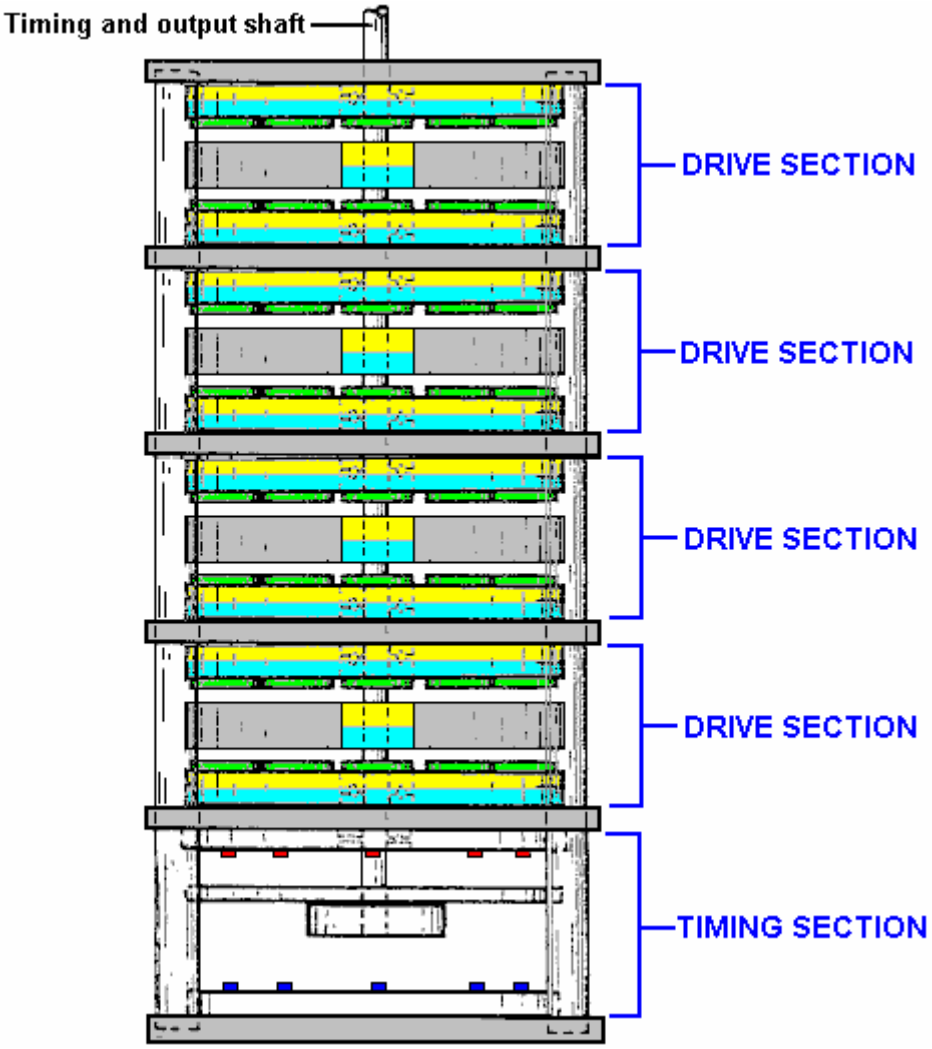


Conventional science takes a quick glance at this arrangement and proclaims that the motor efficiency has to be less than 100% because of the large electrical pulse needed to make the shaft turn. This just demonstrates a complete lack of understanding of how the motor operates. There is no "large electrical pulse" because the motor is **not** driven by electrical pulses, but instead it is driven by the attraction of many pairs of magnets, and only a very small electrical pulse is applied to cancel the backward drag as the magnets move past. To put this in context, the powerful prototype motor built by Charles ran at 20,000 rpm and the power for the coils was supplied by an ordinary 9-volt "dry-cell" battery quite incapable of supplying heavy currents.

The motor is easily made more powerful by using a stator magnet on both side of the rotor magnet, as shown here:



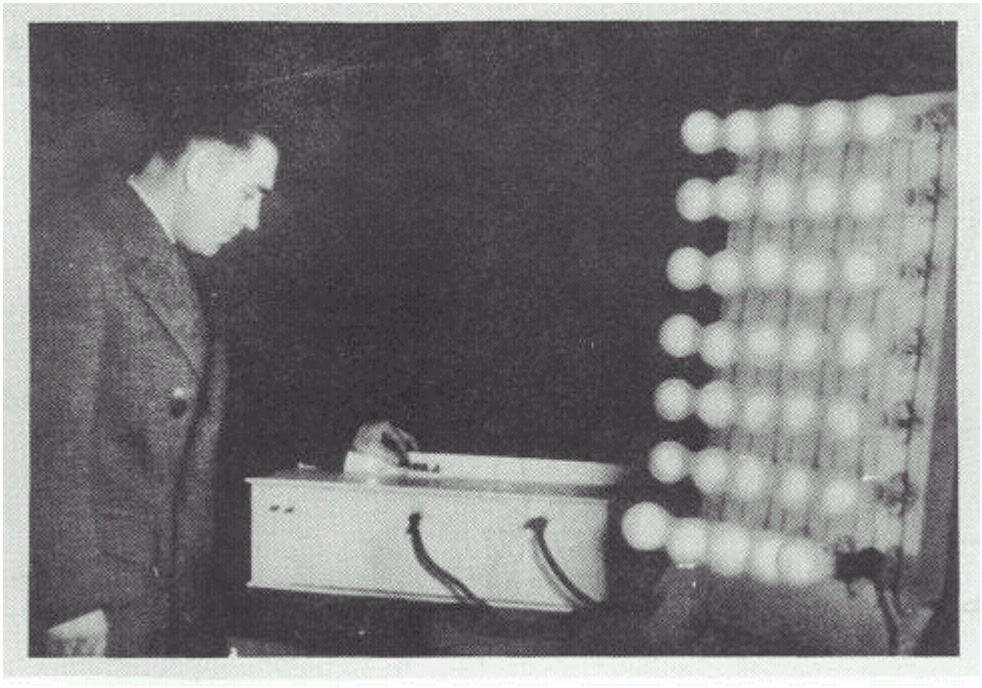
There is no real limit to the power of this motor as layer after layer of magnets can be mounted on a single drive shaft as shown here:



The electrical pulses to the screening coils can be synchronised by the light from Light-Emitting Diodes mounted in the timing section, shining through holes in a timing disc attached to the drive shaft of the motor. The light falling on light-dependant resistors on the other side of the disc, provide the switching for the coil-powering electricity.

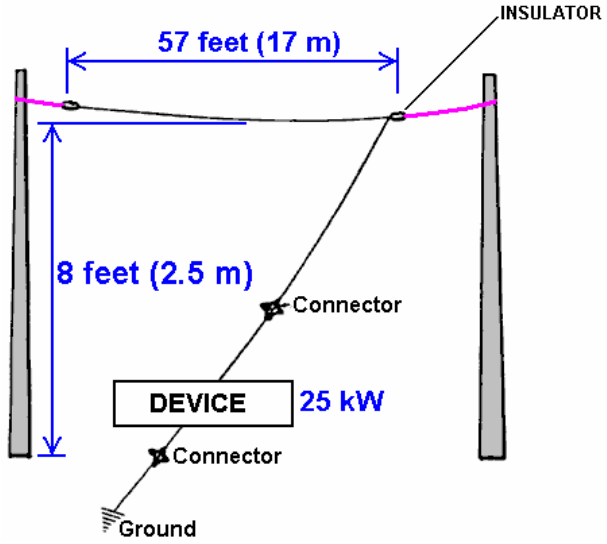
Aerial systems. We are surrounded by so much energy that a simple aerial and earth connection can draw in very large amounts of electrical power from the local environment.

Thomas Henry Moray ran frequent public demonstrations during which he lit banks of light bulbs to show that useful amounts of energy could be drawn from the environment:



Moray's device could produce output powers up to fifty kilowatts and it had no moving parts, just a simple aerial and an earth. In spite of the frequent demonstrations, some people would not believe that this was not a hoax, so Moray invited them to choose a place and he would demonstrate the power available at any location they wanted.

They drove fifty miles out into the countryside and picked a really isolated spot away from all power lines and the very few commercial radio stations in the area. They set up a very simple aerial estimated by one observer to be just fifty seven feet long and only seven or eight feet off the ground at its lowest point:



The earth connection was an eight-foot length of gas pipe which was hammered into the ground. There is no significance in the earth connection being a gas pipe, as that was used just because it was to hand at the time. The bank of lights being powered by Moray's device, grew brighter as the gas pipe was driven further and further into the ground, providing a better and better earth connection. Moray then demonstrated that when the aerial was disconnected, the lights went out. When the aerial was connected again, the lights were lit again. He then disconnected the earth wire and the lights went out and stayed out until the earth wire was connected again. The sceptics were completely convinced by the demonstration (which is most unusual for sceptics as sceptics often refuse to accept anything which contradicts their current beliefs).

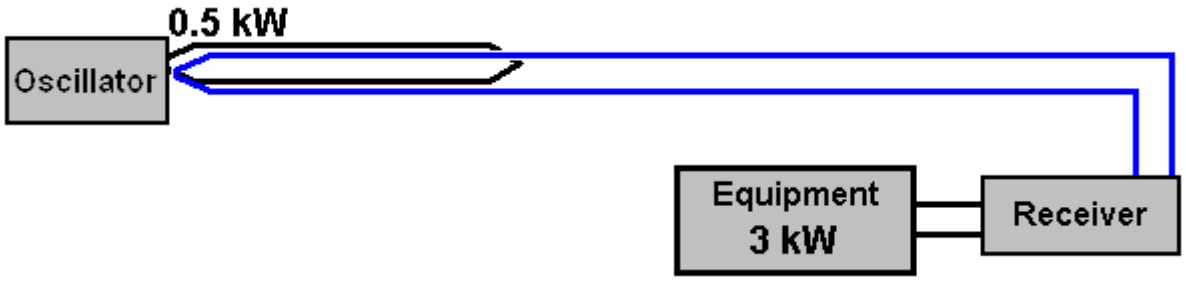
Moray's is one of several excellent and very successful devices which I can't tell you exactly how to replicate (because the details were never revealed and Moray was intimidated into silence) but the important point here is that a 57-foot aerial raised just 8-feet from the ground can provide kilowatts of electrical power at any location, if you know how to do it.

Moray's demonstrations were highly unpopular with some people and he was shot at in his car. He put bullet-proof glass in his car, so they came into his laboratory and shot at him there. They succeeded in intimidating him into stopping his demonstrations or publishing the exact details of how to replicate his aerial power system.

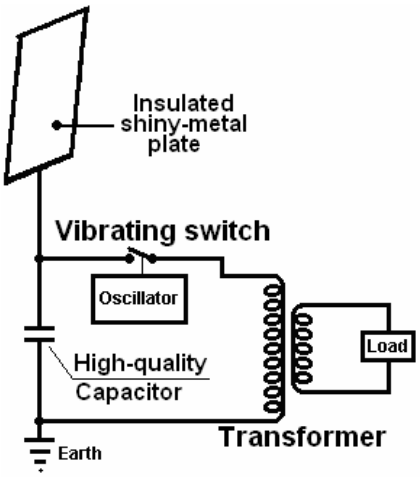
Lawrence Rayburn has recently developed an aerial system with one part raised thirty feet above the ground. He powers his farm with it and has measured more than 10 kilowatts being drawn from it.

Hermann Plauson has a patent which reads more like a tutorial on how to extract useful power from an aerial. He describes installations where one producing 100 kilowatts of excess power he calls a "small" system.

Frank Prentice has a patent on an 'aerial' system where he drives a wire loop alongside a long length of wire mounted just seven or eight inches (200 mm) above the ground. His input power is 500 watts and the power drawn from the system is 3,000 watts, giving an excess of 2.5 kilowatts (COP=6):

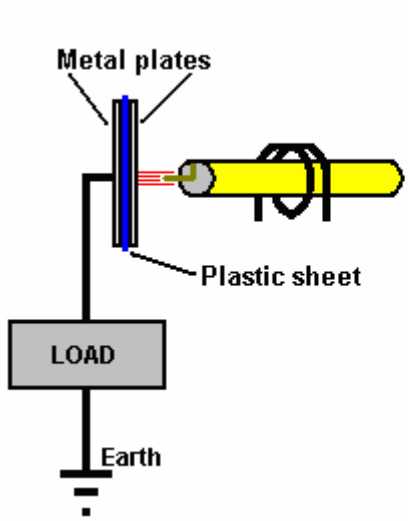


Nikola Tesla, probably the most famous person in the free-energy field, has a patent on an aerial system which uses a shiny metal plate with insulated faces as the main component of his aerial. As is common in this field, a high-quality capacitor is used to store the energy initially and then that power is pulsed through a step-down transformer which lowers the voltage and raises the current available, as shown here:

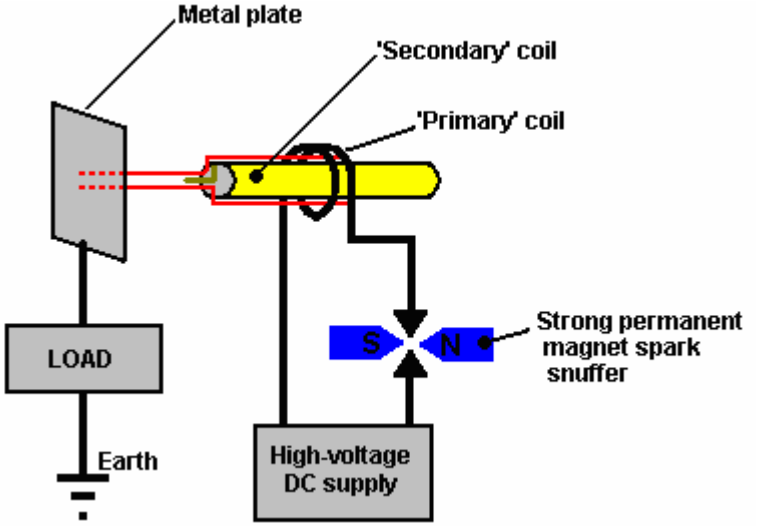


Instead of using an aerial, it is possible to use a **Tesla Coil** which produces very high currents **if** the primary winding is placed in the middle of the secondary winding and not at one end which is the usual configuration. With one method, Tesla directs the output on to a single metal plate and powers a load between the plate and the earth.

Don Smith demonstrates this in a video currently on YouTube. He uses a capacitor made from two metal plates with a sheet of plastic between them, instead of Tesla's insulated single plate. The load is powered between the capacitor and earth. The video shows Don using a 28-watt hand-held Tesla Coil and producing what looks like several kilowatts of power in the earth line.



Don Smith



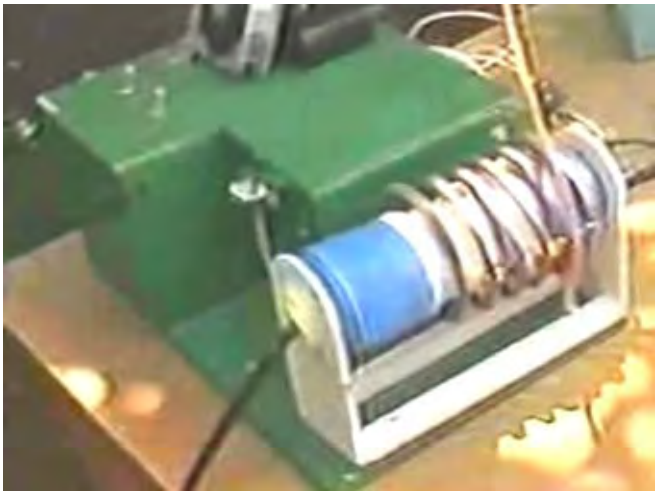
Nikola Tesla

Don points out that the output power is proportional to the **square** of the voltage and the **square** of the frequency: So if you double the frequency and double the voltage there will be 16 times as much output power.

Tariel Kapanadze demonstrates this in a web video of his interview for Turkish TV. It shows him making an earth connection by burying an old car radiator, and then lighting a row of light bulbs from a Tesla Coil style fuel-less device. While the commentary is not in English, the video is very informative. You will notice that this is a substantial power output coming from a device built with a very basic style of construction where bare wires are twisted together to form an electrical connection.

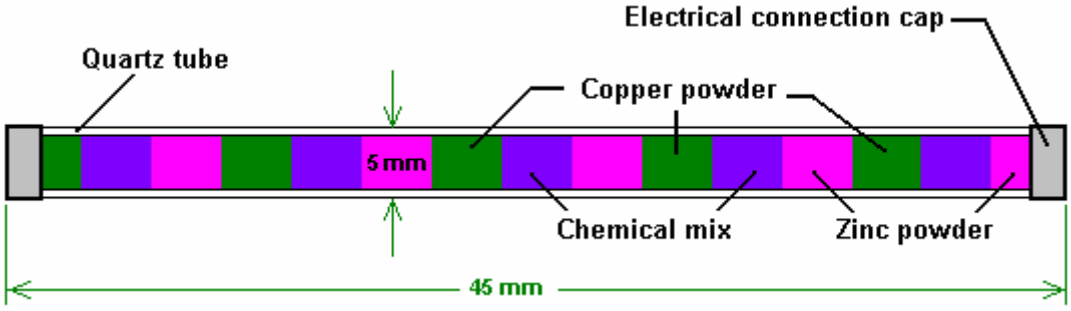
When the starting battery is removed, the equipment is held in the air to show that it is self-contained and self-powered. This is another confirmation that free-energy is all around us and ready to be taken by anyone who knows how. Tariel is seen here lighting a row of five light bulbs hanging from a broom handle placed across the backs of two chairs - not exactly a high-tech, high-cost form of construction this!

This is a picture of his circuit housing, spark gap and output transformer:



However, I can't provide you with the exact details as Tariel has never revealed how he does it and there is every indication that he never will. He says that if he told how it worked, then "you would laugh as it is so simple".

The **Colman / Seddon-Gillespie** 70-year battery. A quite different approach to getting fuel-less power was taken by Colman and Seddon-Gillespie who developed a tiny tube of harmless chemicals - copper, zinc and cadmium:

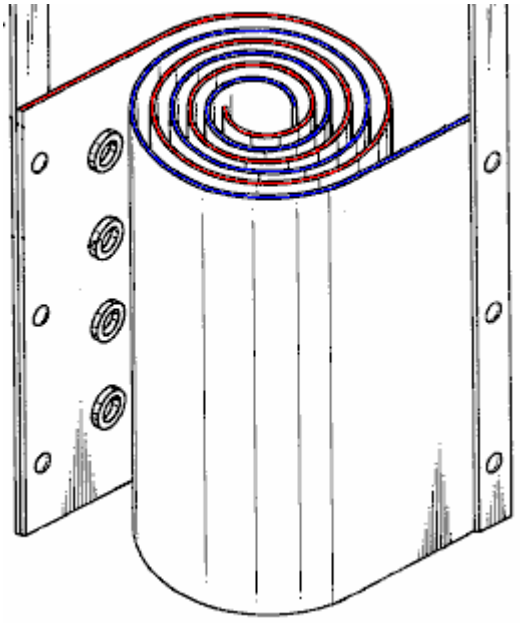


They found that if his tube was subjected to a few seconds of high-frequency electromagnetic radiation, then it became radioactive for about one hour. During that time, a kilowatt of electrical power could be drawn from this tiny tube. Near the end of the hour, another burst of electromagnetic waves keeps the tube radioactive and maintains the output current. Lead shielding is used to make this a safe device. They have a patent on this device. The expected working life of one of these tubes is estimated as being seventy years.

Electrolysis. Michael Faraday did a really excellent job of investigating how much energy was required to change water from it's liquid state into a mixture of hydrogen gas and oxygen gas. Conventional science has latched on to this information and refuses to believe that it is not the last possible word on electrolysis.

This is akin to saying that the fastest a man can propel himself over the ground is by running, and refusing to accept the fact that there might be a later invention of a bicycle which would allow a much faster human-powered speed over the ground.

This is maintained in spite of the fact that a patent has been awarded to **Shigeta Hasebe** for a different style of electrolysis, using magnets and spiral electrodes like this:



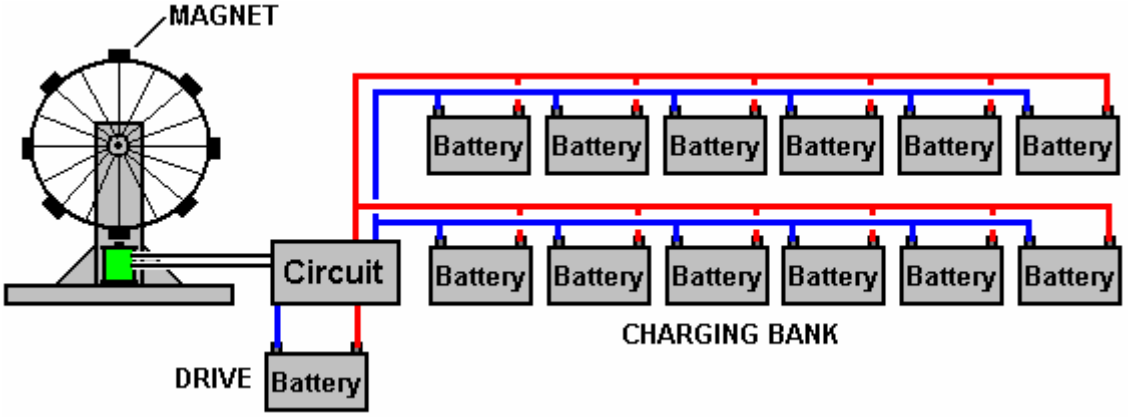
In his patent, Shigeta indicates his disappointment that his laboratory tests only showed an efficiency of ten times greater than that of Faraday while his calculations showed that he could be getting twenty times the Faraday result. The different method, along with the use of powerful magnets at the top and bottom of his electrode pairs, bypassed the limits which Faraday had established by changing the working conditions.

Stanley Meyer of the USA discovered a method of splitting water into it's gas form, using very little power. Stan's work has been replicated by Dave Lawton and many other people. For example, Dr Scott Cramton has produced the "HHO" gas mix produced by the electrolysis of water, at a rate of 6 litres per minute with a power input of just 36 watts (12 volts at 3 amps). This is dramatically better than Faraday thought was possible and it allows power production through recombining the hydroxy gas to give water again, as the power produced is well above the amount of power needed to split the water in the first place. It should be remarked in passing, that most of the power produced when HHO is recombined into water, does not come from the hydrogen (even though in its HHO form it is typically four time more energetic than hydrogen gas), but from charged water clusters which are generated during the electrolysis process.

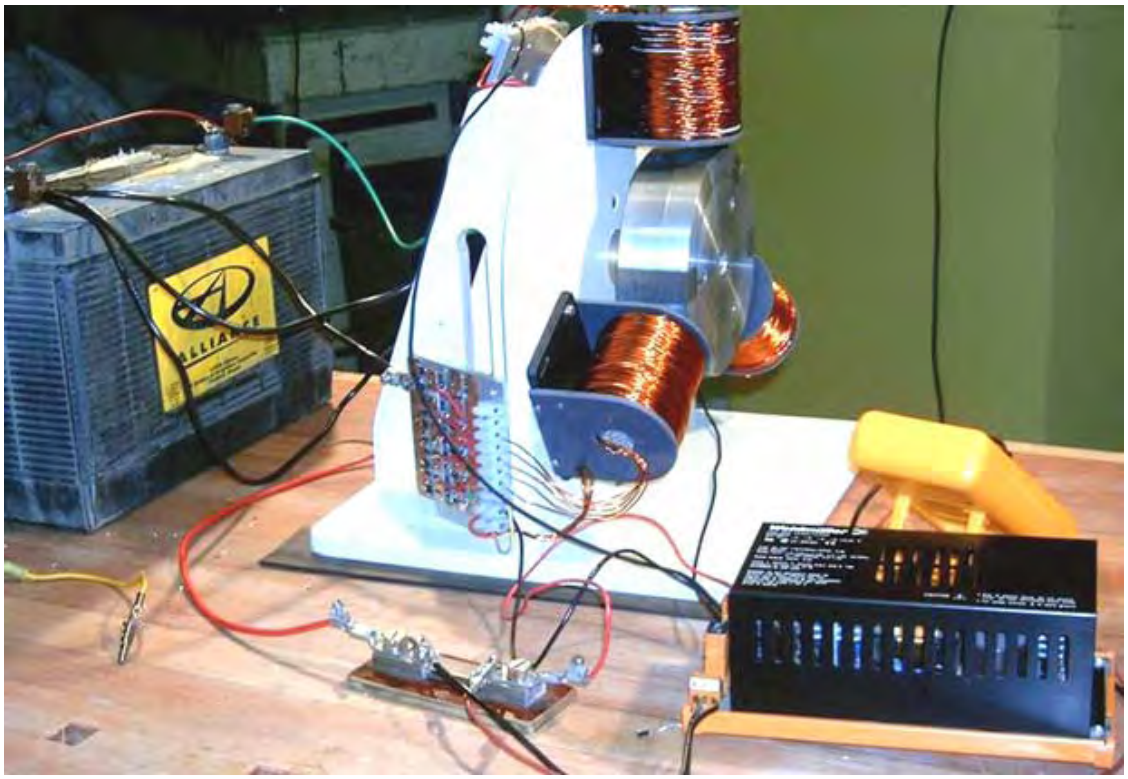
John Bedini of the USA has patented a system for the rapid charging of batteries with a pulsed waveform. Using banks of batteries tends to be very expensive, very space-consuming and replacement batteries are needed at frequent intervals, giving the user a disposal problem and additional cost. Batteries have the serious restriction that they get damaged and their life shortened if the rate of discharge is less than 20 hours. So a 100 Amp-Hour battery can only manage a 5 amp current (60 watts) if it is not to be damaged.

John Bedini's spike-generating system can charge several batteries at the same time. The snag is that you can't use the batteries to power equipment while they are being charged, so you need two sets of batteries. The system is easy to make and use. The best performance that I have come across is where there is thirteen times more power output than the power input.

There are several variations on John's pulser. The most common is a bicycle wheel with ferrite permanent magnets attached to the rim:



As the wheel spins, the approaching magnet generates a voltage in one winding of an electromagnet. This triggers a circuit which powers a second winding of the electromagnet. This pulse pushes the magnet away, keeping the wheel spinning. When the power to the coil is cut off, the resulting "Back EMF" voltage spike is fed to the batteries being charged. If the spike is sharp enough, it can cause an inflow of additional energy from the local environment. Interestingly, the rate at which the wheel rotates is directly proportional to the amount of charge in the batteries being charged. Here is a picture of **Ron Pugh**'s high-quality construction of a Bedini pulse charger:



Conclusion:
The term "Free-Energy" generally means a method of drawing power from the local environment, without the need to burn a fuel. There are many different successful methods for doing this and these methods span many countries and many years.

The amount of power which can be collected can be very high and the few kilowatts needed to power a household is most definitely within the reach of most of the devices mentioned.

****

In this brief introduction, not much detail has been given about the devices mentioned and only a small selection of devices has been covered. Much more detail is available in the various chapters of this eBook

The 'bottom line' is that energy can definitely be drawn from the local environment in sufficient quantities to supply all of our needs. For whatever reason, conventional science appears determined not to accept this basic fact and denies it at every opportunity. It seems likely that vested financial interests are the root cause of this refusal to accept the facts. The true scientific method is to upgrade scientific theory in the light of observed fact and new discoveries, but the true scientific method is not being followed at the present time.

Therefore, I invite you to examine the facts, read the information in this eBook and the additional information on the website http://www.free-energy-info.tuks.nl/ and make up your own mind on the subject. Please note that this is not a fixed body of information and this eBook normally gets a significant upgrade on a regular basis Consequently, I suggest that you download a new copy say, once per month in order to stay up to date with what is happening. Good luck with your research.

Patrick Kelly

Chapter 1: Magnet Power

Note: If you are not at all familiar with basic electronics, you might find it easier to follow parts of this chapter if you read chapter 12 first.

One thing which we are told, is that permanent magnets can't do any work. Oh yes, magnets can support themselves against the pull of gravity when they stick on your refrigerator, but, we are told, they can't do any work. Really?

What exactly is a permanent magnet? Well, if you take a piece of suitable material like 'mild' steel, put it inside a coil of wire and drive a strong electrical current through the coil, then that converts the steel into a permanent magnet. What length of time does the current need to be in the coil to make the magnet? Less than one hundredth of a second. How long can the resulting magnet support its own weight against gravity? Years and years. Does that not strike you as strange? See how long you can support your own body weight against gravity before you get tired. Years and years? No. Months, then? No. Days, even? No.

Well if you can't do it, how come the magnet can? Are you suggesting that a single pulse for a minute fraction of a second can pump enough energy into the piece of steel to power it for years? That doesn't seem very logical, does it? So, how does the magnet do it?

The answer is that the magnet does not actually exert any power at all. In the same way that a solar panel does not put any effort into producing electricity, the power of a magnet flows from the environment and not from the magnet. The electrical pulse which creates the magnet, aligns the atoms inside the steel and creates a magnetic "dipole" which has the same effect that the electrical "dipole" of a battery does. It polarises the quantum environment surrounding it and causes great streams of energy flow around itself. One of the attributes of this energy flow is what we call "magnetism" and that allows the magnet to stick to the door of your refrigerator and defy gravity for years on end.

Unlike the battery, we do not put it in a position where it immediately destroys its own dipole, so as a result, energy flows around the magnet, pretty much indefinitely. We are told that permanent magnets can't be used to do useful work. That is not true.

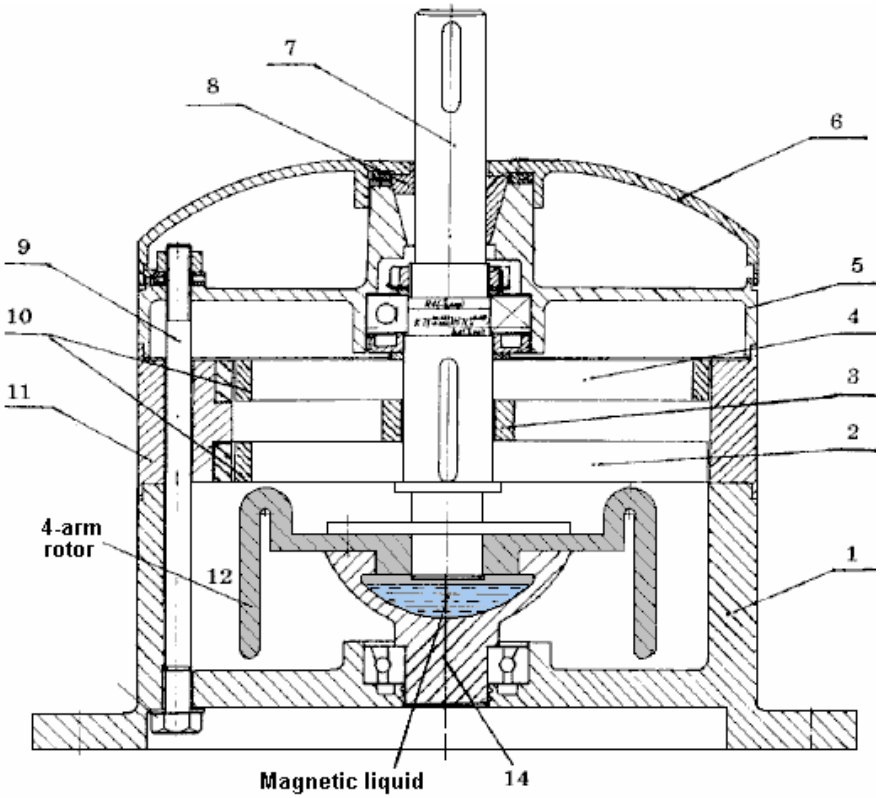
ShenHe Wang's Permanent Magnet Motor.
This is a picture of a Chinese man, ShenHe Wang, who has designed and built an electrical generator of five kilowatt capacity. This generator is powered by permanent magnets and so uses no fuel to run. It uses magnetic particles suspended in a liquid. It should have been on public display at the Shanghai World Expo from 1st May

2010 to 31st October 2010 but the Chinese government stepped in and would not allow it. Instead, they would only allow him show a wristwatch-size version which demonstrated that the design worked but which would be of no practical use in power generation:

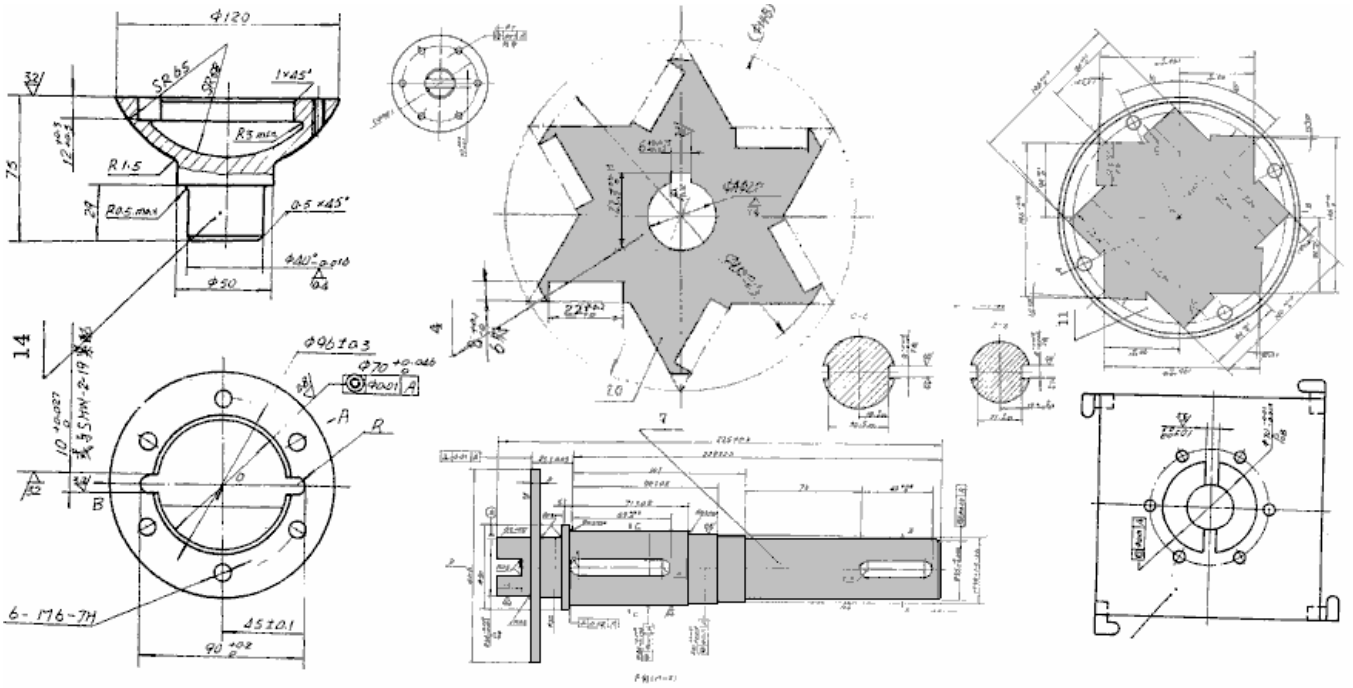
Most inventors don't seem to realise it, but almost every government is opposed to members of the public getting hold of any serious free-energy device (although they are happy to use these devices themselves). Their objective is to dominate and control ordinary people and a major factor in that is to control the supply and cost of power. A second method used everywhere is to control money, and without noticing it, governments manage to take away about 78% of people's income, mainly by concealed methods, indirect taxes, charges, fees, … If you want to know more about it, then visit www.yourstrawman.com but please understand that the reason why free-energy devices are not for sale in your local shop has to do with political control and vested financial interests and has nothing whatsoever to do with the technology. All technological problems have been solved, literally thousands of times, but the benefits have been suppressed by those in power.

Two of Mr Wang's 5 kilowatt generators successfully completed the Chinese government's mandatory six-month "Reliability and Safety" testing programme in April 2008. One large Chinese consortium has started buying up coal-fired electricity generating stations in China in order to refurbish them with pollution-free large versions of Wang's generator. Some information on the construction of the Wang motor is available here: http://www.free-energy-info.tuks.nl//Wang.pdf.

The motor consists of a rotor which has four arms and which sits in a shallow bowl of liquid which has a colloidal suspension of magnetic particles in it:



There is a patent on the motor but it is not in English and what it reveals is not a major amount.



It was Mr Wang's intention to give his motor design to every country in the world and invite them to make it for themselves. This very generous attitude does not take into account the many vested financial interests in each country, not the least of which is the government of that country, which will oppose the introduction of any device which taps into free-energy and which, consequently, would destroy their continuous streams of income. It is even possible that you would not be allowed to go to China, buy one and bring it back with you for use at home.

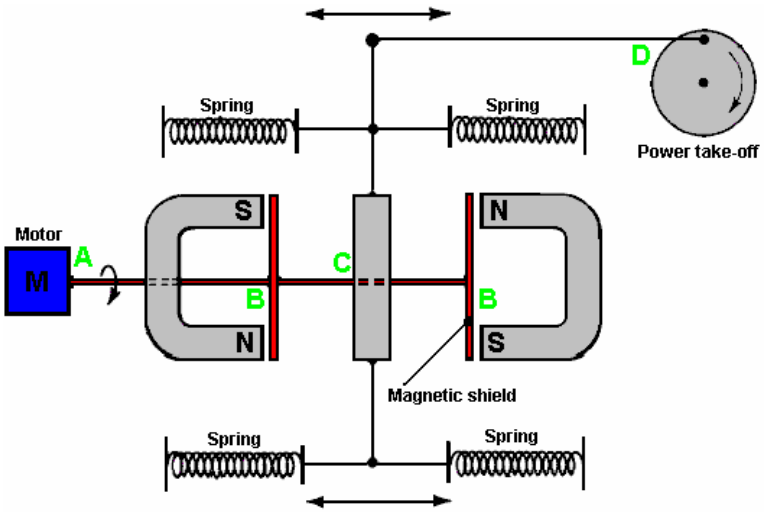
It is not easy to arrange permanent magnets in a pattern which can provide a continuous force in a single direction, as there tends to be a point where the forces of attraction and repulsion balance and produce a position in which the rotor settles down and sticks. There are various ways to avoid this happening. It is possible to modify the magnetic field by diverting it through a soft iron component.

There are many other designs of permanent magnet motor, but before showing some of them, it is probably worth discussing what useful work can be performed by the rotating shaft of a permanent magnet motor. With a home-built permanent magnet motor, where cheap components have been used and the quality of workmanship may not be all that great (though that is most definitely not the case with some home construction), the shaft power may not be very high. Generating electrical power is a common goal, and that can be achieved by causing permanent magnets to pass by coils of wire. The closer to the wire coils, the greater the power generated in those coils. Unfortunately, doing this creates magnetic drag and that drag increases with the amount of electrical current being drawn from the coils.

There are ways to reduce this drag on the shaft rotation. One way is to use an Ecklin-Brown style of electrical generator, where the shaft rotation does not move magnets past coils, but instead, moves a magnetic screen which alternatively blocks and restores a magnetic path through the generating coils. A commercially available material called “mu-metal” is particularly good as magnetic shield material and a piece shaped like a plus sign is used in the Ecklin-Brown generator.

John Ecklin’s Magnetic-Shielding Generator.

John W. Ecklin was granted US Patent Number 3,879,622 on 29th March 1974. The patent is for a magnet/electric motor generator which produces an output greater than the input necessary to run it. There are two styles of operation. The main illustration for the first is:

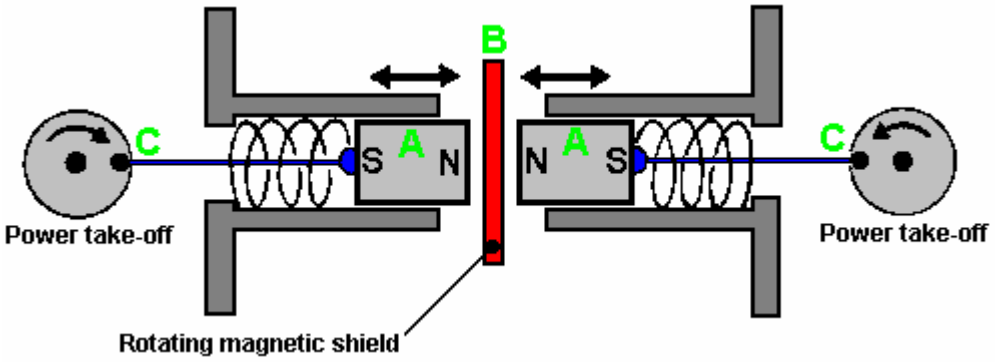


Here, the (clever) idea is to use a small low-power motor to rotate a magnetic shield to mask the pull of two magnets. This causes a fluctuating magnet field which is used to rotate a generator drive.

In the diagram above, the motor at point ‘A’ rotates the shaft and shielding strips at point ‘B”. These rectangular mu-metal strips form a very conductive path for the magnetic lines of force when they are lined up with the ends of the magnets and they effectively shut off the magnet pull in the area of point ‘C’. At point ‘C’, the spring-loaded traveller is pulled to the left when the right-hand magnet is shielded and the left hand magnet is not shielded. When the motor shaft rotates further, the traveller is pulled to the right when the left-hand magnet is shielded and the right hand magnet is not shielded. This oscillation is passed by mechanical linkage to point ‘D’ where it is used to rotate a shaft used to power a generator.

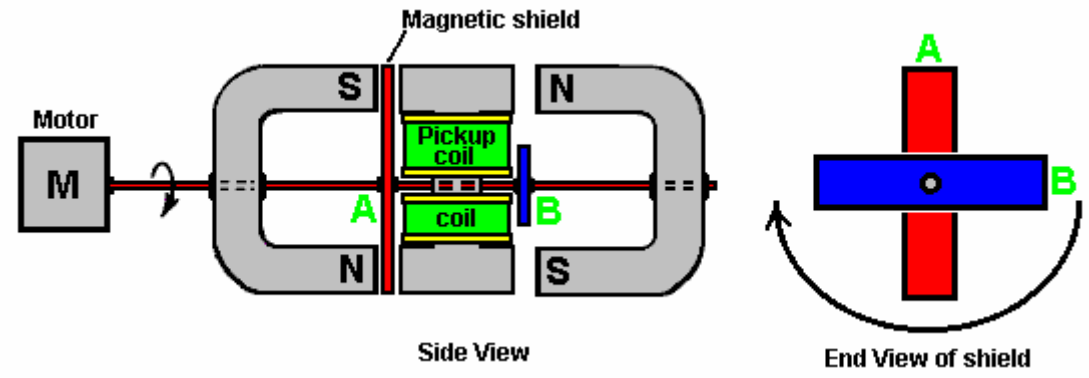
As the effort needed to rotate the magnetic shield is relatively low, it is claimed that the output exceeds the input and so can be used to power the motor which rotates the magnetic shield.

The second method for exploiting the idea is shown in the patent as:



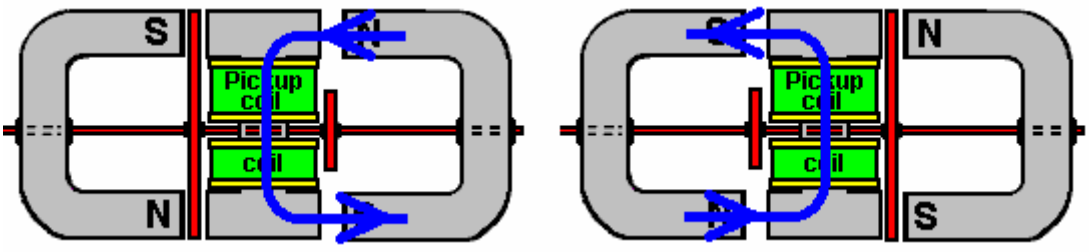
Here, the same shielding idea is utilised to produce a reciprocating movement which is then converted to two rotary motions to drive two generators. The pair of magnets 'A' are placed in a housing and pressed towards each other by two springs. When the springs are fully extended, they are just clear of the magnetic shield 'B'. When a small electric motor (not shown in the diagram) moves the magnetic shield out of the way, the two magnets are strongly repelled from each other as their North poles are close together. This compresses the springs and through the linkages at 'C' they turn two shafts to generate output power.

A modification of this idea is the **Ecklin-Brown Generator**. In this arrangement, the movable magnetic shielding arrangement provides a direct electrical output rather than a mechanical movement:



Here, the same motor and rotating magnetic shield arrangement is used, but the magnetic lines of force are blocked from flowing through a central I-piece. This I-piece is made of laminated iron slivers and has a pickup coil or coils wound around it.

The device operates as follows:

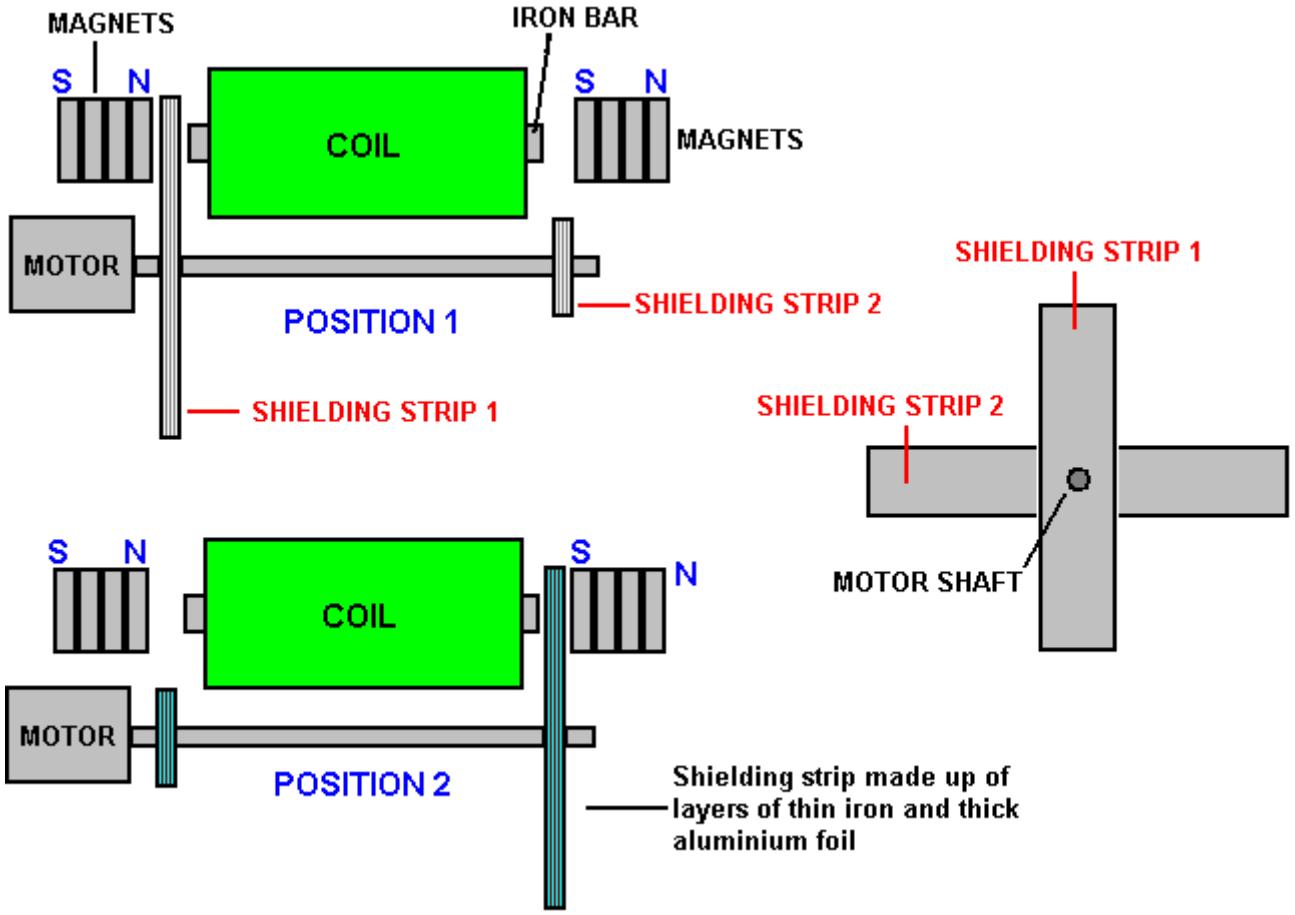


In the position shown on the left, the magnetic lines of force flow **downwards** through the pickup coils. When the motor shaft has rotated a further ninety degrees, the situation on the right occurs and there, the magnetic lines of force flow **upwards** through the pickup coils. This is shown by the blue arrows in the diagram. This reversal of magnetic flux takes place four times for every rotation of the motor shaft.

While the Ecklin-Brown design assumes that an electric motor is used to rotate the mu-metal shield, there does not seem to be any reason why the rotation should not be done with a permanent magnet motor.

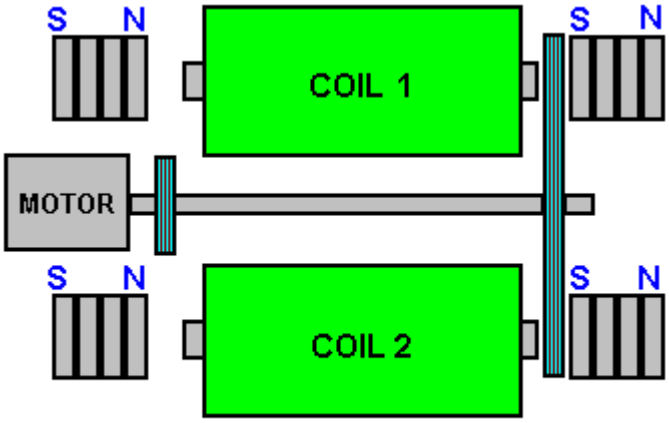
Toroidal shapes are clearly important in many devices which pull in additional energy from the environment. However, the Ecklin-Brown generator looks a little complicated for home construction, the principle can be used with a much more simple style of construction where the cores of the output coils are straight bars of suitable material such as ‘soft’ iron or perhaps the more readily available masonry anchors:

If using the masonry anchors, be sure to cut the conical end off as it alters the magnetic effect in an undesirable way. Using a hand hacksaw and a vise, cutting the end off is a very easy thing to do and that allows an ordinary helical coil to be wound either directly on the shaft or on a simple bobbin which slides on to the shaft. With any such coil, the voltage produced increases as the number of turns in the coil increases. The maximum current draw depends on the thickness of the wire as the thicker the wire, the greater the current which it can carry without overheating.

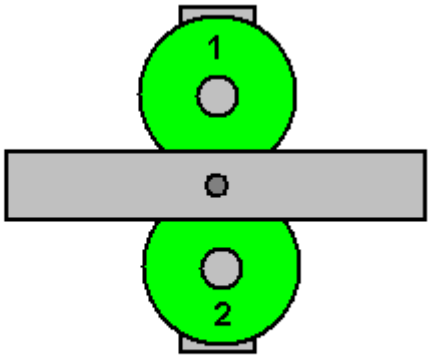


We can use an ordinary magnet or set of magnets at each end of the straight core to cause a strong magnetic field to flow through the core of our coil. As the motor spins the two screening arms they pass alternately between the magnet at one end of the core and then the magnet at the other end of the core, creating a fluctuating magnetic field passing through the coil.

The drawing shows just one output coil, but there could be two coils:

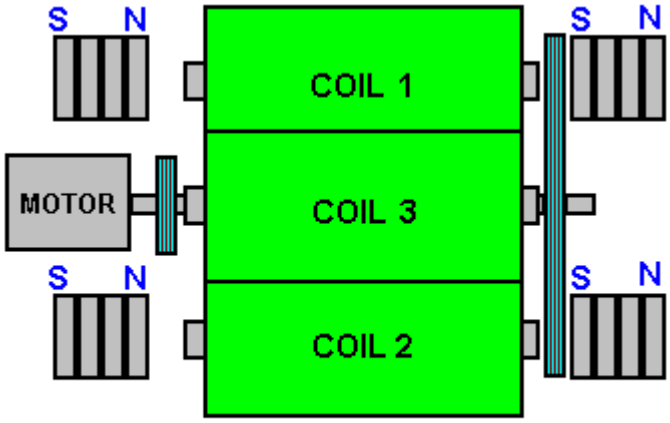


SIDE VIEW

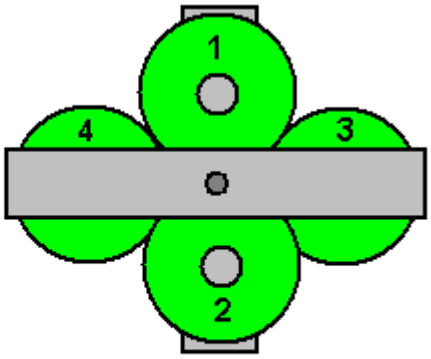


END VIEW

Or there could be four coils:



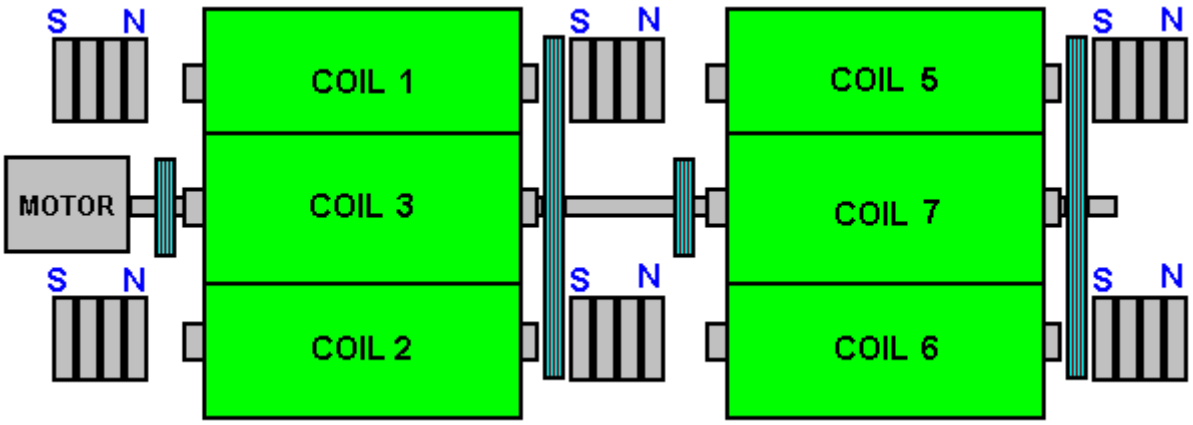
SIDE VIEW



END VIEW

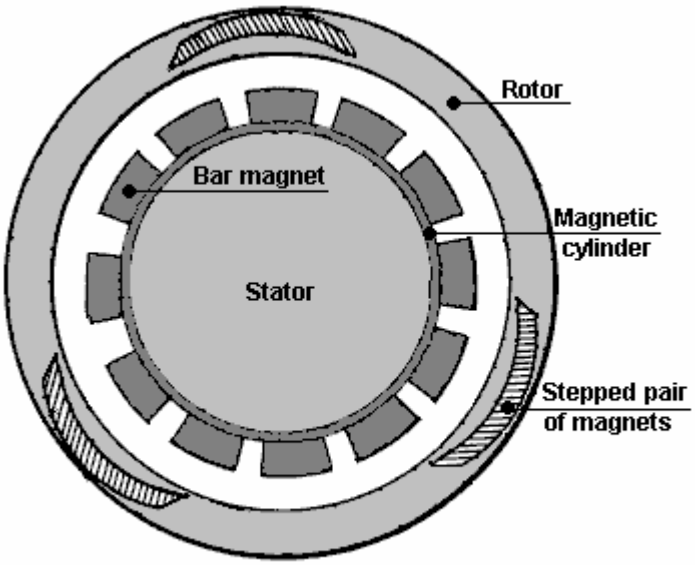
The coils can be connected in parallel to increase the output current, or they can be connected in series (in a chain configuration) to increase the output voltage. While the drawings show the shields connected directly to the motor drive shaft (a short length of plastic sleeving from a piece of wire would probably be used to help with alignment of the motor shaft and the shielding axle) there is no reason why the shielding should not be on a separate axle mounted in bearings and driven by a belt and pulley wheel arrangement.

With a separate shielding axle, allows a long, stiff axle to be used and that allows there to be additional coils and magnets. The result could be like this:



Howard Johnson's Permanent Magnet Motor.

Returning to permanent magnet motors themselves, one of the top names in this field is Howard Johnson. Howard built, demonstrated and gained US patent 4,151,431 on 24th April 1979, from a highly sceptical patent office for, his design of a permanent magnet motor. He used powerful but very expensive Cobalt/Samarium magnets to increase the power output and demonstrated the motor principles for the Spring 1980 edition of *Science and Mechanics* magazine. His motor configuration is shown here:

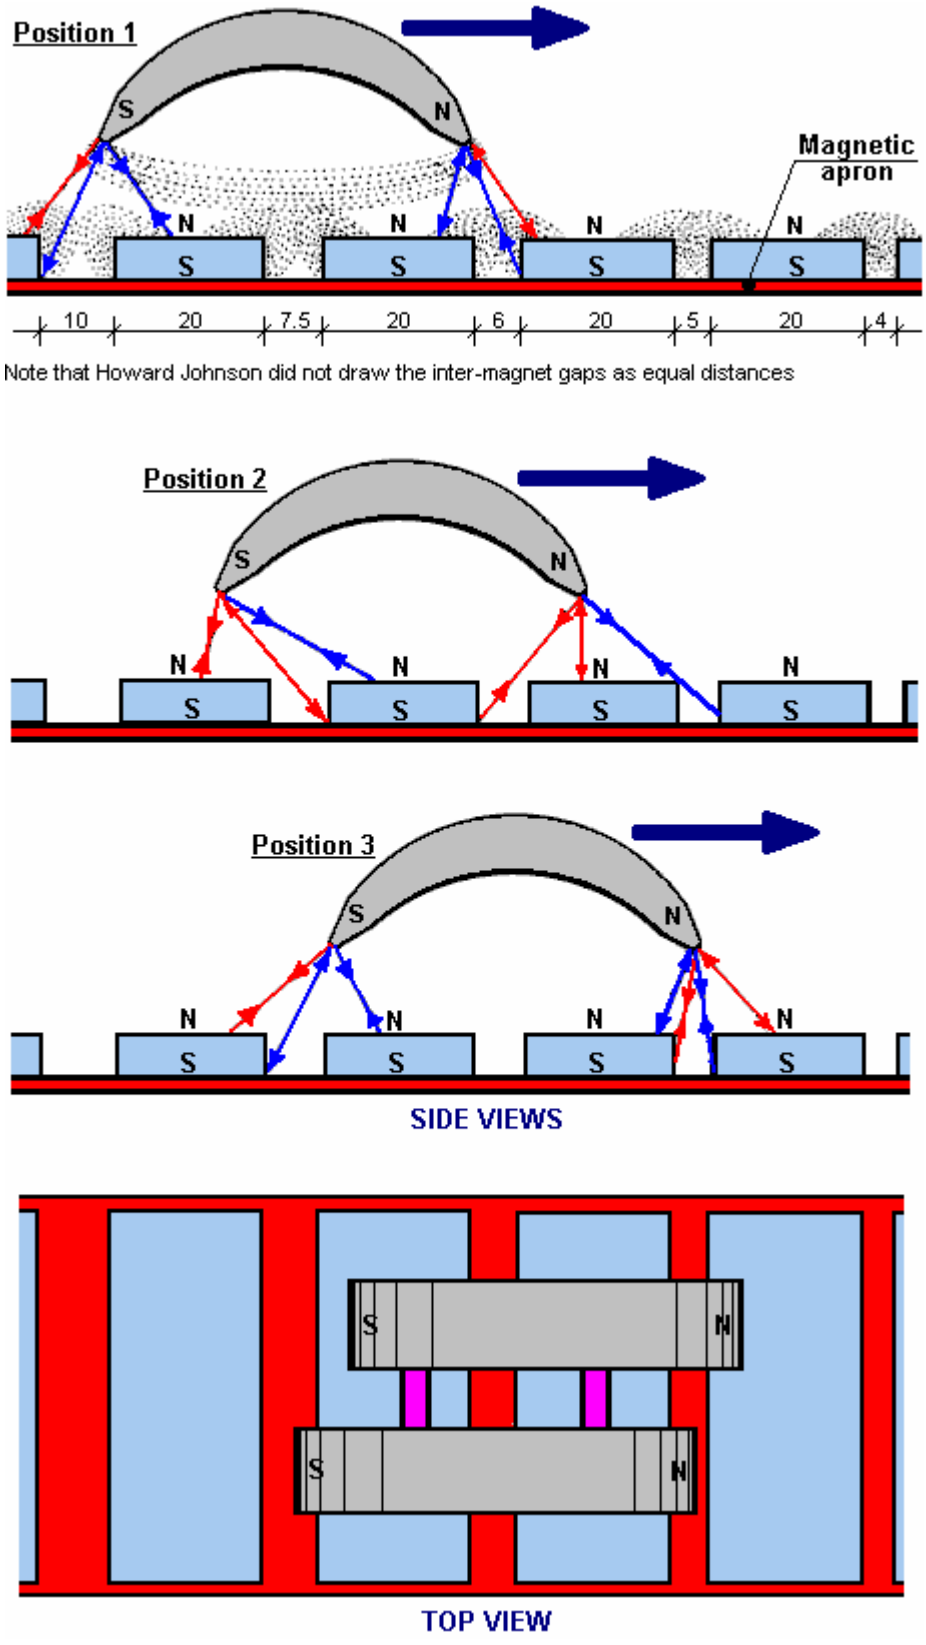


Note that the gaps between the magnets are not a constant width.

The point that he makes is that the magnetic flux of his motor is always unbalanced, thus producing a continuous rotational drive. The rotor magnets are joined in stepped pairs, connected by a non-magnetic yoke. The stator magnets are placed on a mu-metal apron cylinder. Mu-metal is very highly conductive to magnetic flux (and is expensive). The patent states that the armature magnet is 3.125" (79.4 mm) long and the stator magnets are 1" (25.4 mm) wide, 0.25" (6 mm) deep and 4" (100 mm) long. It also states that the rotor magnet pairs are **not** set at 120 degrees apart but are staggered slightly to smooth out the magnetic forces on the rotor. It also states that the air gap between the magnets of the rotor and the stator are a compromise in that the greater the gap, the smoother the running but the lower the power. So, a gap is chosen to give the greatest power at an acceptable level of vibration.

Howard considers permanent magnets to be room-temperature superconductors. Presumably, he sees magnetic material as having electron spin directions in random directions so that their net magnetic field is near zero until the electron spins are aligned by the magnetising process which then creates an overall net permanent magnetic field, maintained by the superconductive electrical flow.

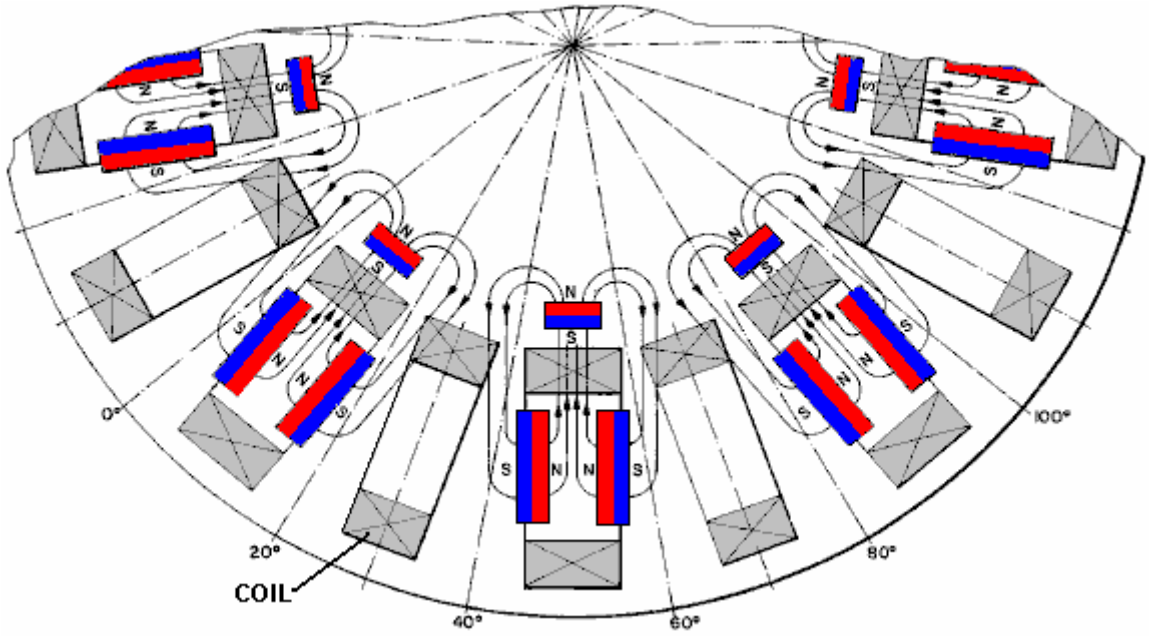
The magnet arrangement is shown here, with the inter-magnet gaps assessed from the drawing in Howard's patent:



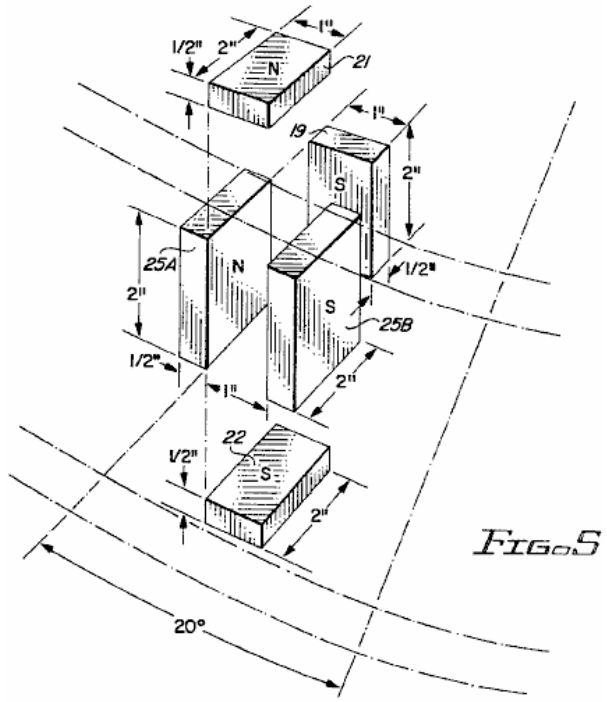
A magazine article on this can be seen at http://newebmasters.com/freeenergy/sm-pg48.html.

The "Carousel" Permanent Magnet Motor/Generator.

US Patent 5,625,241, included in the Appendix, presents the specific details of a simple electrical generator powered by permanent magnets alone. This generator can also be used as a motor. The construction is not particularly complicated:



It uses an arrangement where permanent magnets are associated with every second coil set around the rotor. Operation is self-powered and the magnet arrangement is clearly defined:



And the physical arrangement of the device is not particularly complicated:

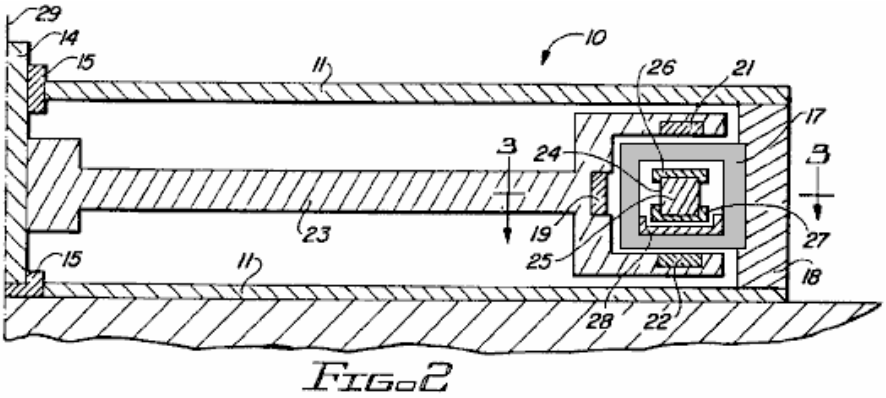


FIG. 2

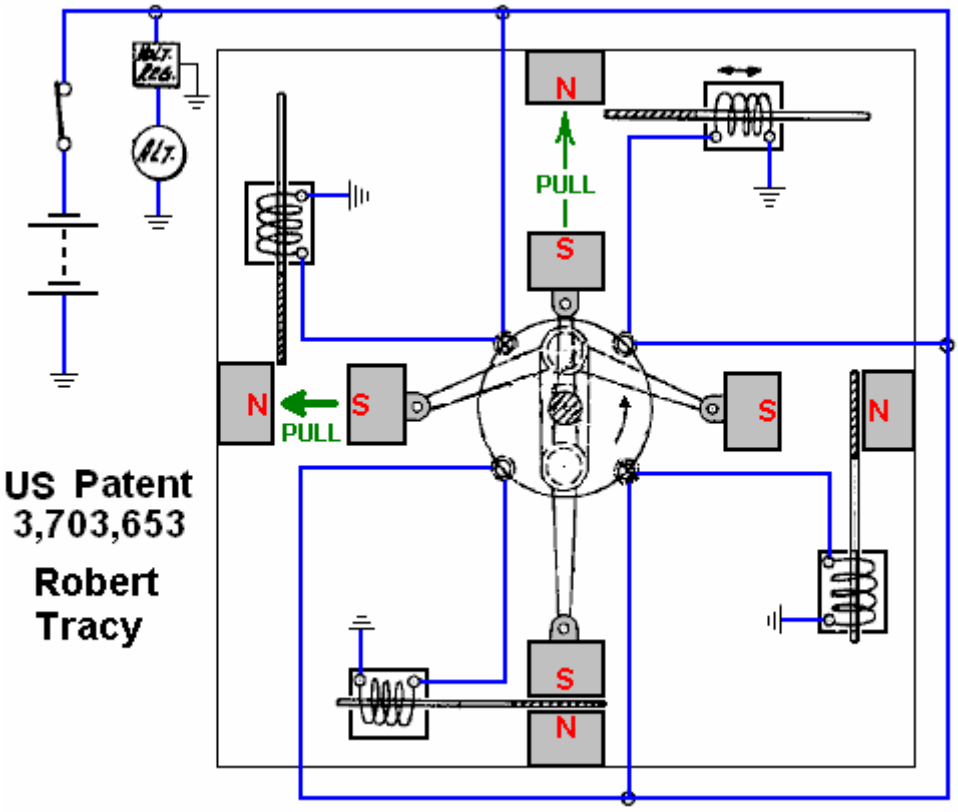
This is a patent which is definitely worth reading and considering, especially since it is not a complicated presentation on the part of the authors, Harold Ewing, Russell Chapman and David Porter. This seemingly very effective generator appears to be overlooked at the present time. It seems quite clear that permanent magnet motors are a wholly viable option for the home constructor and they are capable of substantial power outputs over long periods, however, it should be noted that motors using magnets alone are notoriously difficult to get operational and while it can be done, motors which use moving shielding or pulsed electrical shielding are much more viable for the first-time constructor – motors such as the Charles Flynn motor or the Stephen Kundel motor.

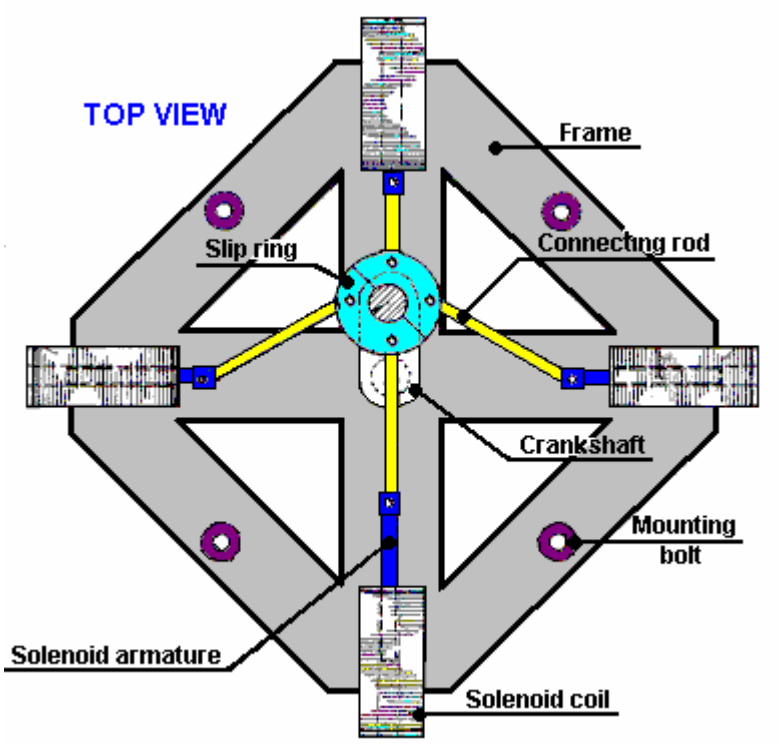
Robert Tracy's Permanent Magnet Motor.

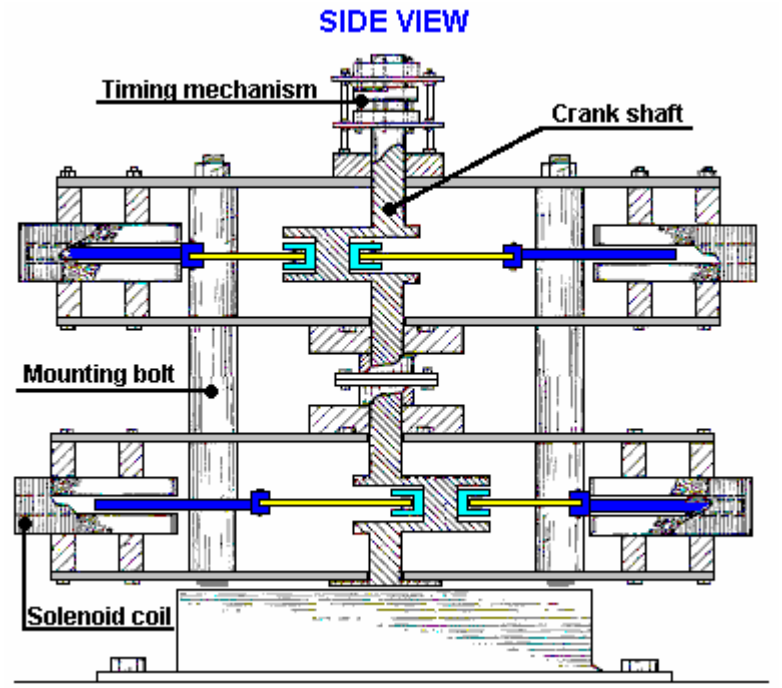
Some people have opted for permanent magnet motors where the field is shielded at the appropriate moment by a moving component of the motor. Robert Tracy was awarded US Patent Number 3,703,653 on 21st November 1972 for a "Reciprocating Motor with Motion Conversion Means". His device uses magnetic shields placed between pairs of permanent magnets at the appropriate point in the rotation of the motor shaft:



Ben Teal's Electromagnet Motor.

Motors of this kind are capable of considerable power output. The very simple motor, originally built by Ben Teal using wood as the main construction material, was awarded US Patent Number 4,093,880 in June 1978. He found that, using his hands, he could not stop the motor shaft turning in spite of it being such a very simple motor design:



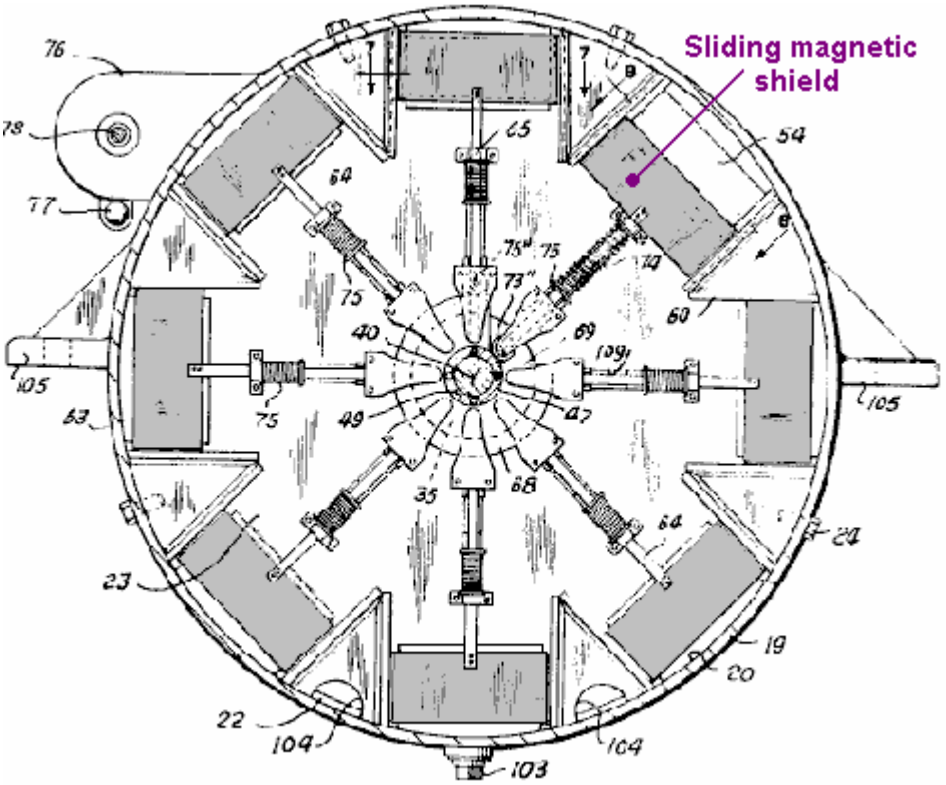


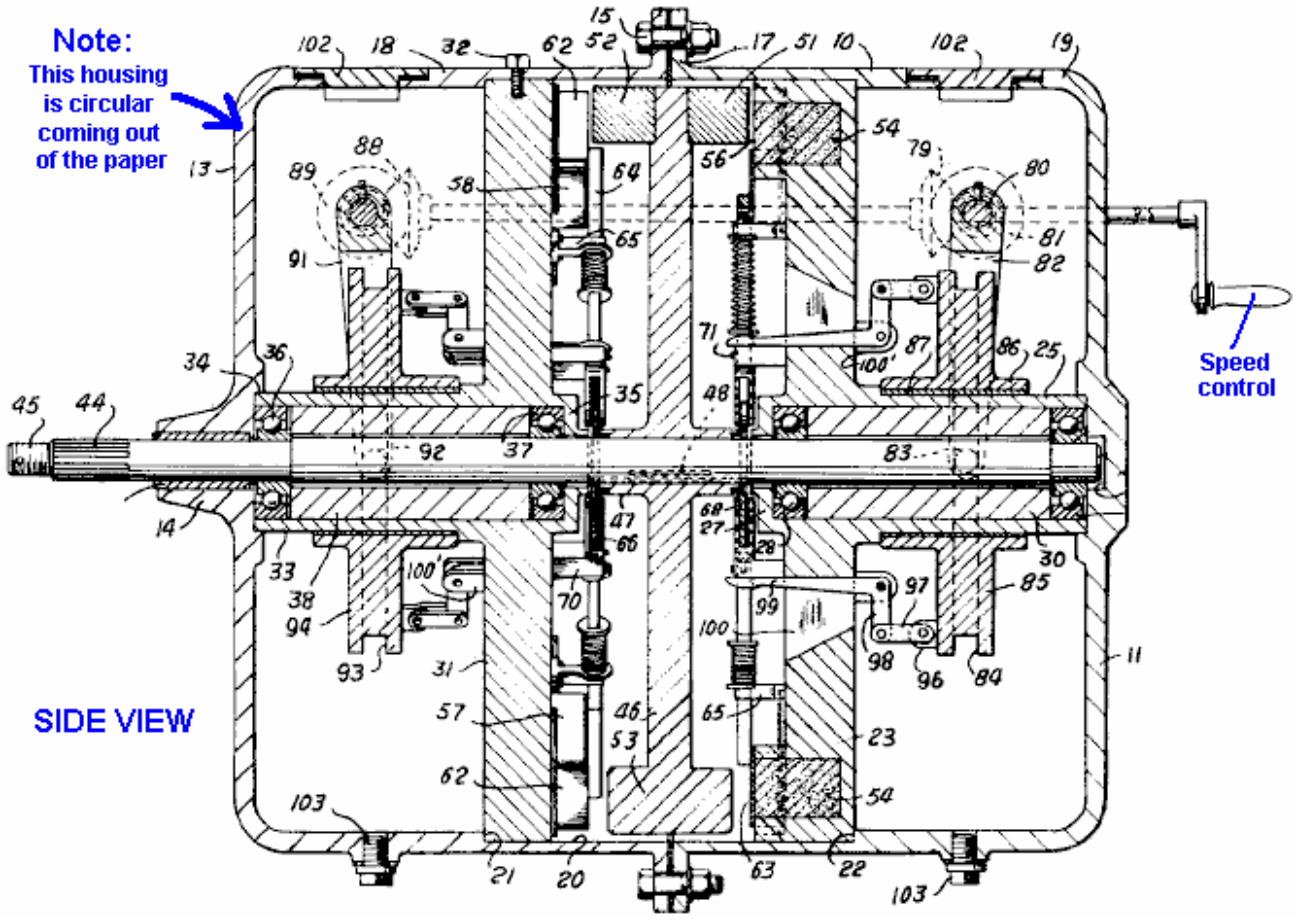
The motor operation is as simple as possible with just four switches made from springy metal, pushed by a cam on the rotor shaft. Each switch just powers it's electromagnet when it needs to pull and disconnects it when the pull is completed. The resulting motor is very powerful and very simple. Additional power can be had by just stacking one or more additional layers on top of each other. The above diagram shows two layers stacked on top of one another. Only one set of four switches and one cam is needed no matter how many layers are used, as the solenoids vertically above each other are wired together in parallel as they pull at the same time.

The power delivered by the Teal motor is an indication of the potential power of a permanent magnet motor which operates in a rather similar way by moving magnetic shields to get a reciprocating movement. Placing a resistor and capacitor across each switch contact both suppresses sparks and feeds current back to the battery when the contact opens, and this extends the battery life considerably.

The Jines Permanent Magnet Motor.

James E. Jines and James W. Jines were awarded US Patent 3,469,130 on 23rd September 1969 “Means for Shielding and Unshielding Permanent Magnets and Magnetic Motors Utilising the Same” and which is in the Appendix. This magnet motor design uses selective shielding of the drive magnets to produce a continuous force in one direction. It also has a mechanical arrangement to progressively adjust the shielding to adjust the power of the motor.

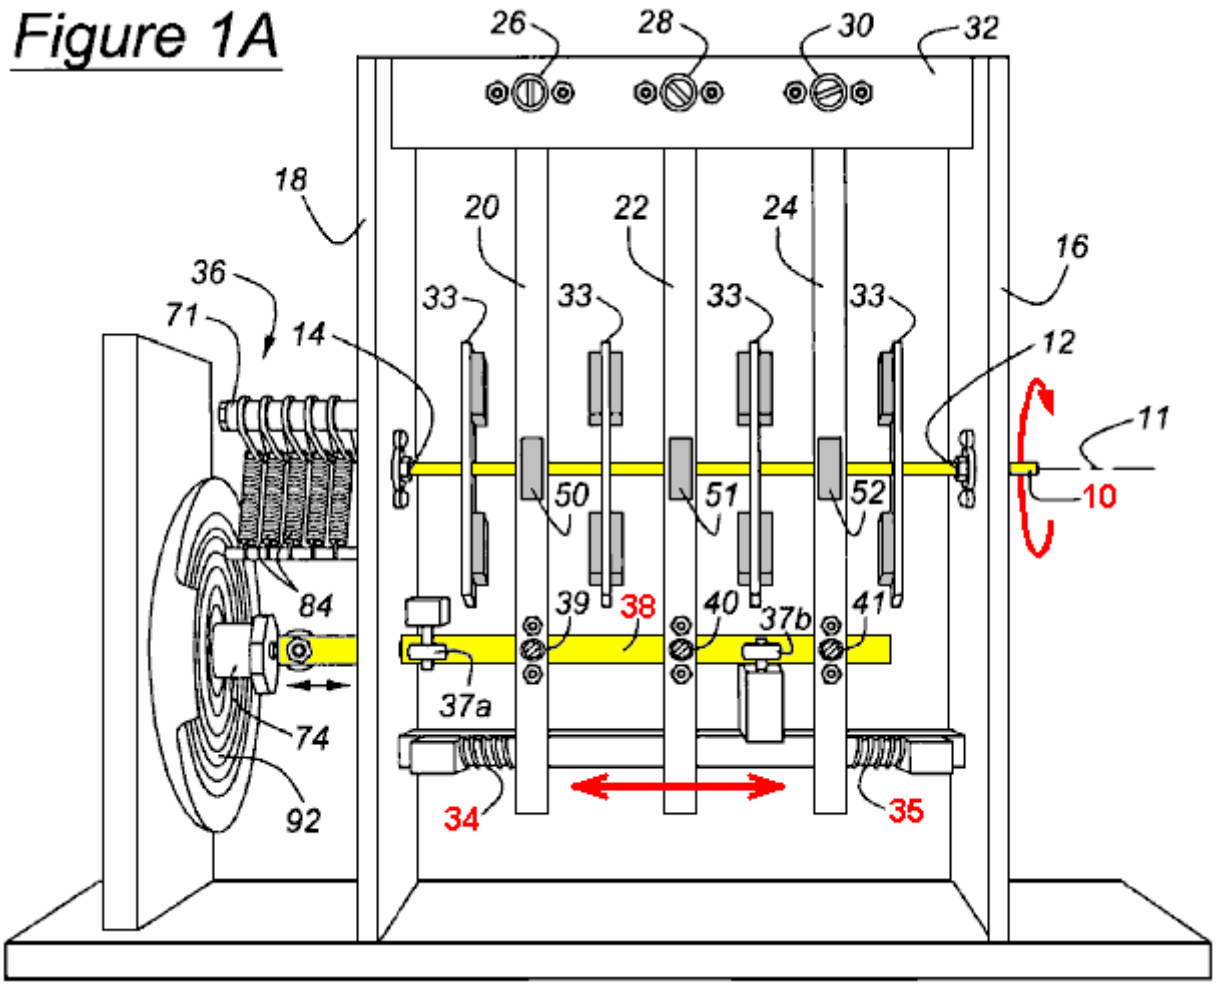




This is a very interesting design of magnetic motor, especially since it does not call for any materials which are not readily available from many suppliers. It also has the advantage of not needing any form of exact adjustment or balancing of magnetic forces to make it operate.

Stephen Kundel's Permanent Magnet Motor.

Stephen Kundel's motor design is shown in full detail in his patent which is shown on page A - 968 of the Appendix. It uses a simple oscillating motion to position the "stator" magnets so that they provide a continuous rotational force on the output shaft:



Here, the yellow arm marked **38**, rocks to the right and left, pushed by a solenoid coil **74**. There is no obvious reason why this rocking motion could not be achieved by a mechanical linkage connected to the rotating output shaft **10**. The three arms **20**, **22** and **24**, being pivoted at their upper points, are pushed into a central position by the springs **34** and **35**. The magnets **50**, **51** and **52**, are moved by these arms, causing a continuous rotation of the output drive shaft **10**. The movement of these magnets avoids the position where the magnets reach a point of equilibrium and lock into a single position.

Figure 2

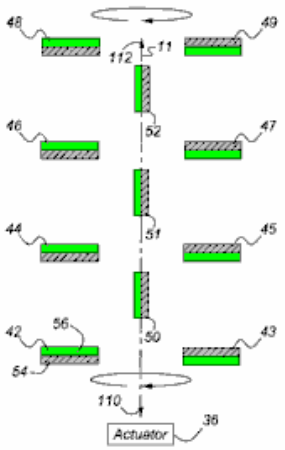


Figure 3

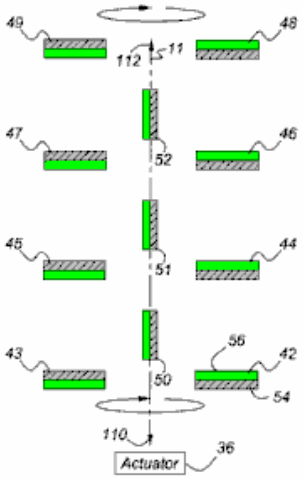
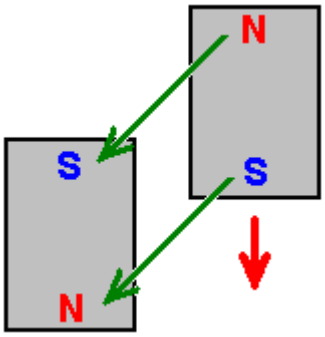


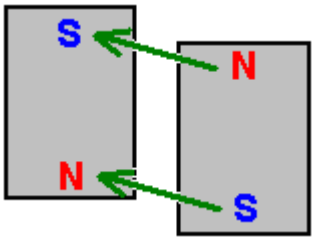
Figures 2 and 3 show the position of the magnets, with the Figure 3 position showing a point in the output shaft rotation which is 180 degrees (half a turn) further on than the position shown in Figure 2.

Some other, more powerful magnet arrangements which can be used with this design are shown in the full patent in the Appendix.

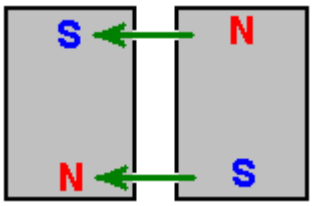
This design does not seem to appeal to many constructors in spite of the fact that it must be one of the easiest magnet motors to set up and make work. The output power level can be as big as you want as additional layers of magnets can be added. The operation is very simple and it can, perhaps, be seen more easily if just one lever arm is considered. The lever arm has just two working positions. In one position it acts on one set of rotor magnets and in the second position it acts on a second set of rotor magnets. So, we will look at each set in turn. If there are two magnets near each other, one fixed in position and the other free to move like this:



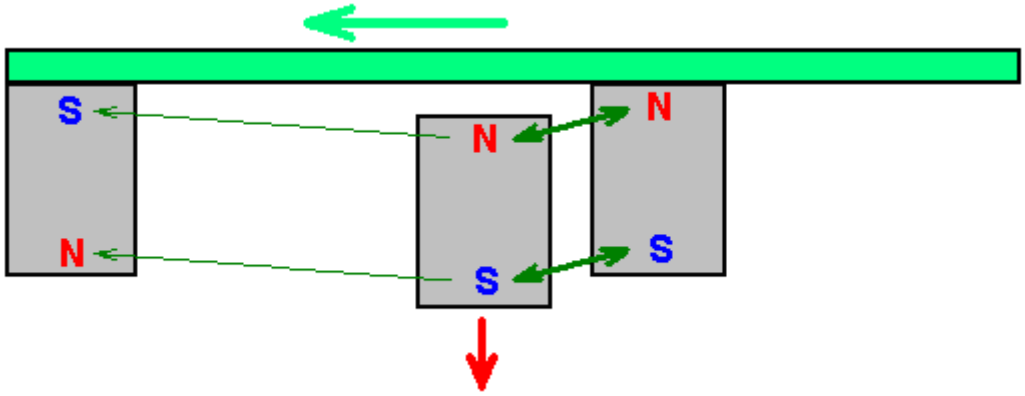
The magnets have a strong attraction to each other because of the North and South poles attracting each other. However, as the two South poles repel each other, the movement of the approaching magnet is not directly along the green arrows shown but initially is in the direction shown by the red arrow. This situation continues with the moving magnet approaching he fixed magnet and the pull between them getting stronger all the time. But, the situation changes immediately the moving magnet reaches it's closest point to the fixed magnet. Momentum starts to carry it past, but at that point the direction of the pull between the magnets starts to oppose the onward movement of the moving magnet:



If the fixed magnet remains in that position, then the moving magnet will oscillate briefly and come to a halt directly opposite the fixed magnet like this:



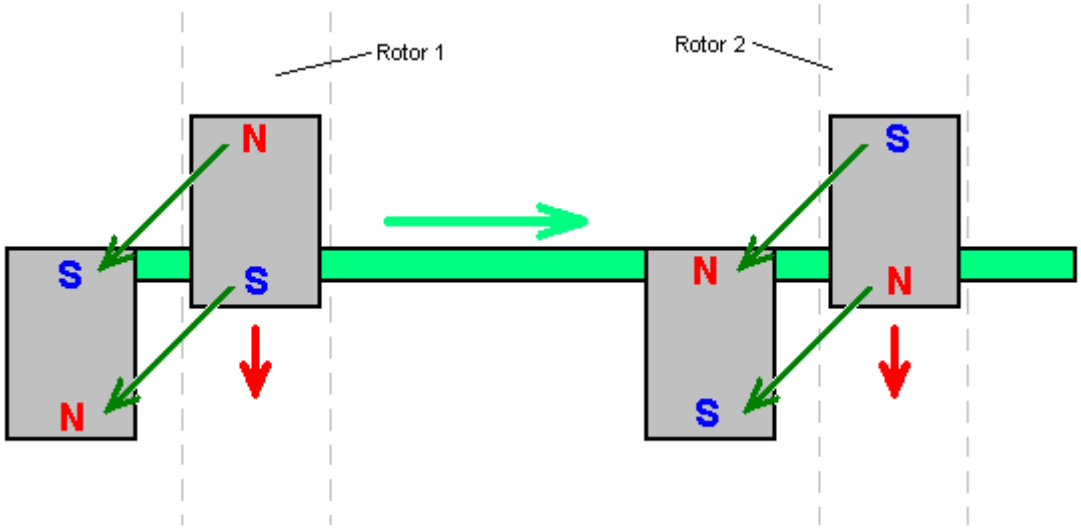
The attraction forces between the two magnets is now wholly horizontal and there is no force on the movable magnet to cause it to move. This is simple stuff, understood by anyone who has examined permanent magnets in order to see what they do. Stephen Kundel is well aware of this, and so he moves the "fixed" magnet rapidly out of the way before the reverse-direction pull slows the moving magnet down. He moves the magnet sideways and slides another one into position like this:



The new magnet is now much closer to the moving magnet and so has a much greater influence on it. The poles of the new magnet match the poles of the moving magnet which causes them to push apart very strongly, driving the moving magnet onwards in the direction it was moving in. The moving magnet moves very quickly and so gets out of the range of the fixed magnets quite quickly, at which point, the "fixed" magnets of the stator are moved back into their original position where they act in the same way on the next moving magnet attached to the rotor.

This very simple operation only requires a small force to move the stator magnets sideways between their two positions, while the force between the stator magnets and the rotor magnets can be high, producing considerable rotational power to the axle on which the rotor discs are attached.

The efficiency of the system is further boosted because when the stator magnets are in the first position shown, the second "fixed" magnet is not sitting idle but instead, it acts on the magnet of the next rotor disc:



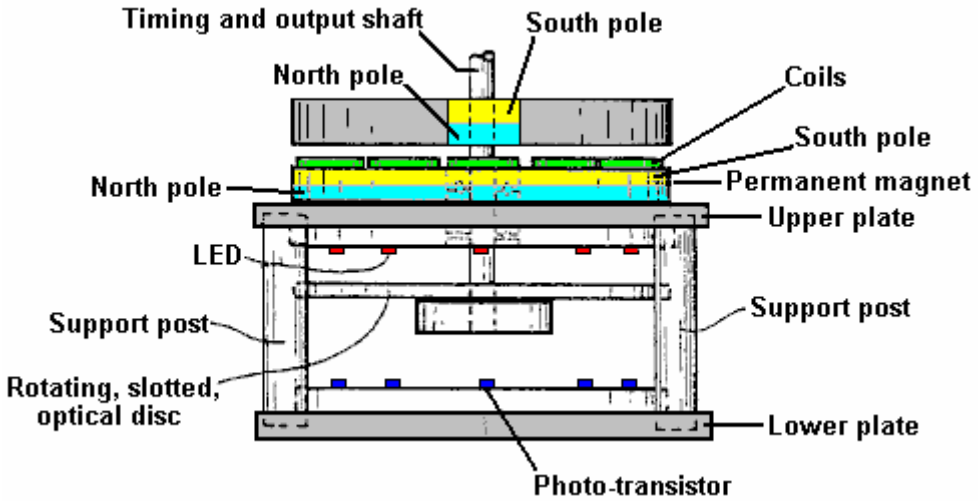
For this, the magnets attached to Rotor disc 2 have to be positioned so that their poles are the reverse of those attached to Rotor disc 1. Stephen uses a loudspeaker to wobble the horizontal bar on which the stator magnets are mounted, backwards and forwards as a loudspeaker has that mechanism already built into it. Don Kelly's

permanent magnet motor also uses this very simple idea of moving the stator magnets out of the way at the appropriate moment.

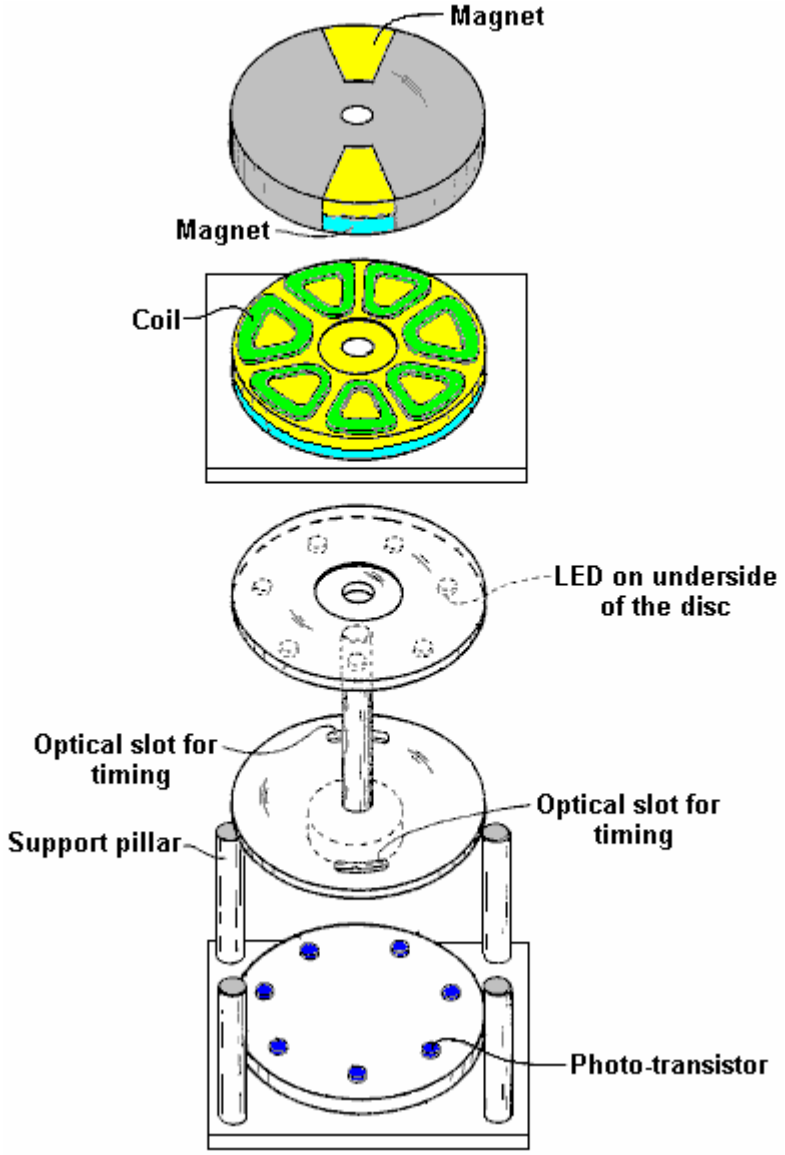
Charles “Joe” Flynn’s Permanent Magnet Motor.

Patent US 5,455,474 dated 3rd October 1995 and shown in full in the Appendix, gives details of this interesting design. It says: “This invention relates to a method of producing useful energy with magnets as the driving force and represents an important improvement over known constructions and it is one which is simpler to construct, can be made to be self starting, is easier to adjust, and is less likely to get out of adjustment. The present construction is also relatively easy to control, is relatively stable and produces an amazing amount of output energy considering the source of driving energy that is used. The present construction makes use of permanent magnets as the source of driving energy but shows a novel means of controlling the magnetic interaction or coupling between the magnet members and in a manner which is relatively rugged, produces a substantial amount of output energy and torque, and in a device capable of being used to generate substantial amounts of energy.”

The patent describes more than one motor. The first one is like this when seen from the side:

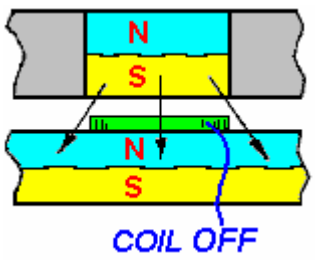


An exploded view, shows the different parts clearly:

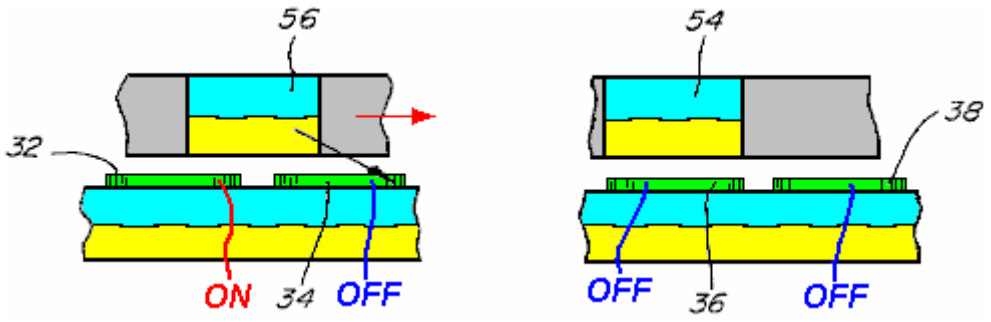


This construction is relatively simple and yet the operation is powerful. The power is provided by three magnets, shown shaded in blue and yellow. The lower magnet is in the form of a disc with the poles arranged on the large, circular, flat faces. This is the stator magnet which does not move. Positioned above it is a disc made of non-magnetic material (shaded in grey) and which has two magnets embedded in it. This disc is the rotor and is attached to the central vertical shaft.

Normally, the rotor would not rotate, but between the two discs there is a ring of seven coils which are used to modify the magnetic fields and produce powerful rotation. The powering up of these coils is very simple and it is arranged by shining a beam of Ultra Violet light from one of the Light-Emitting Diodes through a slot in an optical-timing disc attached to the rotating shaft. The LEDs and the photo-transistors are aligned with the centres of the seven coils. The position and width of the slot controls which photo-transistor gets switched on and for how long it remains powered up. This is a very neat and compact arrangement. The really interesting part of the design is how the coils modify the magnetic fields to produce the output power of the device. The orientation of the magnet poles can be swapped over, provided that this is done for all three magnets.



Shown here is the situation when one of the rotor magnets has rotated to where it is above one of the coils which is not yet powered up. The South pole of the rotor magnet is attracted to the North pole which is the entire upper face of the stator magnet as shown by the three arrows. If a voltage is applied to the coil, then this magnetic coupling is disrupted and altered. If any torque is developed as a result of the coil being powered up, then it will be developed to either side of the energised coil. If the coil is not powered up, then there will be full attraction between the magnets and no rotational force will be produced. You will notice that there are two rotating magnets (an even number) and seven coils (an odd number) so when one of the rotor magnets is above a coil, then the other isn't. This staggering of the two positions is essential for generating smooth, continuous rotational torque and self-starting without any need to rotate the shaft manually.

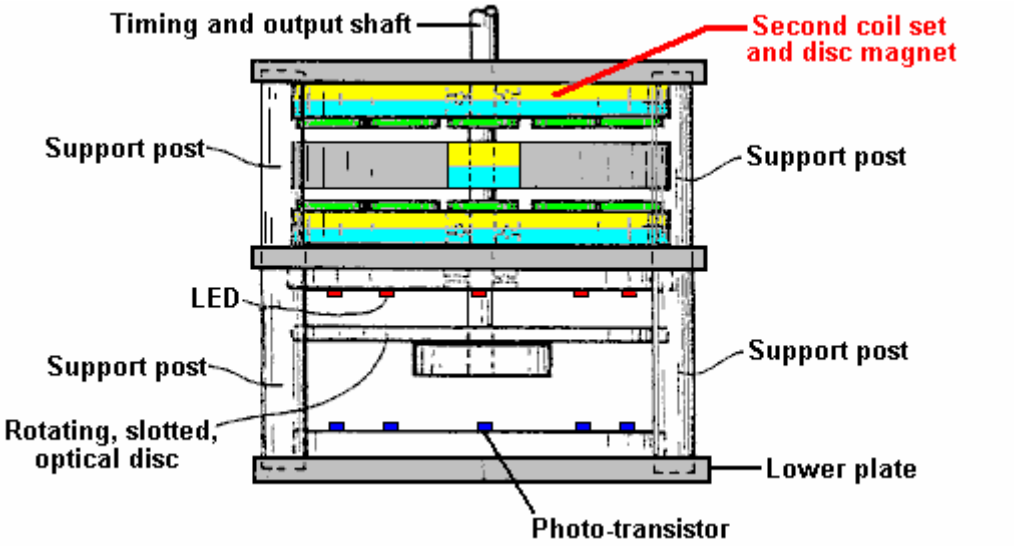


The diagram above shows a piece from both sides of the rotor disc, to explain the operation of the coils. On the left, magnet **56** overlaps coil **32** and coil **34**. Coil **32** is powered up and this breaks the magnetic link on the left hand side of magnet **56**. But, coil **34** is not powered up, so the attraction between magnet **56** and the disc magnet under the coils remains. Even though this attraction is at a downward angle, it creates a push on the rotor, driving it towards the right as shown by the red arrow.

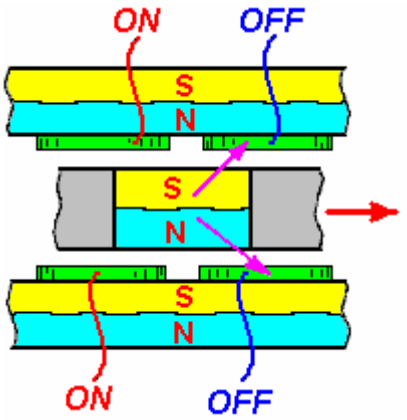
While this is happening, the situation around the other side of the rotor disc, is shown on the right. Here, magnet **54** is above coil **36** and that coil is not powered up, so there is no resulting drive in either direction - just a downward pull on the rotor magnet, towards the stator magnet below it. The adjacent coil **38** is also not powered up and so has no effect on the rotation. This method of operation is **very** close to that of the motor design of Robert Adams described in the next chapter. It is important to understand that this method of operation is nothing like that of the John Bedini pulsers where the rotation of a disc is caused by the electrical pulse applied to a coil creating a repulsion thrust to a rotor magnet. Instead, here, the coil acts as a magnetic shield, being provided with the minimum possible power to do its job. The coil is, in effect, a shield which has no moving parts, and so is a very clever mechanism for overcoming the tendency for the rotor magnets to lock on to the stator magnets and preventing rotation.

At any moment, six of the seven coils in this design are inactive, so in effect, just one coil is powered. This is not a major current drain. It is important to understand that the power of this motor is provided by the permanent magnets pulling towards each other. Each of the two magnets applies a horizontal pull on the rotor every seventh of a turn, that is, every 51.1 degrees in the rotation. As the coils are an uneven number, the rotor gets a magnetic pull every 25.5 degrees in the rotation, first from one rotor magnet and then from the other rotor magnet.

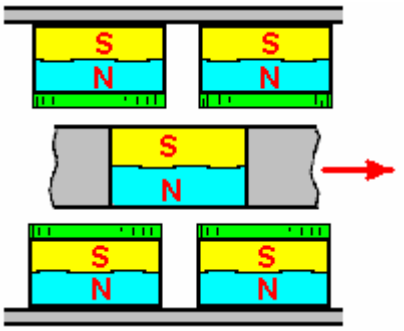
It follows then, that the power of the motor can be increased by adding more magnets. The first step in this search for additional power is to add a second disc magnet and coils on the other side of the rotor, so that there is a second pull on the magnet. This has the added advantage that it balances the downwards pull of the first disc magnet with an upward pull, giving an enhanced and balanced horizontal thrust as shown here:



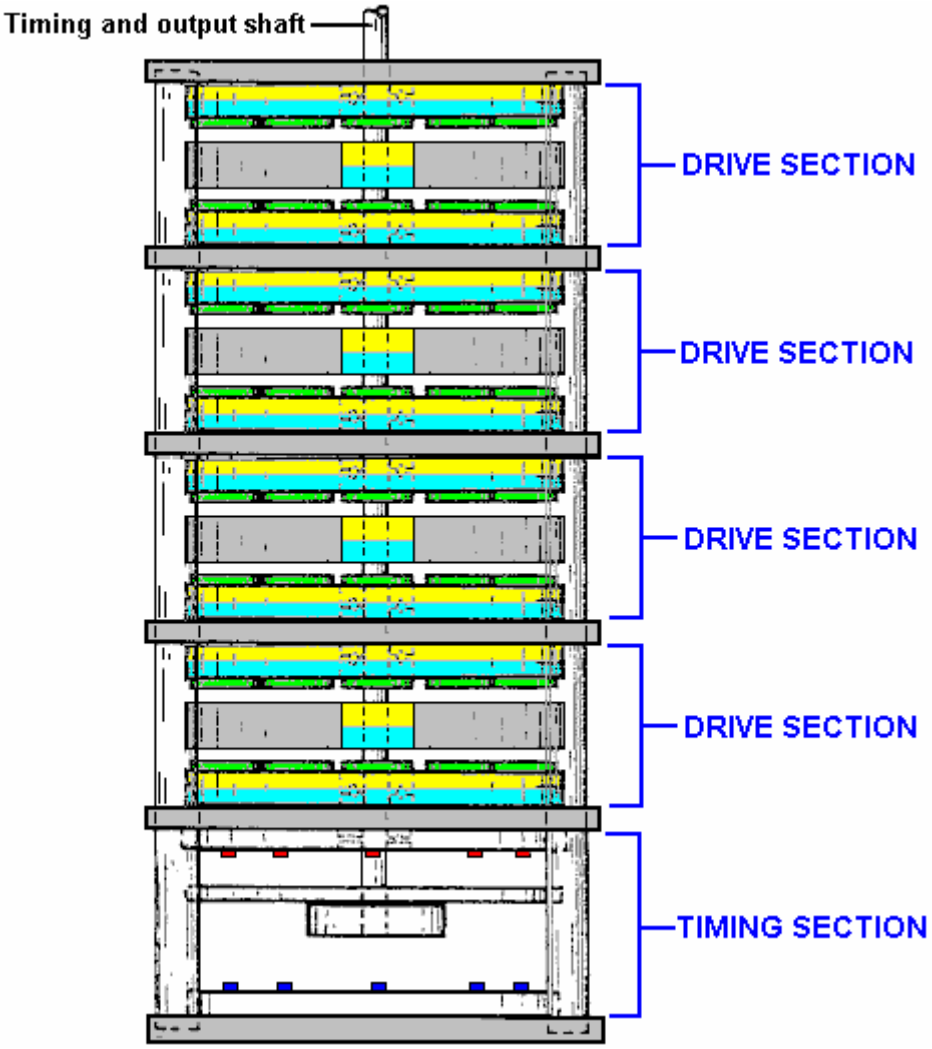
The coil switching with the additional layer of coils is shown here:



This produces a larger horizontal thrust. While this design goes for optimum performance, I suggest that a much more simple form of construction with a ring of standard circular neodymium magnets could be used instead of one large disc magnet, and ordinary circular coils placed on top of the circular magnets, and this allows large diameter rotors to be constructed, the larger diameter giving greater output shaft power:

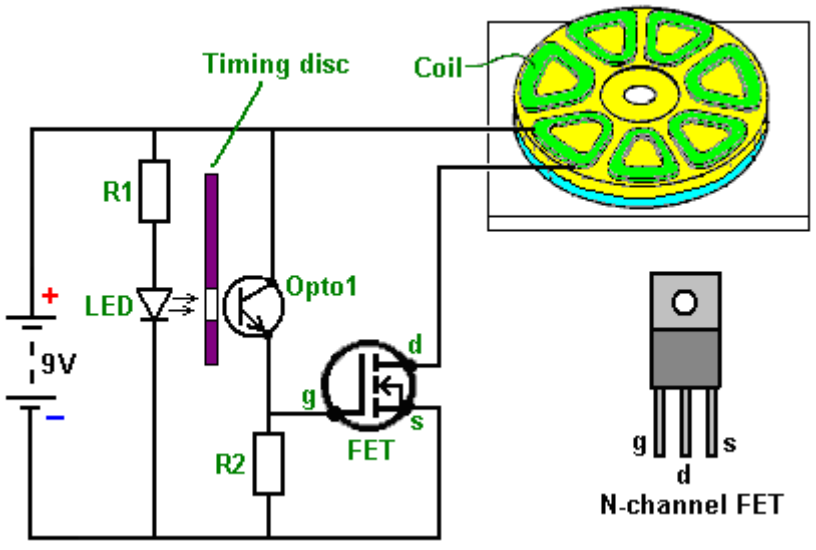


To increase the power of the output shaft further again, additional sets of magnets and coils can be added as shown here:



It should be remembered that the timing section shown above could be replaced by a NE555 timer circuit which generates a steady stream of On / Off pulses. When those pulses are fed to the coils, the motor rotates, slaving itself to the pulse rate. This gives an immediate speed control for the motor as well as avoiding the need for the precise positioning of the slotted disc which allows the LEDs to shine directly on to the phototransistors at the appropriate instant. If that approach is taken, then the timing section shown above would be omitted.

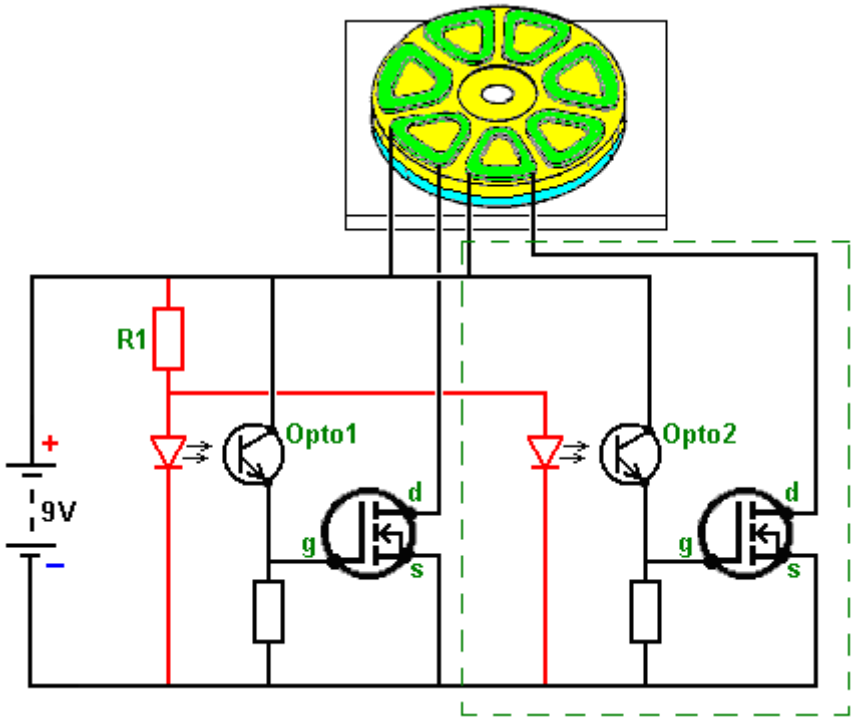
The circuitry that Charles specifies for powering the coils to block the magnetic fields of the permanent magnets uses N-channel MOSFETs and is very simple. Here is his circuit for driving one of the coils:



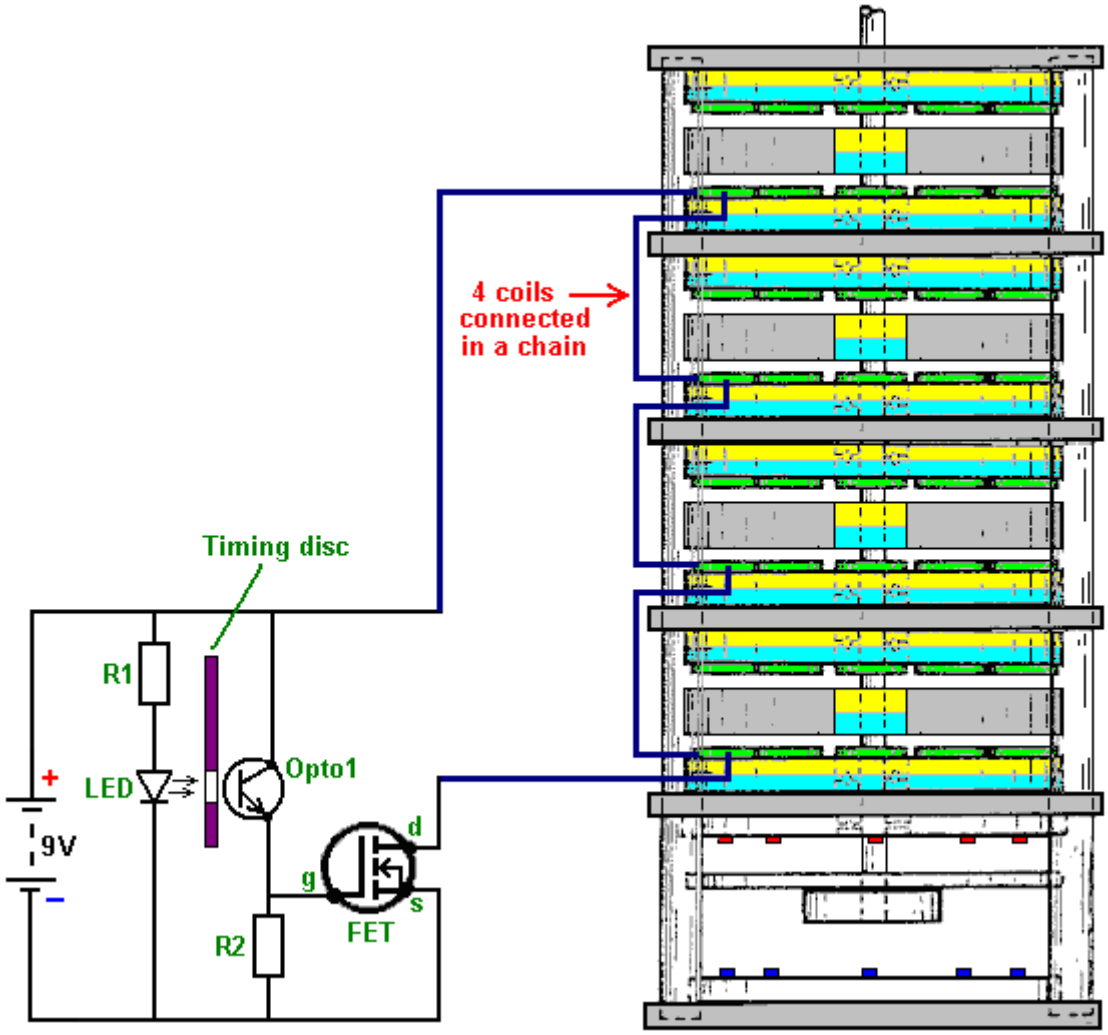
Just five components are used. The current through the coil is controlled by a transistor. In this case it is a Field-Effect Transistor usually called a "FET". The most common type of FET is used, namely an "N-channel" FET which is the rough equivalent to an NPN transistor as described in Chapter 12. A FET of this type is switched off when the voltage on it's "gate" (marked "g" in the diagram) is 2.5 volts or lower. It is switched on when the voltage on it's gate is 4.5 volts or more.

In this circuit we want the FET to switch on when the motor's timing disc is in the right position and be off at all other times. This is arranged by shining the light from a Light-Emitting Diode or "LED" through a hole in the timing disc which rotates with the shaft of the motor. When the hole is opposite the LED for the coil which is to be powered up, light shines through the hole and on to a light-sensitive device, Charles has opted to use a Light-Sensitive transistor, but a light-dependent resistor such as an ORP12 could be used instead. When the light shines on the "Opto1" device in the circuit diagram, it's resistance falls dramatically, raising the voltage on the gate of the FET and switching it on. When the timing disc hole moves past the LED, the light is cut off and the FET gate voltage drops down, switching the FET off. This arrangement causes the coil of the motor to be switched on and off at just the right time to give a powerful rotation of the motor shaft. In the circuit, the resistor "R1" is there to make sure that the current flowing through the LED is not excessive. The resistor "R2" has a low value compared to the resistance of "Opto1" when no light falls on it, and this holds the gate voltage of the FET down to a low value, making sure that the FET is completely off.

As you can see, this is basically a very simple circuit. However, as one of these circuits is used for each coil (or each pair of coils if there is an even number of coils in this slice of the motor), the circuit in the patent looks quite complicated. It is actually very simple. The resistor "R1" is used to limit the current flow through all of the LEDs used and not just one LED. You could, of course, use one resistor for each LED if you wanted to. The circuit for powering two coils (and not showing the timing disc) looks like this:



The section inside the green dashed line being the identical circuit for the second coil. This addition to the circuit is made for each coil, at which point, the motor is ready to run. If, as would be normal, several layers of magnets are being used, then the coils positioned above each other can be connected in a chain like this:

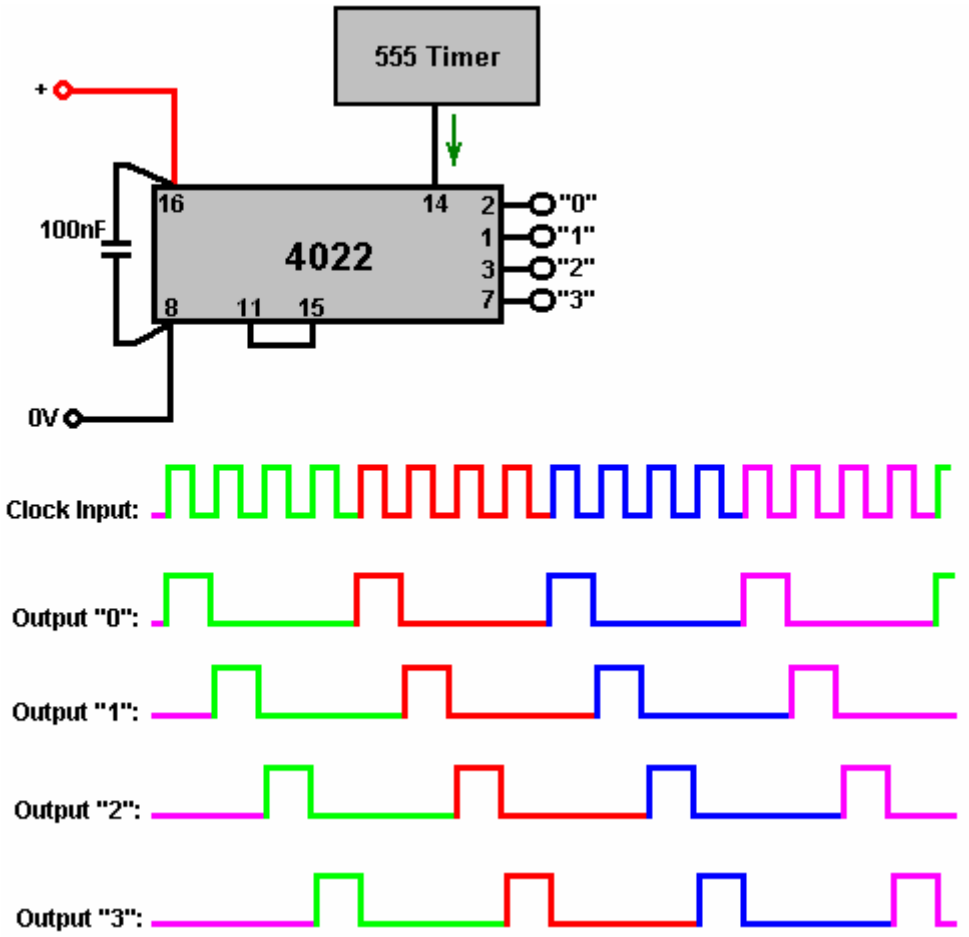


Connecting several coils "in series" (in a chain) like this, reduces the number of electronic components needed and it makes sure that the pulses to each of these coils is at exactly the same instant. Alternatively, it is possible to wire these coils across each other "in parallel", the choice is generally dictated by the resistance of the coils. The patent drawing shown above seems to indicate that there is a big gap between the LEDs and the optical devices. This is probably not the case as most people would choose to keep the gap between the LED and the light-dependent device as small as possible, mounting them so that they are just clear of the timing disc on each side of it.

In this patent, Charles Flynn remarks that this magnet motor can be used for almost any purpose where a motor or engine drive is required and where the amount of energy available or required to produce the driving force may vary little to nil. Charles has produced motors of this type which are capable of rotating at very high speed - 20,000 rpm and with substantial torque. Lesser speeds can also be produced, and the motor can be made to be self-starting. Because of the low power required to operate the device, Charles has been able to operate the motor using just a nine volt, off-the-shelf dry battery.

One application which seems most appropriate for this motor design is the Frenette heater shown in Chapter 14. Using this motor to drive the discs inside the heater drum would produce a heater which appears to be driven by just a nine-volt battery. However, while that is the appearance, the reality is that the power of this motor comes from the permanent magnets and **not** from the battery. The battery current is only used to prevent the backward pull of the magnets and it is **not** used to drive the motor.

While the use of a timing disc is a very satisfactory arrangement, it is also possible to use electronic circuitry instead of the mechanical timing disc, the opto devices and the LEDs. What is needed here is a device which produces a series of voltage pulses which can be used to drive the gate voltage of each FET from below 2.5 volts to over 4.5 volts. It looks as if the well-known 555 timer chip would be suited to this task and it would certainly run off the nine-volt battery. However, we have more than one set of coils which need to be run. For example, if we have say, four sets of coils to drive by powering up four different FET transistors one after the other, then we could use a "Divide-by-Eight" chip, like the 4022 chip. This chip can be set to divide by any number from two to eight. All that is needed to select the number to divide by, is one connection between two of the pins on the chip.



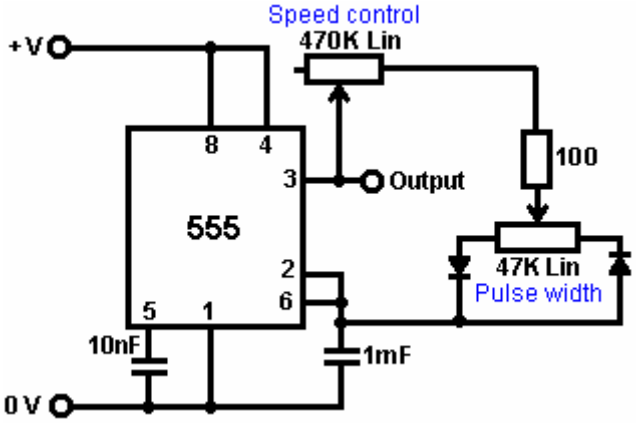
The output voltage on the pins marked "1", "2", "3" and "4" goes high one after the other as shown in the diagram above. So, each of these output pins would be connected to the FET gates in that order and the FETs would get switched on in that same order.

With the 4022 chip, the connections for the rate of division are as follows:

For ‘Divide by 7’ operation, connect pin 10 to pin 15
For ‘Divide by 6’ operation, connect pin 5 to pin 15
For ‘Divide by 5’ operation, connect pin 4 to pin 15
For ‘Divide by 4’ operation, connect pin 11 to pin 15
For ‘Divide by 3’ operation, connect pin 7 to pin 15
For ‘Divide by 2’ operation, connect pin 3 to pin 15

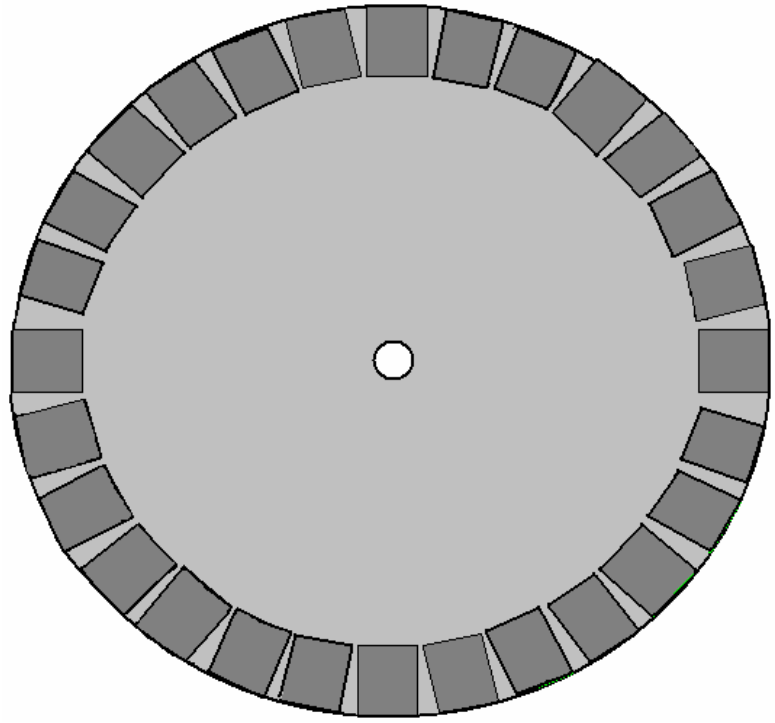
When using a circuit like this, the pulse rate from the 555 chip is set to a very low value like half a second, so that the motor shaft can get started. Once it gets moving, the pulse rate is gradually increased to speed the motor up. One advantage of this method is that it allows speed control, and if the motor was being used to power a Frenette heater, then the speed control would also act as a temperature control for the heater.

A possible 555 chip circuit might be:



As this allows the speed to be controlled and when the required speed is reached, the pulse width can then be adjusted to give the minimum current draw to maintain that speed. There are, of course, many other suitable circuits which could be used instead of this one and Chapter 12 will fill you in on some of them as well as explaining how circuits work and how to build them.

If it so happens that it is difficult to find suitable circular magnets with the poles on opposing faces, then I suggest that it should be possible to use standard rectangular magnets throughout and rectangular coils as shown here:



And while this arrangement is not as magnetically efficient as a circular magnet, it does have the convenience of allowing the construction of a rotor of any chosen size. Ideally, unlike the stator shown above, there should be an odd number of magnets, or failing that, an odd number of coils. Alternatively, the rotor could have an odd number of magnets so as to allow self-starting. But, it should be noted that if the motor is to be driven by an electronic pulsing system, then it is very much more simple to have an even number of magnets on the stator and start the motor moving by hand. This is because with an odd number of stator magnets, the opto sensors are not exactly opposite each other and so do not fire together. With an even number of stator magnets, the coils which are 180 degrees apart can be wired together as they fire at exactly the same time. With the slotted optical timing disc, the slots are exactly opposite each other and match the width of the rotor magnets, but the coils (nearly) opposite each other are not powered on and off at exactly the same time, although their powered arcs are likely to overlap for part of their operation. This could be catered for electronically by using a monostable delay for the coil on the opposite side of the disc.

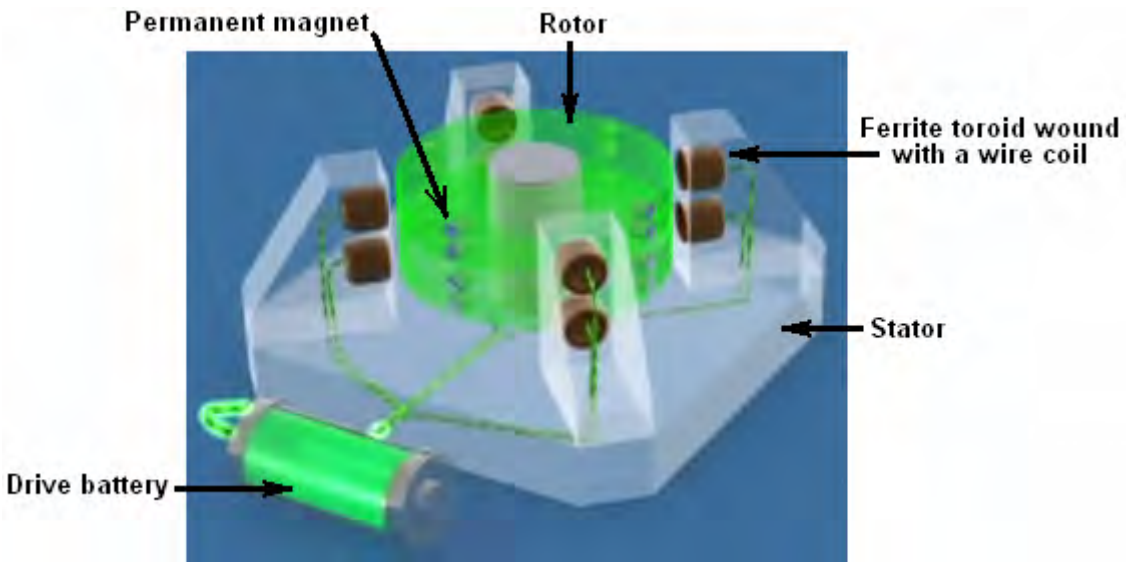
The objective of each coil is to just, and only just, cancel out the magnetic field of the permanent magnet underneath it. The magnetic field produced by the coil depends on the current flowing in the coil, the number of turns in the coil and the area of the coil. The current flowing depends on the diameter of the wire and the voltage applied to it. It is probably necessary to mount just one magnet on the stator and experiment with the coil until

your current drive and coil allow the rotor to spin freely. Whatever the coil result is, should be ok for all of the magnets even though they are likely to vary in strength a bit.

Steorn's Magnetic Devices.

The Irish company Steorn have produced a system which is almost identical to the Charles Flynn magnet motor just described. They call their device "Orbo" and its operation is pretty much the same. The advance made by Steorn is that they have devised a very clever magnetic masking system using ferrite toroids wound with a copper wire coil. This is a slick method of switching magnetic attraction on and off. When the coil carries a sufficient current it generates a circular magnetic field spiralling around the toroid and not going outside the toroid. This field does not have an attraction for outside magnets. It makes no difference if the direction of the current flow through the coil is reversed as the resulting magnetic field just spins around the toroid in the opposite direction and performs exactly the same magnetic blocking of the ferrite ring which forms the toroid. If no current flows, then the copper wire does not block off the influence of the ferrite ring and the permanent magnets on the rotor are strongly attracted to it, causing the rotor to spin.

On their web site www.steorn.com, Steorn illustrate their design like this:



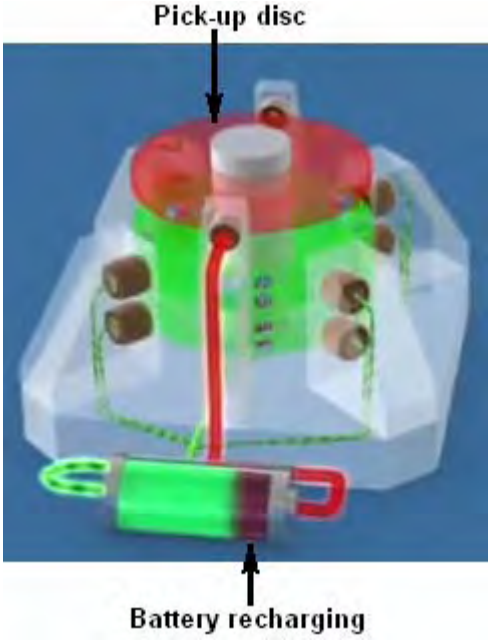
In this implementation, eight ferrite rings are mounted on the stator in four locations ninety degrees apart. These are wound with copper wire coils which can be powered by a battery, via a timing mechanism. The rotor has embedded in it, eight pairs of small permanent magnets, also spaced ninety degrees apart.

In exactly the same way as the Adams motor described in chapter 2, the current through the coils is set to the minimum level which allows the rotor to spin freely. The timing mechanism is then switched in and the motor and the rotor given a spin. The rotor magnets are strongly attracted to their corresponding ferrite rings mounted on the stator posts and this accelerates the rotor.

If no current is passed through the coils, then the rotor will oscillate backwards and forwards for a short time before coming to rest with the magnets as close to the ferrite rings as possible. To prevent this happening, the timing circuit senses when the magnets reach the ferrite rings, and passes that minimum current through the coils, trapping the rings inside a magnetic field which has no effect on the rotor magnets. The momentum of the rotor causes it to spin on past the stator rings to a position where the magnets are closer to the next rings than they are to the ones which they have just passed, at which point, the current is cut off and the magnetic attraction to the ferrite rings returns. This is identical to one mode of operation of the Adams motor.

The next step is also identical to that of the Adams motor, namely, to add on some pick-up coils to convert some of the rotating magnetic energy into electrical energy, either to recharge the driving battery or to power other equipment, or both.

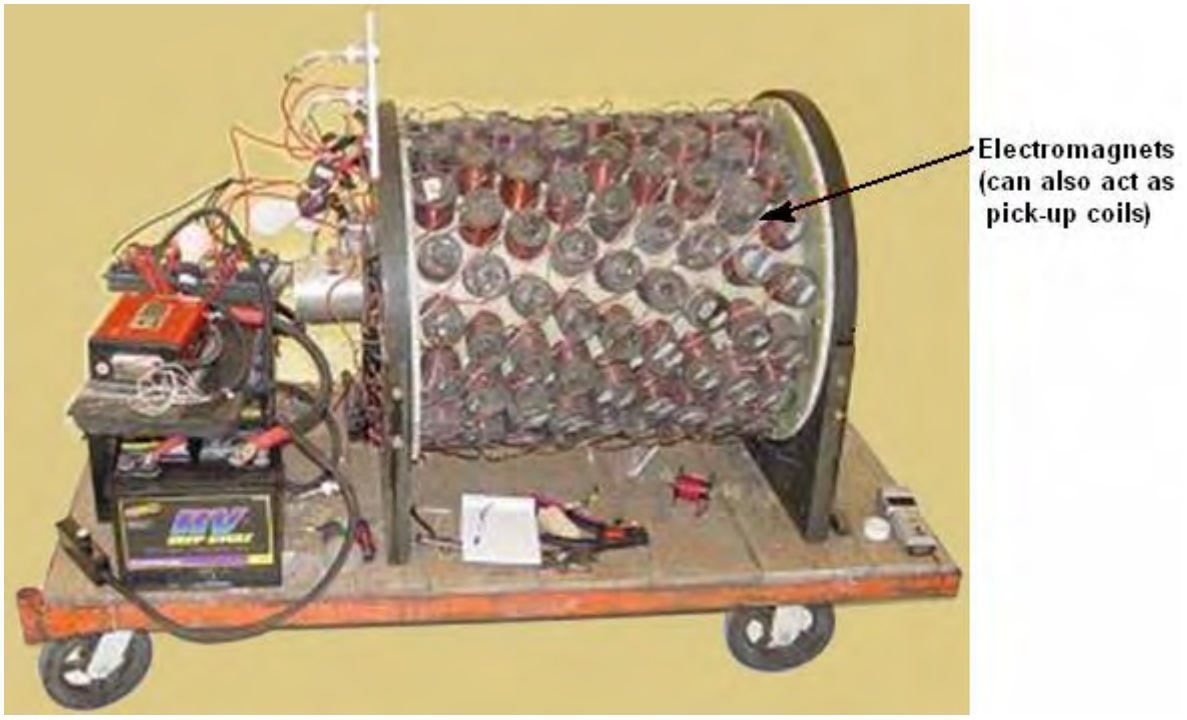
Steorn's arrangement for doing this is to add an additional disc, containing permanent magnets, to the rotor and positioning wire coils opposite those magnets as is normal for a generator. Steorn choose to show the resulting energy charging up the battery again:



Video presentations on this style of motor/generator are at:
http://www.youtube.com/watch?v=AXamGLyRkt8&NR=1
http://www.youtube.com/watch?v=rg3rLqYMzN4&feature=related and
http://jnaudin.free.fr/steorn/indexen.htm

We tend to think of this style of magnet-powered motor as being low-power. This is probably because it is often the case that the demonstration proof-of-principle implementations shown are minor devices. These motors can be very powerful and the one shown here, designed and built by Mr Sung of China has an output power of 20 kilowatts or twenty-seven horsepower:

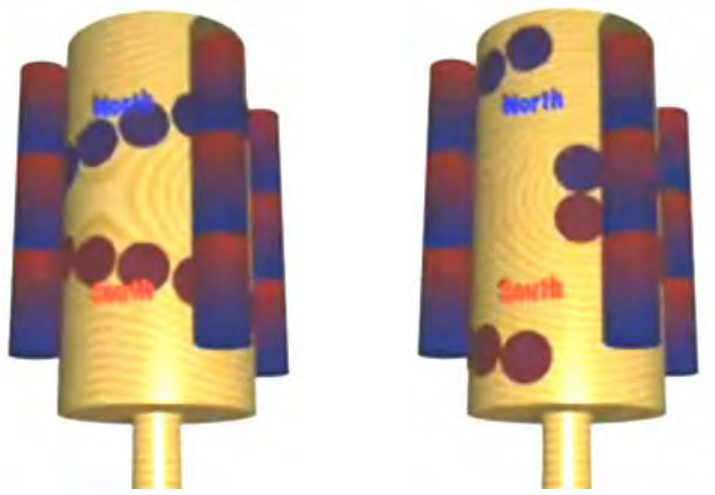
And another design which has a larger diameter and about 144 magnets has a reported output of 225 horsepower:



You will notice that each ring of magnets is positioned further around the rim of the cylinder providing powerful pulses from 64 magnets every 22.5 degrees of rotation, so it is little wonder that the motor has considerable shaft power. Some of the coils can be switched to collect power if the working conditions do not need the full shaft output power, charging the drive battery. The rotating inner cylinder has permanent magnets mounted on it.

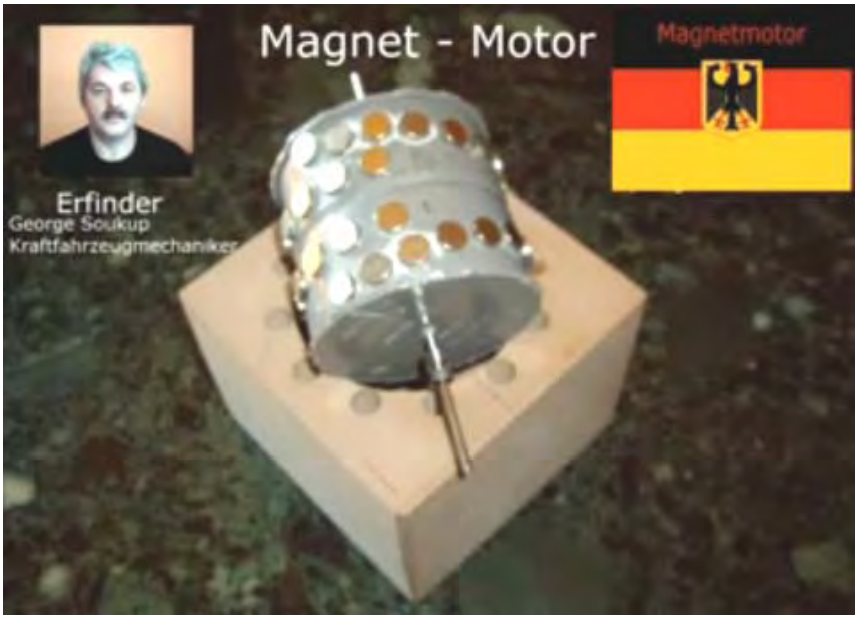
George Soukup's Permanent Magnet Motor.

There used to be a video on the web, showing a magnet motor built on the "V" style of magnet placement which has two sets of permanent magnets spaced like this:



This style of magnet arrangement (North magnets shown in blue and South in red) has a locking point where the switch from wide spacing to narrow spacing occurs and this causes the rotation to stop there.

The implementation shown in this video has the V magnets spaced rather more widely apart as shown here:



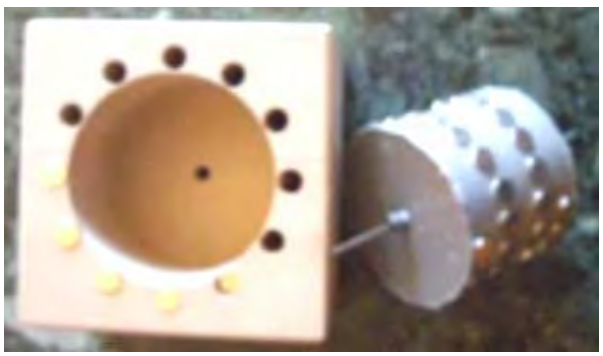
The taper is much less pronounced with an inner gap some four times greater than the gap to the outer ring. It also appears that the last inner magnet has a greater gap around the drum than the remaining ring of magnets.

The housing is very simple looking, with an evenly spaced ring of twelve holes to take long magnets with alternating North and South magnetised areas along their length. You will notice from the photographs, that George has cavities to take up to twelve stacks of stator magnets, although he only uses any five of them for his demonstrations.

The housing has considerable clearance for the drum and magnets. The rear shaft bearing is just set into the back of the housing:

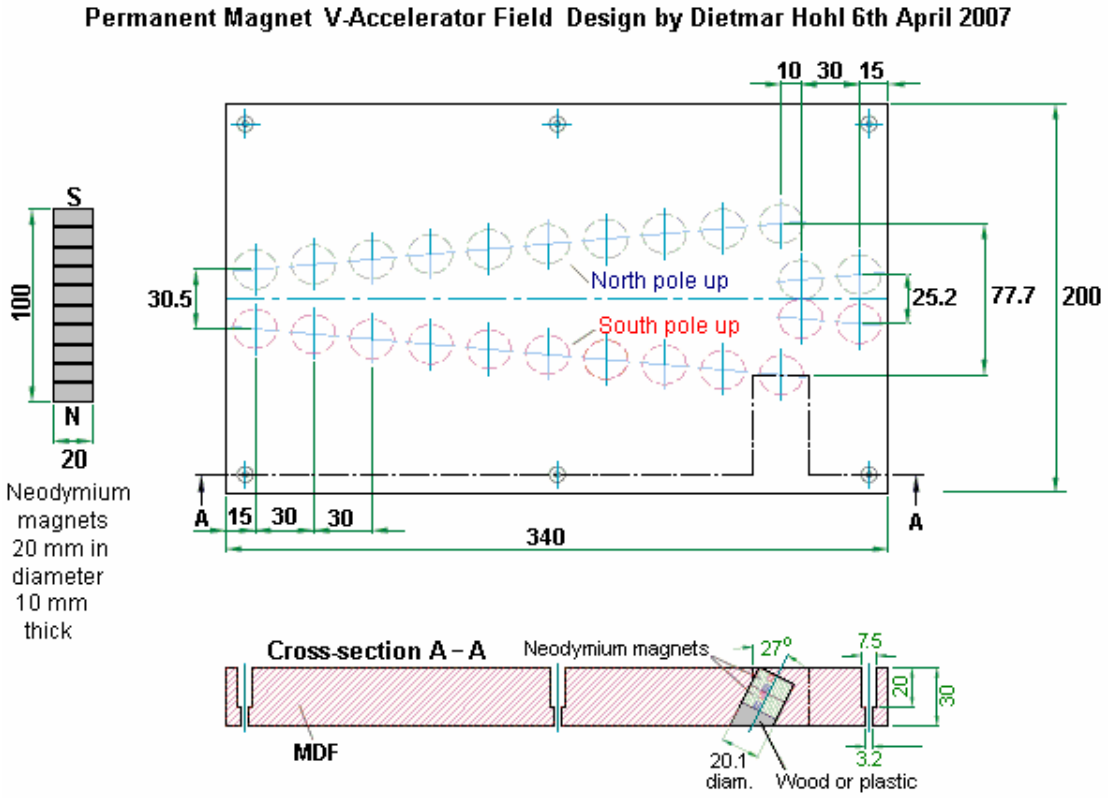
The front has two sheets of acrylic, one to hold the insert magnets in place and one to provide the shaft's front bearing support:

As there is no commentary with the video it is a little difficult to pick up all of the details, but it seems that positioning stator magnets allows the motor to overcome the normal sticking point of the typical V-motor arrangement. The video shows various arrangements including the non-symmetrical grouping shown here where four or five consecutive magnets are used and the remaining slots left empty:



Dietmar Hohl's Permanent Magnet Motor

If you would like to make a simple motor of this type, then the information provided by Dietmar Hohl, passed to me by Jes Ascanius of Denmark, shows you how. He uses 20 mm diameter round neodymium magnets 10 mm thick, stacked in pairs in the stator of this layout:

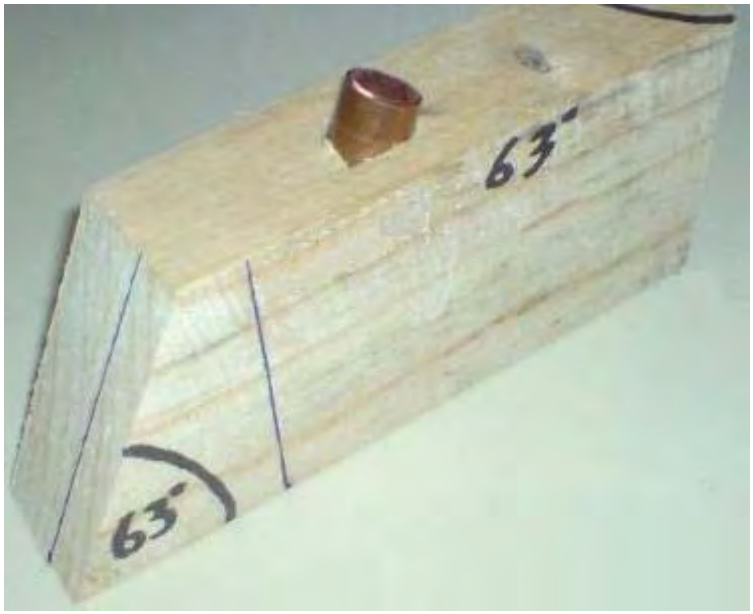


This shows a magnetic gate arrangement built on a flat piece of Medium-Density Fibreboard 30 mm thick. The holes drilled in it are 20.1 mm in diameter and positioned so as to take two of the 10 mm thick magnets stacked together. The holes are drilled at an angle of 63 degrees to the horizontal or 27 degrees to the vertical, whichever way you prefer to think of it. On one side of the board, the inserted magnets have their North poles facing upwards, while on the other side of the board, the magnets are inserted with their South poles facing upwards. Dietmar shows six holes to take bolts or screws to fasten the piece of MDF to a larger board or table. Those do not form any part of the magnetic system and can be omitted. A video of one version of it in action can be found at http://www.free-energy-info.tuks.nl//Vtrack.mpg.

The gate operates by causing a stack of ten of the magnets to roll along the V-shaped track and pass smoothly across the junction with the next set of V-positioned magnets. There can be as many of these V-sets as you want and the magnet stack will still keep rolling. This is one of the few magnetic gate designs which adapts to drum operation as a motor rotor.

The magnets are positioned at an angle in order to use the magnetic fields at the edge of the magnets. They are stacked in pairs in order to increase their power. The power of the motor depends on the strength of the magnets, how close the stator magnet stacks are to the VF-track magnets and the number of stacks of stator magnets. If you decide to construct one of these motors, then it is suggested that you make things easier for yourself by keeping the curvature low, using three or four of the Vs. With Dietmar's dimensions, a 2-V drum would be 216.5 mm (8.5") in diameter, a 3-V drum would have a 325 mm (12.8") diameter and a 4-V drum a diameter of 433 mm (17") and those dimensions include the 30 mm (1 3/16") strip which holds the magnets, so the inner drum diameters are 30 mm less in each case.

When making the motor drum, it is possible to use a flexible material to hold the magnets. This allows the strip to be laid out flat while the holes are drilled, and then attached to the outside of a rigid drum with a 60 mm lesser diameter than the ones mentioned above. Jes Acanius of Denmark shows how a jig can be made to make drilling the holes easier:



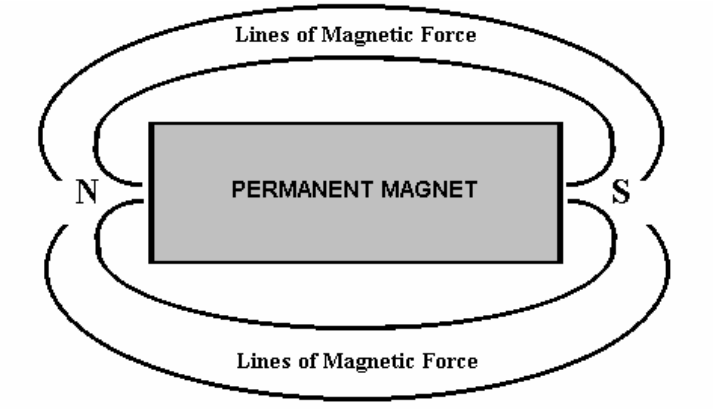
This one has had a length of copper pipe inserted at the correct angle, in order to direct the drill bit at the exact angle required. This motor has been successfully replicated by Jes Ascanius of Denmark who used 10 mm magnets which were to hand, and again with square magnets which were pushed into round holes and not even angled in this proof-of-concept implementation which only took one hour to build using scrap material to hand, and which did work:

With Dietmar's design using angles magnet pairs, the number of magnets needed is quite high. For a single V, there are 58 magnets. For a 2-V version, 106 magnets. For a 3-V version, 154 magnets and for a 4-V version, 202 magnets if there is only one stack of stator magnets, so ten extra magnets need to be added to the count for each additional ten-magnet stack of stator magnets. The motor power is likely to increase as the diameter increases as the lever arm that the magnet has to turn the drum, increases – double the diameter to (almost) double the power.

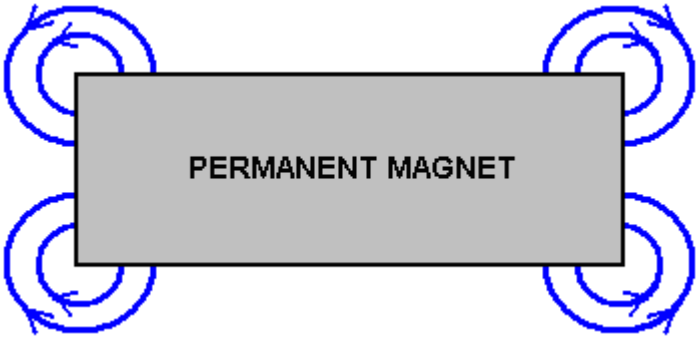
Simple Permanent Magnet Motors

It is very difficult to use the power of permanent magnets to make a motor powered by them alone. The Dietmar Hohl design shown above is one of the very few which can readily be made and tested at home. The problem is that almost all magnets have a symmetrical magnetic field, while what is needed for a magnet-powered motor is an asymmetrical magnetic field. Consequently, magnets have to be combined in ways which distort their normal field shape. You will notice that in the Hohl motor, the drive magnets are angled and that is an important feature of using magnets in motors.

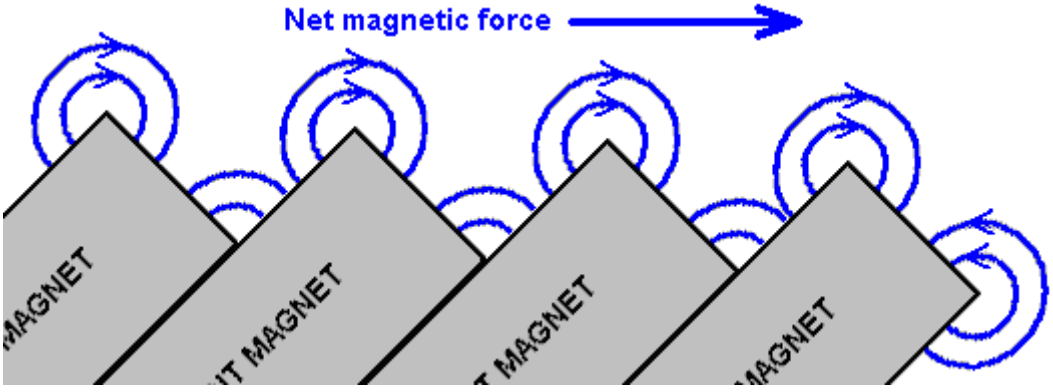
Schools currently teach that the field surrounding a bar magnet is like this:



This is deduced by scattering iron filings on a sheet of paper held near the magnet. Unfortunately, that is not a correct deduction as the iron filings distort the magnetic field by their presence, each becoming a miniature magnet in it's own right. More careful measurement shows that the field actually produced by a bar magnet is like this:

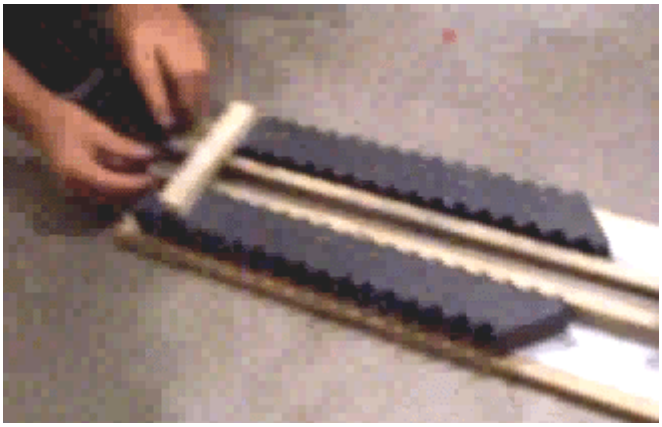


There are many lines of force, although these diagrams show only two of them. The important factor is that there is a rotating field at each corner of a typical bar magnet. It follows then that if a row of magnets is placed at a an angle, then there will be a resulting net field in a single direction. For example, if the magnets are rotated forty five degrees clockwise, then the result would be like this:



With this arrangement, the opposing corners of the magnets as shown here, are lower down and so there should be a net magnetic force pushing to the right just above the set of magnets. However, the situation is not as simple and straightforward as you might imagine. The additional lines of magnetic force which have not been shown in the diagram above, act further out from the magnets and they interact, creating a complex composite magnetic field. It is frequently found that after four or five magnets that a short gap needs to be left before the line of magnets is continued on.

Two boys; Anthony and Andreas, have used this magnet arrangement to create a magnetic track and they have a lot of fun, sending a magnet sliding between two of these rows of angled magnets. Initially, they used the cheaper ceramic magnets and got a very satisfactory movement when using a neodymium magnet as the moving component:



You will notice that they have managed a row of 18 ceramic magnets on each side of their track and the results which they are getting are very good. They have three videos on the web at the present time:

https://www.youtube.com/watch?v=Vo2-Qb3fUYs

https://www.youtube.com/watch?v=VeXrFfw4RSU

https://www.youtube.com/watch?v=VTbFfEEE_qU

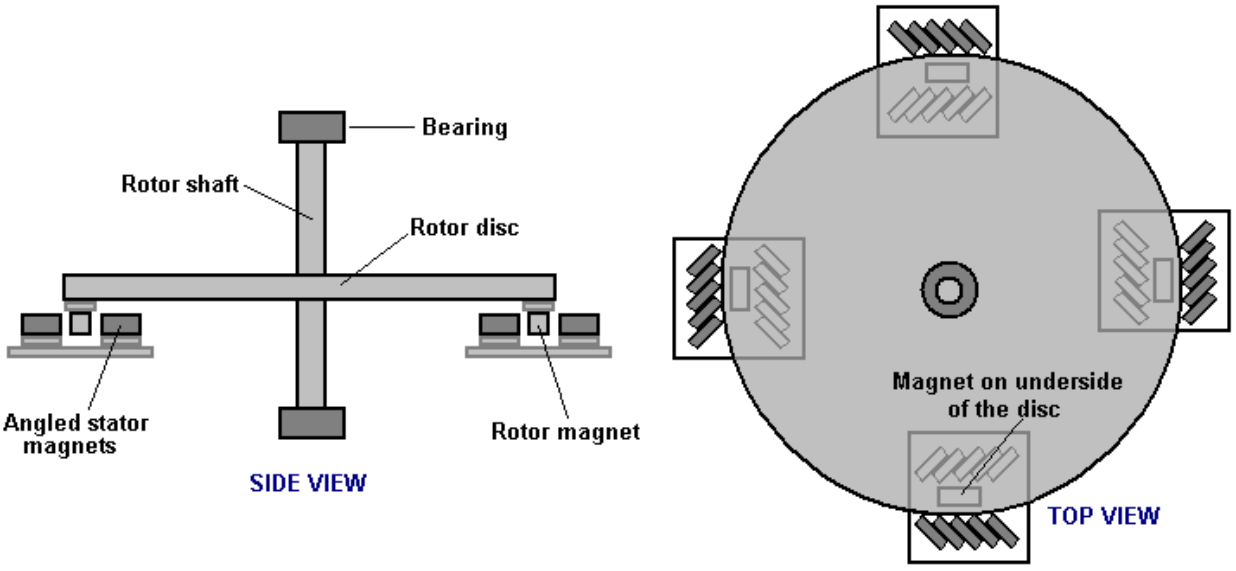
The moving magnet is made up of four 12 mm x 12 mm x 12 mm (or half-inch by half inch by half inch) neodymium magnets attached North - South - North - South - North - South - North - South:

They have not disclosed all of the details of what they are using (accidentally rather than by intention). The ceramic stator magnets are 48 mm x 20 mm x 10 mm with the poles on each of the main faces. They position each magnet with it's North pole facing towards the track and they angle the magnets at 45 degrees. There is a 15 mm gap between the stator magnets and the moving magnets on both sides of the track. Wooden strips direct the moving magnets.

Neodymium magnets have very different characteristics to those of ceramic magnets (and that is not just strength of the magnetic field). It is not unusual for experimenters to find that devices will work well with one type of magnet but not with the other type. Here the developers have also tried using two sets of five angled neodymium magnets on each side of their track and the result was a more powerful thrust on their moving magnets.

The magnets are held in place in this picture, by wooden dowels driven into the base plank. They used these in order to avoid any magnet-fastening material which could alter the magnetic field.

The next step would be for them to power a motor using their magnetic track technique. However, this has been tried many times and the conclusion is that it is **VERY** hard to change a straight magnetic track into one which forms a complete circle. Therefore, I would suggest the following arrangement:

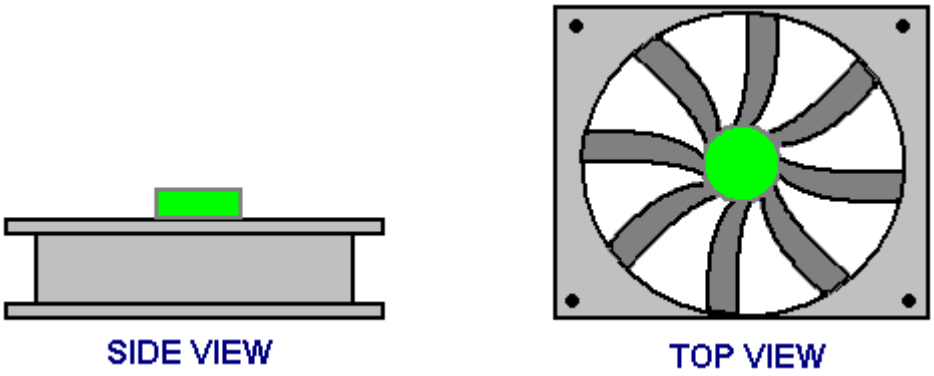


Here, a simple disc rotor has four magnets (of the type used to move down the magnetic track) attached to the underside of the disc and positioned so that they move through four short sets of four, or at the outside, five angled stator magnets as the disc spins. It does not matter if the rotor shaft is horizontal or vertical. If the disc spins well, then sets of two air-core pick-up coils can be positioned between each of the stator magnet arrays so that electricity is generated as the rotor magnets pass by overhead. If a constructor decides to attach two rotor discs to the one rotor shaft, then the two rotors should be positioned so that the rotor shaft gets pushed every 45 degrees of rotation rather than every 90 degrees as shown here. This style of motor is definitely within the scope of the average person to build should they be inclined to do so.

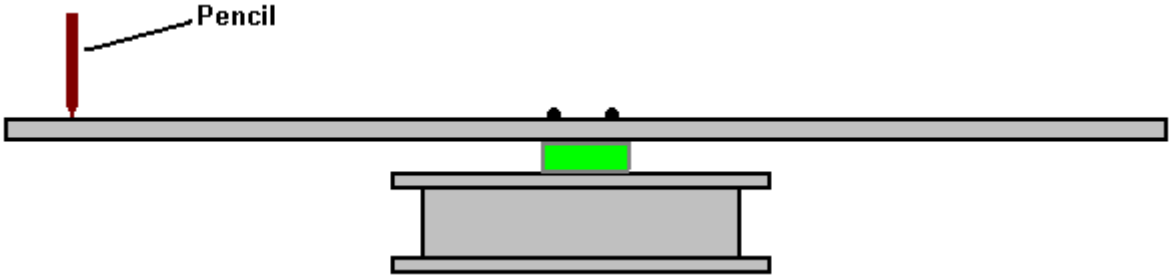
I have been asked to say how I personally would go about constructing a prototype of this nature. As I have very limited constructional skills, I would do it like this:

For the bearing, I would pick a computer cooling fan, as these have very good bearings and if one is not to hand inside an old, obsolete computer, then they can be bought very, very cheaply. The diameter of the fan is not important. These fans generally look something like this:

As the part of the fan which spins round does not normally project above the stationary frame, a spacing disc of wood or plastic is needed to provide the clearance. The disc is glued to the centre of the fan using perhaps, Impact Evostick, epoxy resin or super glue. It would then look like this:



A square of wood can then be screwed to the spacer, like this:



And as I am hopeless at creating good-quality mechanical devices, I would then hold a pencil very steadily against a support and give the wood a spin, so that the pencil draws a perfect circle exactly centred on the bearing of the fan. Then, marking the wood and the spacer so that there is no doubt as to which way round the wood is attached to the spacer, I would unscrew the wood and cut around the pencil line very carefully, smoothing the edges of the disc gently with fine sandpaper. Screwing the disc back in place, a spin should confirm that the edge of the disc stays steadily in place with no wavering of the edge. Actually, if the disc is not perfect, that is not a major problem as it is the rotor magnets which need to be positioned accurately, and for that, another pencil line can be produced by spinning the disc when the desired position has been determined.

Permanent magnets vary enormously in size and strength, so when magnets are purchased, it is a matter of testing them using a track of the type used by Anthony and Andreas. The stator magnets are angled at about 45 degrees to the track and with just four on each side, it is a case of finding the spacing between the two sets of angled magnets which pushes the stator magnets furthest along the track.

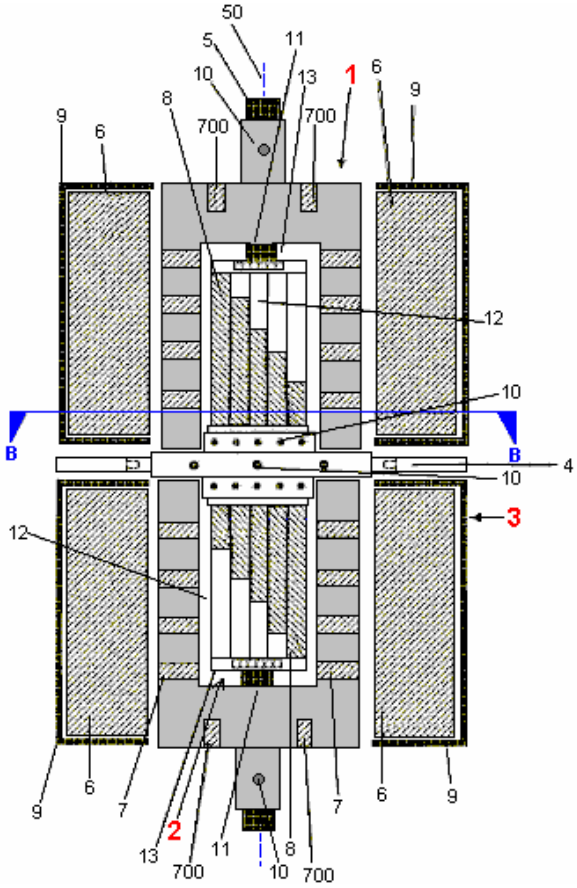
Muammer Yildiz's Permanent Magnet Motor.

Muammer Yildiz has developed a powerful permanent magnet motor, patented it, and demonstrated it to the staff and students of a Dutch university. During the demonstration, the mechanical power output was estimated at 250 watts and immediately after the demonstration, the motor was completely taken apart to show that there were no hidden power sources. There is a video showing this demonstration, located at:
http://pesn.com/2010/04/22/9501639_Yildiz_demonstrates_magnet_motor_at_Delft_University/

Please note that this is an attempted translation of the German language text of his patent and so, the accuracy of the content is not absolutely certain although it is likely to be reasonably accurate.

Patent EP 2,153,515 **17th February 2010** **Inventor: Muammer Yildiz**

DEVICE HAVING AN ARRANGEMENT OF MAGNETS



ABSTRACT

The device has a rotating axial drive shaft **5** supported so that it rotates inside a stator **2**, which is surrounded by an outer stator **3**. The rotor is firmly connected to the drive shaft. The outer stator has dipole magnets **6** which are positioned on the inner surface of a circular cylinder **9**. These outer magnets are evenly spaced around the surface of the surrounding cylinder.

DESCRIPTION

This invention is a device for generating an alternating magnetic field that interacts with a stationary magnetic field. The interaction of a stationary magnetic field with an alternating magnetic field has been used for some time, for example in brushless DC motors and in magnetic levitation.

One object of this invention is to provide an improved device for generating an alternating magnetic field that interacts with a stationary magnetic field. This is achieved as described in Claim 1, by the special arrangement of the dipole magnets of the inner stator, the rotor and the outer stator which creates a magnetic effect which keeps the rotor floating freely between the inner stator and the outer stator, and this acts as a magnetic bearing.

Surprisingly, it has been shown that the special layout of the dipole magnets of the inner stator, the rotor and the outer stator during rotation of the rotor, generates an alternating magnetic field is which allows a largely loss-free movement of the rotor as it spins between the inner stator and the outer stator. This very useful effect can be used for a variety of technical applications, for example, a particularly low-friction bearing is preferred for supporting a shaft which has to rotate at high speed.

In the following description, when mathematical terms, especially geometric terms, are used - terms such as “parallel”, “perpendicular”, “plane”, “cylinder”, “angle”, etc. as is typical when producing technical drawings, but it must be understood that these things are never achieved in practice, due to the manufacturing tolerances of the components. It is therefore important to realise that this description refers to the ideal situation, which will never be achieved. Therefore, the reader needs to understand that generally accepted tolerances will be involved in practice.

The output shaft spins around one axis, called the “shaft axis”. The shaft itself is preferably constructed as a straight cylinder of circular cross-section.

In a preferred embodiment of this invention, the magnets project slightly out of the inner stator. This is also the case for both the rotor and the outer stator. A partial overlap of two magnets is achieved when a plane perpendicular to the shaft axis, passes through both of the two magnets and the two magnets are considered to overlap if this situation occurs.

A partial overlap of three magnets occurs when a plane perpendicular to the shaft axis runs through each of the three magnets. The degree of overlapping does not affect the description and the amount of overlap of any two of the three magnets can be anything from 1% to 100%, where the magnets overlap completely.

In a particularly preferred embodiment of the invention, the magnets of the inner stator and the rotor are able to align completely. In addition to this, the outer stator is constructed so that it can be rotated around the shaft axis so that the contact ratio between the magnets of the rotor and the magnets of the outer stator can be adjusted to give any degree of overlap from 0% to 100%.

Three imaginary cylinders are produced. One by the magnets of the inner stator, a second by the rotor magnets as they spin around the shaft axis and the third is created by the magnets of the outer stator. The axes of these three cylinders is the same as the shaft axis.

Ideally, the rotor will have the shape of a drum or a cup, that is, a hollow cylinder with a circular cross-section or a piece of pipe whose one end face is covered by circular disk. In the centre of the disc, the rotor has a hole through which the shaft passes. The disc can also have a collar which is used to clamp the rotor to the shaft by means of a bolt passing through the drive shaft or by grub screws tapped into the collar. Whichever method is used, the rotor magnet assembly is connected securely to the drive shaft. The use of a clamping screw has the advantage of allowing the rotor to be taken apart for maintenance or repair. The hollow cylinder section of the rotor, is arranged so that there is a small air gap between it and both the inner and outer stators.

The hollow rotor cylinder has two, or more, permanent magnets mounted on it. These are equally spaced around the circumference of the rotor cylinder and positioned so as to be parallel to the drive shaft axis. The outer stator is cylindrical in shape and surrounds the rotor, leaving a small air gap between them and it’s axis is aligned with the drive shaft axis. Ideally, the magnets mounted on the inside of the outer stator cylinder, are aligned with the drive shaft axis and their pole faces are at right angles to the shaft axis. That is, a line drawn through the North and South pole faces of these magnets will point at the drive shaft, and so one pole face will face the rotor.

It is also possible for the magnets of the outer stator to be rod-shaped and to form a complete ring around the inner face of the outer stator cylinder. If this is done, then the magnetic rings need to be separated from each other by non-magnetic spacers and the whole length of the outer stator will be covered with these magnetic rings and spacers. In this case, the inner and outer stators are mounted in a fixed relationship to each other by means of brackets or other mounting methods.

Ideally, the rotor is held in position by the magnetic fields of the two stators and “floats free” between them. This is the preferred method. However, it is possible for the drive shaft to run the entire length of the device and to be supported in roller bearings.

One possible construction is to have both of the stators made in two separate parts. These need to be exactly symmetrical relative to the drive shaft axis. The outer stator pieces can also be arranged to be capable of rotational adjustment relative to the inner stator which always has a fixed position. Another option with this particular arrangement is to have the distance of the outer stator components adjustable, so that the air gap between the rotor and the outer stator magnets can be manually adjusted.

An angle “alpha” is defined as the angle between the magnetic axis of a magnet of the inner stator and a tangent to the circumference of the inner stator at that point. An angle “beta” is defined as the angle between the magnetic axis of a rotor magnet and a tangent to the rotor circumference at that point. An angle “gamma” is defined as the angle between the magnetic axis of a magnet of the outer stator and a tangent to the circumference of the outer stator at that point. In a preferred embodiment of this invention, each of these angles

is between 14 degrees and 90 degrees.

It is a particular advantage if the permanent magnets of both the inner and outer stator have a either a rectangular or trapezoidal cross-section when seen as being cut by a plane perpendicular to the shaft axis. It is also particularly advantageous if the rotor magnets have a circular cross-section when viewed as being cut by that plane perpendicular to the shaft axis. Other, non-symmetrical magnet cross-sections are possible, such as trapezoidal, triangular, or irregularly shaped cross sections.

It is possible for all of the magnets of the inner stator to have identical shapes. Similarly, it is possible for all of the magnets of the outer stator to have identical shapes. It is also possible for all of the rotor magnets to have the same shape. However, the positioning of the magnetic North and South poles of the various magnets will not be identically position as will be seen from the following detailed description.

The magnets of the inner stator, the rotor and the outer stator have a magnetic orientation which causes them to repel each other at every angular position of the rotor. For example, the magnets of the inner stator can have their North poles facing outwards and in that case, the magnets on the rotor will have their North poles facing inwards towards the inner stator. Similarly, the magnets of the outer stator would then have their South poles facing inwards in order to repel the (outer) South poles of the rotor magnets.

Further features, details and advantages of the invention will be apparent from the following description of an embodiment of the invention and the associated drawings as shown here:

surface of the rotor. In this view, the fins between the magnets are not show in order to emphasise the stepping of the magnets relative to each other.

DETAILED DESCRIPTION

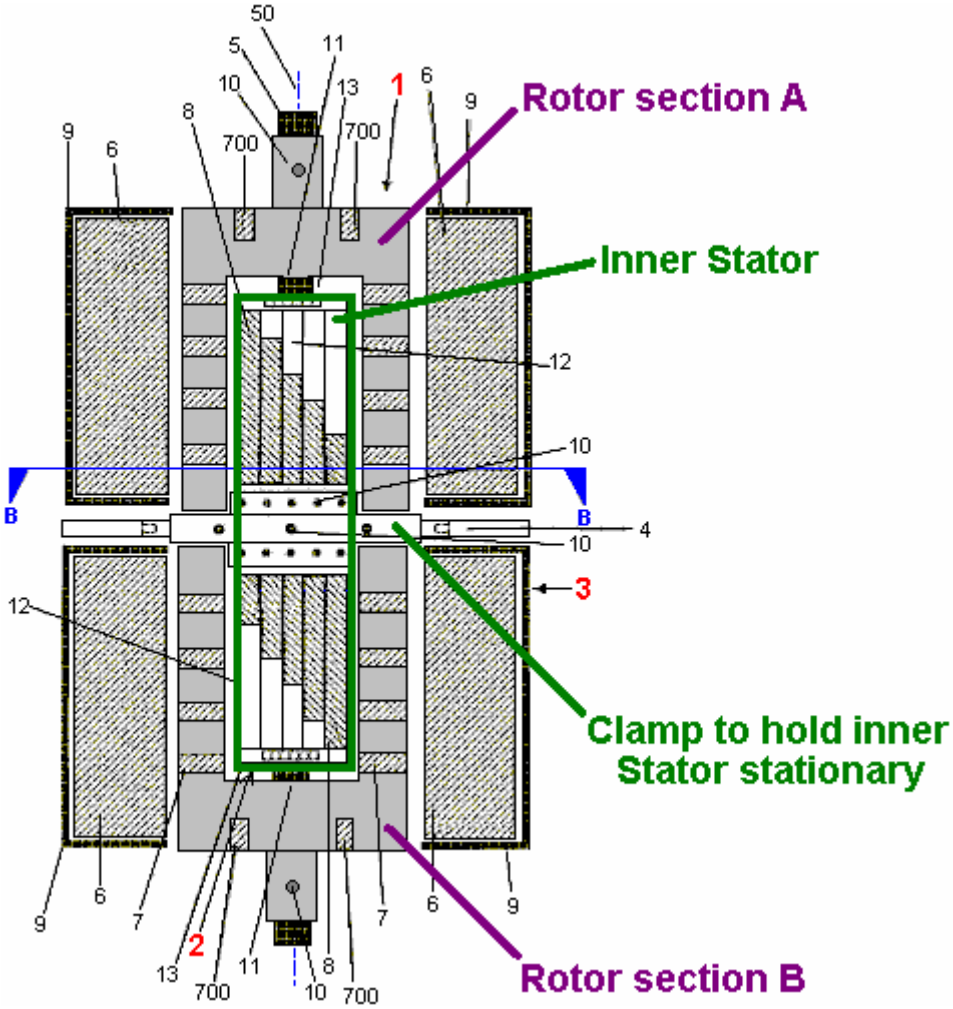

Fig.1 shows a schematic representation of the device having an inner stator **2**, a rotor **1** and an outer stator **3**, which are arranged coaxially around the shaft axis **50** of a pivoting rod-shaped shaft **5**. The cylindrical inner stator **2** has at each end, an end cap **13** which is in the form of a circular disc with a ball-race bearing **11** mounted on it. The bearing **11**, maintains the position of the inner stator **2** relative to shaft **5**. The drive shaft **5** is normally made from a non-magnetic material such as plastic, (not steel) and typically, has a diameter of 10 mm to 40 mm and a length of 100 mm to 400 mm.

The inner stator **2** has a core **12** with magnets **8** mounted on it's outer surface. The inner stator **2** is held stationary by a mounting device **4**, which is secured in position in a mechanical housing (not shown), and is held firmly fixed in this way.

The rotor **1** consists of two mirror-image rotor drums, each with a pipe section and a circular disc section which is clamped rigidly to drive shaft **5** by means of grub screws **10**. Each of the rotor drums has magnets **7** mounted on it. These magnets **7**, are positioned in five distinct places and they have one magnetic pole facing towards the shaft and the other pole facing radially outwards.

The rotor drums are positioned so that there is a cylindrical air gap between them and the inner stator **2**. This air gap is usually of the order of 3mm to 50 mm. Although the two halves of the rotor are separated by the clamping mechanism **4** which prevents the inner stator from rotating, the rotor halves are positioned so that the magnets within them are balanced and so there is no irregular force generated when shaft **5** is spun at high speed. At the ends of the rotor drums there are magnets **700** as the objective of this design is to have the rotor suspended magnetically.

The outer stator **3** is composed of two separate half cylinders **9**. Each of these cylinders **9**, contains magnets **6** mounted on it's inner face. Although each section of the outer stator consists of a hollow cylinder, the outer ends of the stator housing form a complete disc which surrounds the drive shaft **5** and forming a complete enclosure rather than leaving the device open at the ends. There is an air gap between the faces of the magnets mounted on the inner surface of the cylindrical frame **9** and the faces of the magnets mounted on the rotor. These sets of magnets face each other and the air gap between them is also typically 3 mm to 50 mm. The magnets on each of the stators are parallel to the shaft axis **50**. The outer stators is constructed so that it can be moved relative to the inner stator, thus altering their magnetic overlap. This alteration can be made by moving the outer stator when the motor is actually running.

The magnets designated **6**, **7**, and **8**, are dipole magnets and in a preferred embodiment, these are permanent magnets, for example, consisting of SmCo (samarian cobalt) and/or NdFeB (neodymium/iron/boron). It is also possible for one or more of these magnets to be an electromagnet. The magnetic flux density of the magnets **6**, **7**, and **8** is preferably in a range from 0.4 to 1.4 Tesla.

The frame is preferably made from a non-magnetic material such as aluminium with a wall thickness from 2 mm to 10 mm.

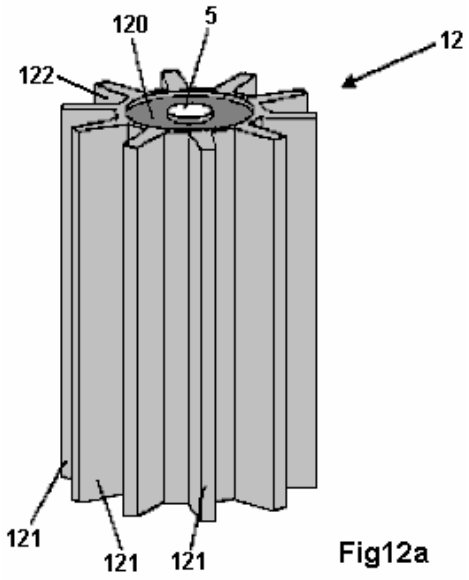

Fig12a

Fig.12a shows an inner stator frame made from a non-magnetic material (such as aluminium or copper). The frame **12** has a circular cylinder **120** which has attached to it's outer surface, radial ribs **121**. Each of these ribs extends along the central axis of the cylinder **120** along the full length of the cylinder, that is, from its' base to the top surface. The ribs are distributed uniformly over the cylinder circumference, forming grooves **122**. Cylinder **120** has a central hole along it's axis for shaft **5** to run through. Both of the end surfaces of cylinder **120** are recessed to accommodate one of the ball bearings **11**. The diameter of the stator core 12 is typically 50 mm to 500 mm with a length of 100 mm to 300 mm. The width of the ribs **121** is generally not more than 100 mm and is usually about 20% of the length of the ribs **121**.

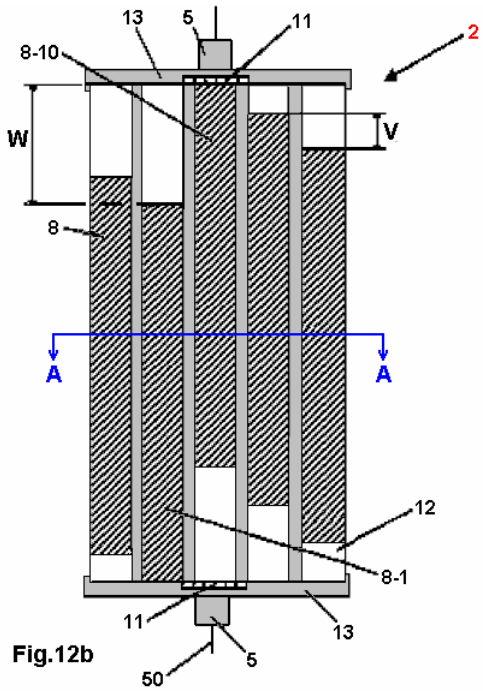

Fig.12b

Fig.12b shows a schematic representation of the inner stator **2**. The inner stator **2** is composed of the inner stator frame **12**, the magnets **8** and the end caps **13**. The magnets **8** are of equal length but their length is less than the length of the stator core **12**. These magnets form the outer surface of the stator. They are seated in the grooves **122** and held in position by the ribs **121**. The first magnet **8-1** is inserted flush with the end cap **13**. The other magnets 8 each have an axial offset **V** along the shaft axis **50** arranged so that there is an even stepping of the magnets with the final magnet **8-10** butting up against the second end plate **13**. The axial offset V is the total overall gap **W** divided by (n - 1), where n is the number of magnets and so, **V** varies with the number of magnets used. In a typical arrangement, **V** is 5% of the length of the magnets **8**.

The end caps **13** have a diameter of 50 mm to 500 mm and a thickness of 5 mm to 20 mm. A typical length for the magnets **8** is 100 mm. The magnet dimensions are arranged so that when they are positioned in the grooves **122**, the inner stator **2** has a substantially uniform outer surface.

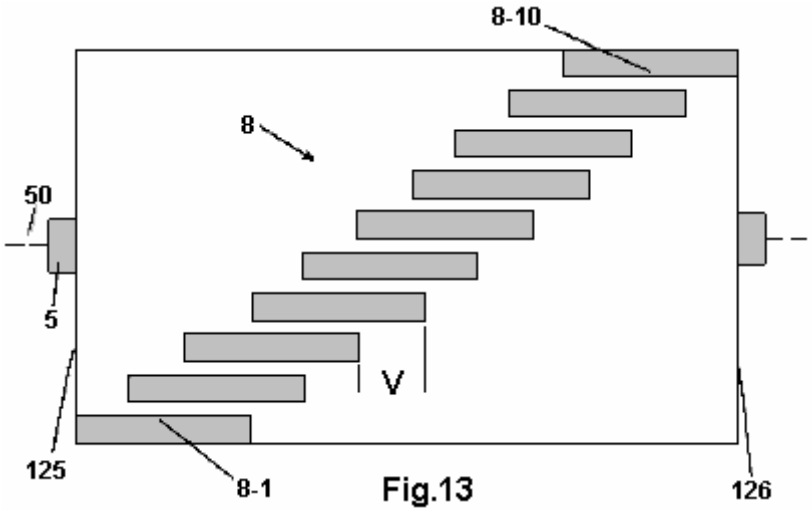

Fig.13

Fig.13 shows an opened-out view of the outer surface of the inner stator **2**. Here, ten magnets **8** are arranged with even spacing. The under side of the magnets taper in the direction of the shaft axis **50** and so they have a lesser width near the centre of the stator than they do at the outside surface. The first magnet **8-1** is positioned

with its end face aligned with the base **125** of the inner stator core **12**. The remaining nine magnets (8-2 to 8-10) are each offset by the amount **V** with the last magnet **8-10** reaching the top surface of the inner stator core **126**.

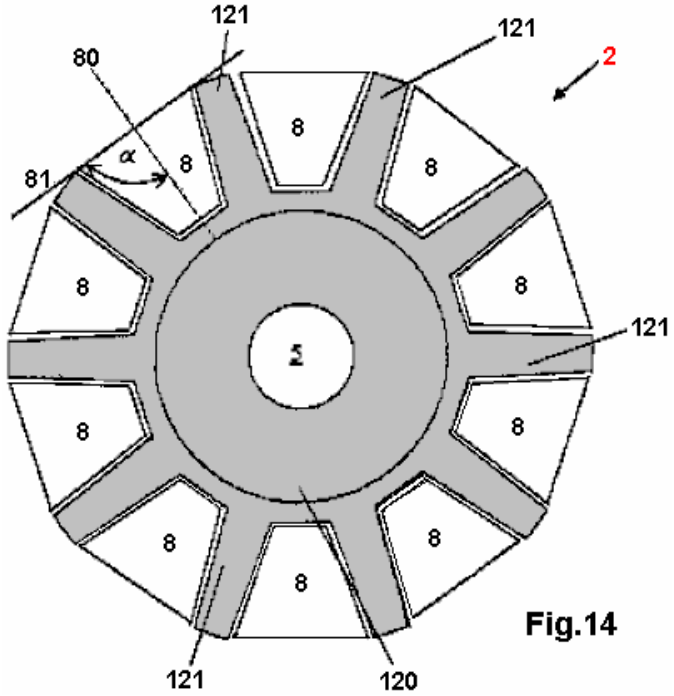

Fig.14

Fig.14 shows a cross-section through the inner stator **2** along the plane **A--A** of **Fig.12b**. The inner stator **2** has a hollow cylinder **120**, through which the central axis of the shaft **5** passes. Running along the outer surface of the cylinder are the ribs **121**. The hollow cylinder **120** typically has a diameter of 100 mm and a length of 170 mm. In the gaps formed between the ribs **121** the magnets **8** are placed. When seen in the plane **A--A** these magnets have a trapezoidal cross-section. These magnets have two magnetic poles and the magnets are positioned so that the magnetic axis **80** which runs through the two poles is radial within the section plane **A--A**. An angle **α** [alpha] formed at the intersection of the magnetic dipole axis **80** of a magnet **8** and the tangent **81** to the ribs **121** can have a value between 14 degrees and 90 degrees. In the case shown in **Fig.14** the angle alpha is 90 degrees.

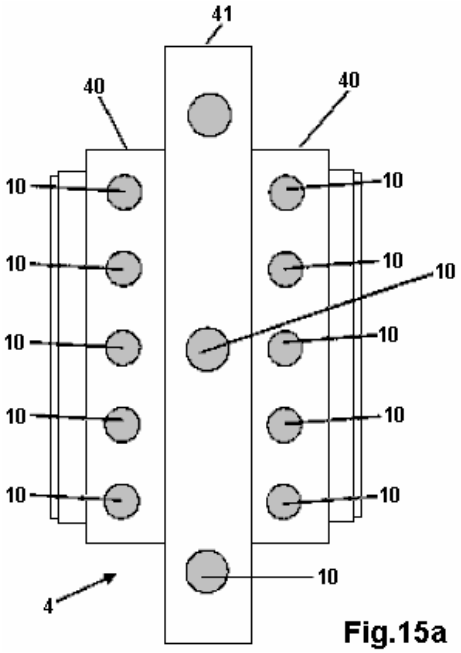

Fig.15a

Fig.15a shows the fastening device **4** in a view perpendicular to the shaft axis **50**. The fastening device **4** has an inner hollow cylinder **40** with a smaller radius and an outer fixing ring plate **41** with larger radius. The inner hollow cylinder **40** and the outer ring fastening plate **41** are connected together. The hollow cylinder **40** is used for receiving and fixing the inner stator **2** by means of screws **10**. The fastening ring **41** is part of a mechanical housing (not shown) for holding the device firmly positioned.

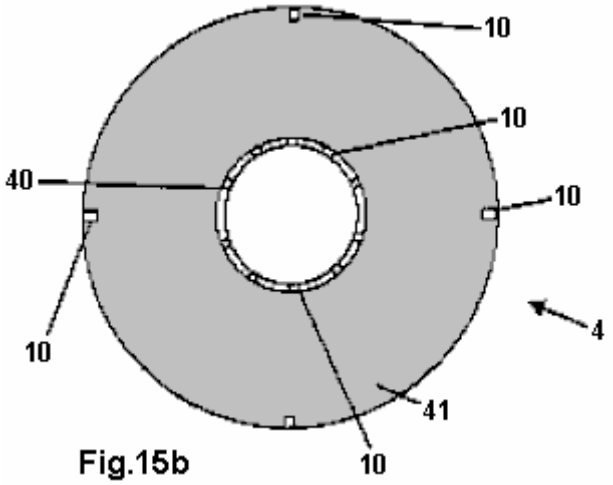

Fig.15b

Fig.15b shows the fastening device **4** in a view in the direction of the shaft axis **50**. The mounting ring plate **41** has at it's periphery, four screws **10** for attachment to the mechanical housing of the hollow cylinder **40** which has on its circumference, a number of screws **10** for fixing the inner stator in place.

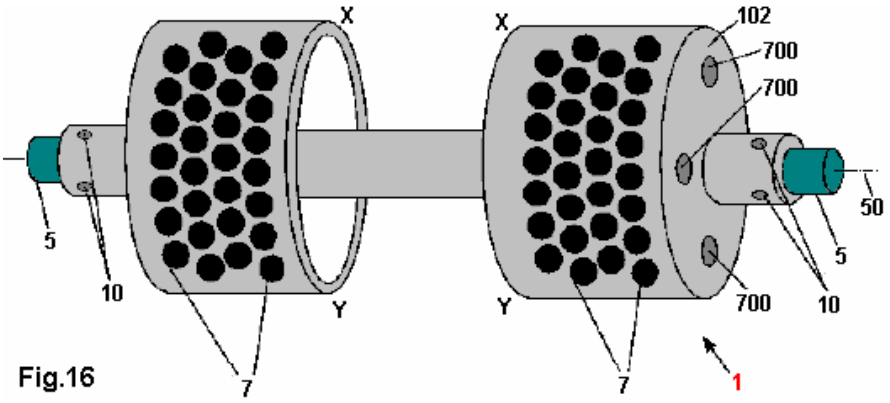

Fig.16

Fig.16 is a view of the rotor **1**, which is clamped to shaft **5** by means of the screws **10**. The rotor **1** consists of two separate drums attached to a central hollow shaft. Mounted in its outer surface are a series of magnets **7** sunk into circular holes. The rotor itself is constructed using a non-magnetic material such as aluminium or copper. The distance between the two rotor drums is 15 mm and they have an outer diameter of 165 mm, a height of 70 mm and a wall thickness of 26 mm. Each rotor drum has a top surface annular disk **102**, into which two or more magnets **700** are sunk. These are positioned uniformly around the circumference of the disc as shown in the diagram. The magnetic dipole axis of magnets **700** is parallel to the shaft axis **50**.

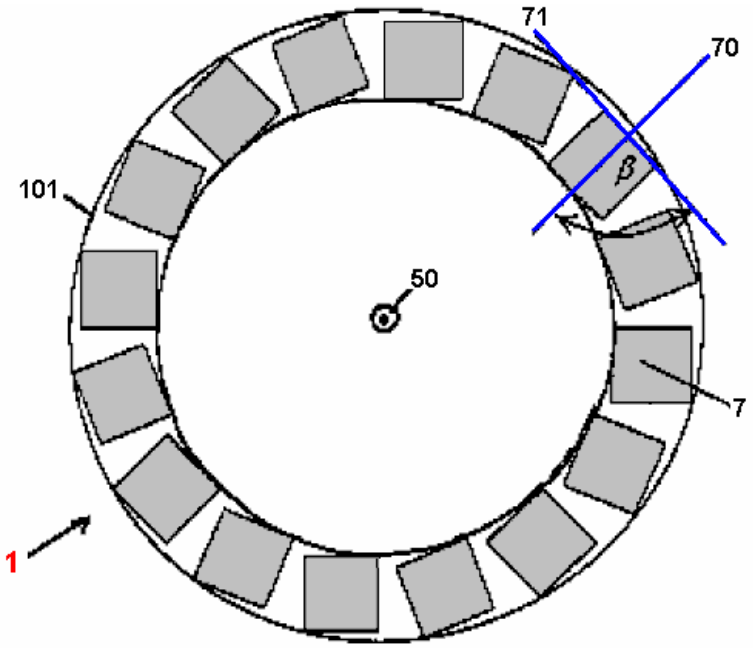

Fig.17a is a schematic representation of the possible orientations of the rotor magnets **7** when seen as viewed looking parallel to the shaft axis **50**. The magnetic dipole axis **70** of rotor magnets seven is in a plane which is radial to the shaft axis **50**. The angle **β** [beta] between the magnetic dipole axis **70** and the tangent **71** breaks through the outer periphery of the hollow cylinder **101** of the rotor **1** and this angle can have values between 14 degrees and 90 degrees.

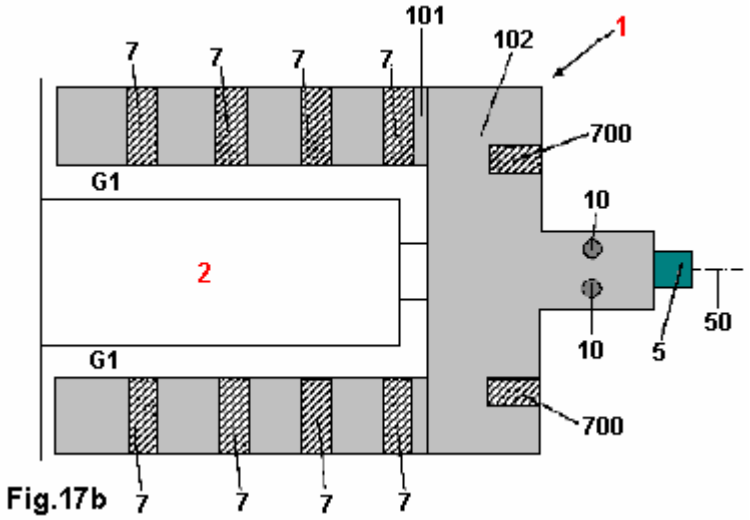

Fig.17b

Fig17b is a schematic view of one rotor drum and part of the inner stator **2**, where the view is perpendicular to the shaft axis **50**. The rotor **1** is clamped to the shaft **5** by the screws **10** and held rigidly in position. The shaft **5** passes through a ball bearing inset into the inner stator **2** and so can rotate freely relative to the inner stator. The rotor has two drum, or bell-shaped, sections which surround the inner stator. The rotor **1** has a hollow cylindrical section **101**, which extends away from the top surface **102**. Since the inner stator is fixed and prevented from rotation by it's anchoring device (component **4** in **Fig.1**), the rotor spins the hollow cylinder **101** around it. The hollow cylinder **101** of rotor **1** is separated from the inner stator **2** by an annular air gap **G1**. The hollow cylinder **101** of rotor **1** has magnets **7** sunk into holes in it. The top surface **102** of the rotor **1** also has holes in it and these are used to install the magnets **700** in it.

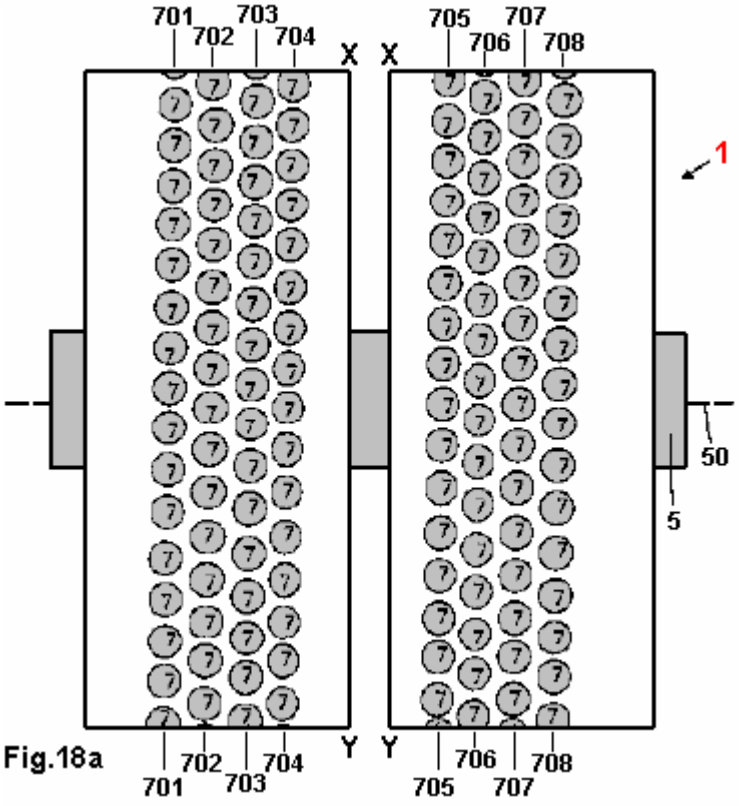

Fig.18a

Fig.18a shows the outer surfaces of the two halves of the rotor drum **1** laid out flat instead of curved into a circle in the **X--Y** plane shown in **Fig.16**. This surface is perpendicular to the shaft axis **50** and rows of magnets **7** are positioned in rows **701 to 708**. Each of these rows is slightly offset in relation to the row beside it, resulting in a zig-zag layout of the magnets **7**.

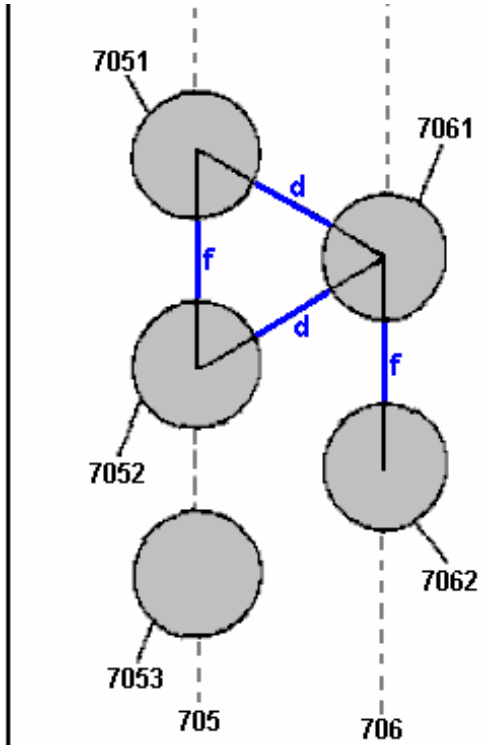

Fig.18b shows, in enlarged detail, the positioning of the magnets **7** shown in **Fig.18a**. The centres of the magnets **7** in the rows **705** and **706** have a constant separation **f** between their edges. The distance between any two adjacent rows, say, **705** and **706**, is chosen so that the arrangement is as shown in **Fig.18b** with constant magnetic separation of length **d** between the edges of the magnets in adjacent rows. For example, the magnets **7051** and **7052** are exactly the same distance apart as magnets **7061** and **7062** the adjacent row **706**. Also, the centres of the three magnets **7051, 7052** and **7061** form an isosceles triangle. This relationship holds for all of the

magnets in all seven series **701** to **708**. Although the magnets **7** are shown in the diagrams as being circular, they could well be other shapes such as square or hexagonal.

The length **d** ranges from about 3 mm to 50 mm. A distance which is particularly preferred, is 5 mm. The distance **f** ranges from about 10 mm to 70 mm.

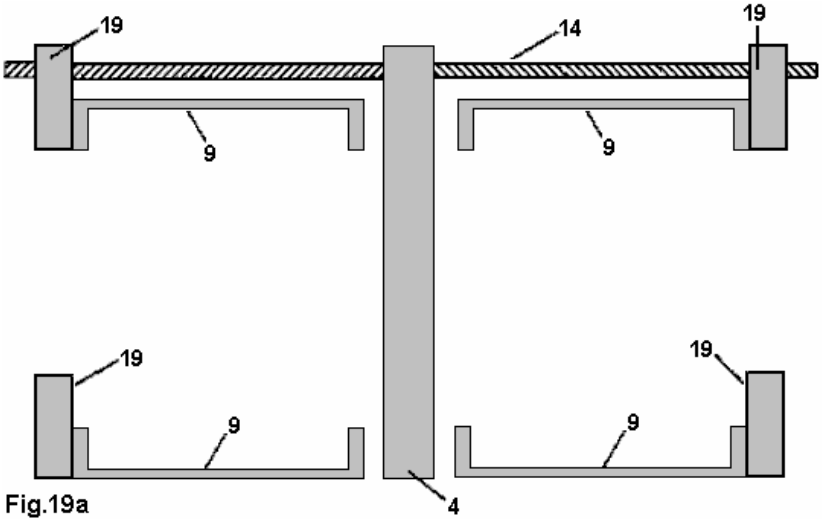

Fig.19a

Fig.19a shows a longitudinal section through the mechanical housing for the device, i.e. a section parallel to the shaft axis **50**. The mechanical housing includes the support piece **4** for clamping the inner stator **2** to prevent it from rotating, the mount **19** for guiding the movable halves of the outer stator **3**, and a rotating threaded rod **14** which can move both halves of the outer stator **3** relative to the rotor and/or the inner stator **2**. The gear shaft **14** has two threaded sections with threads which run in opposite directions (right-hand and left-hand threads). The rotation of this shaft causes the two halves of the outer stator housing to move in a symmetrical manner in opposite directions, inwards or outwards. The guide devices **19** are mounted on the gear shaft **14** and so they only move in one plane. The outer cylindrical sections **9** which house the outer stator **3** are firmly attached to the end caps **19**. Typically, this mechanical housing has a height of 400 to 600 mm, a width of 400 mm and a depth of 530 mm.

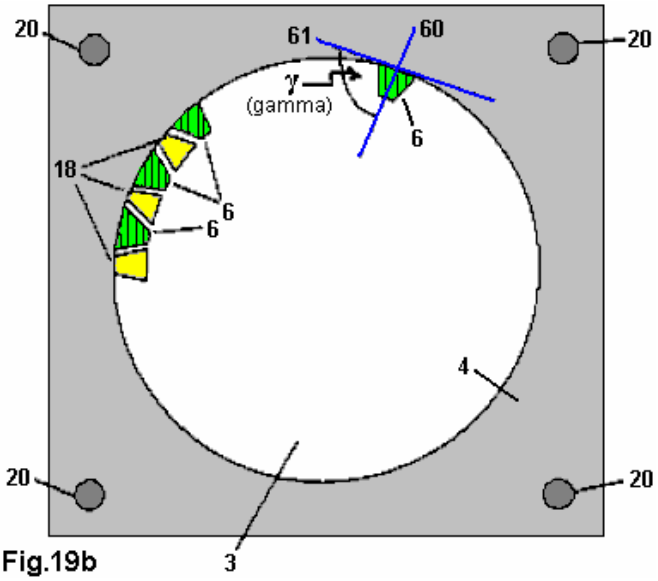

Fig.19b

Fig.19b is a section through the outer stator **3**, the section plane is perpendicular to the shaft axis **50**. The outer stator **3** has arranged in it, a ring of non-magnetic fasteners **18**, between which magnets **6** are secured. For reasons of clarity, only some of the magnets **6** are shown although these magnets are mounted on the entire circumference of the outer stator **3**. The size of the magnets **6** and the non-magnetic fasteners **18** is chosen so that they form a hollow cylinder whose central axis is in the direction of the shaft axis **50**. The magnetic dipole axis **60** of the magnets **6** are perpendicular to the shaft axis **50**. An angle **γ** [gamma] between the magnetic dipole axis **60** and a tangent **61** to the outer periphery of the hollow cylindrical outer stator **3** is between 14 degrees and 90 degrees. The outer stator **3** is connected to the mounting block **4**, which includes the mounting columns **20**.

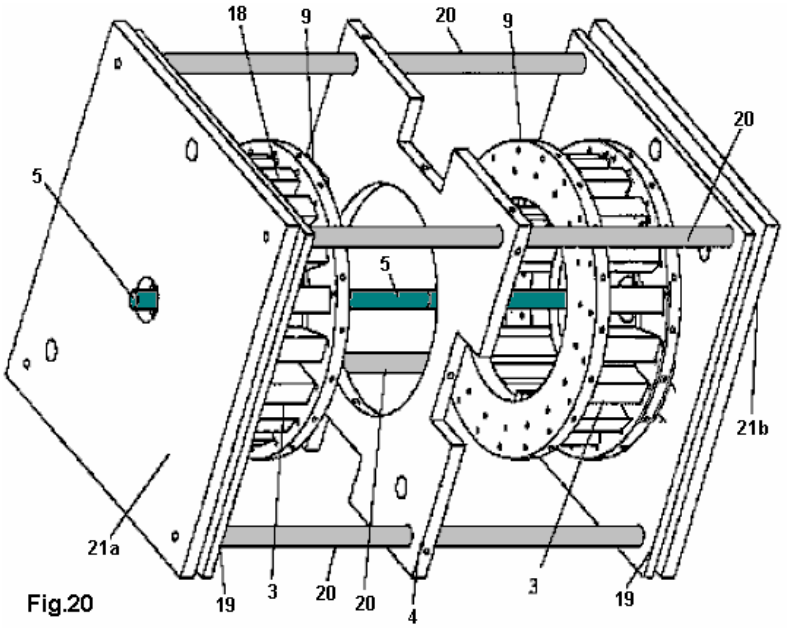

Fig.20

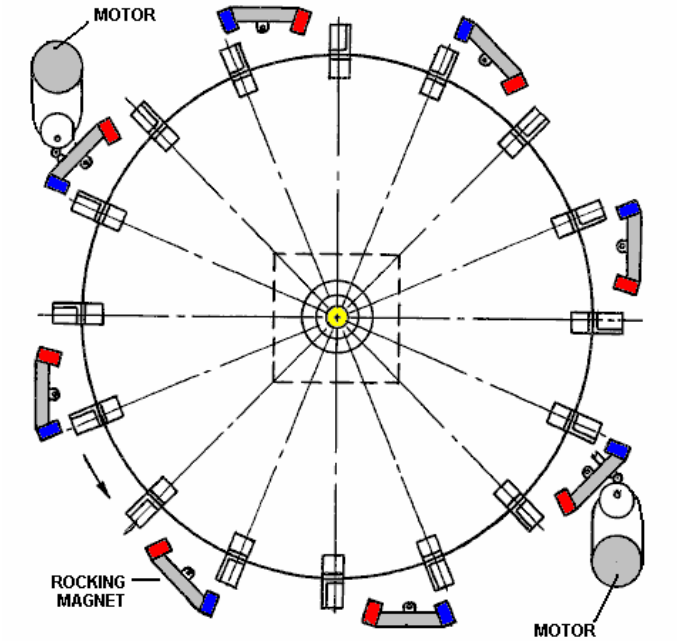
Fig.20 is a perspective view of the mechanical housing for the device. Additional practical details are available in the patent.

Donald Kelly's Permanent Magnet Motor.

In 1979, Mr Kelly was granted a patent on a permanent magnet motor design. He comments that apart from it being very difficult to generate sufficient power to mechanically move the stator magnets slightly to achieve continuous rotation, the resulting rate of revolutions is very low. For those reasons, he has opted to move the stator magnets slightly using small DC motors. His design is included here as it is a concept which is relatively easy to understand. The overall idea is not unlike that of Stephen Kundel who rocks the stator magnets with a solenoid, as shown earlier in this chapter. The objective here is to use a small electrical current to generate a powerful rotation far greater than would be possible from the electrical current itself, and so, produce what is in effect, a power multiplication through the use of permanent magnets. A slightly reworded copy of his patent is shown in the Appendix.

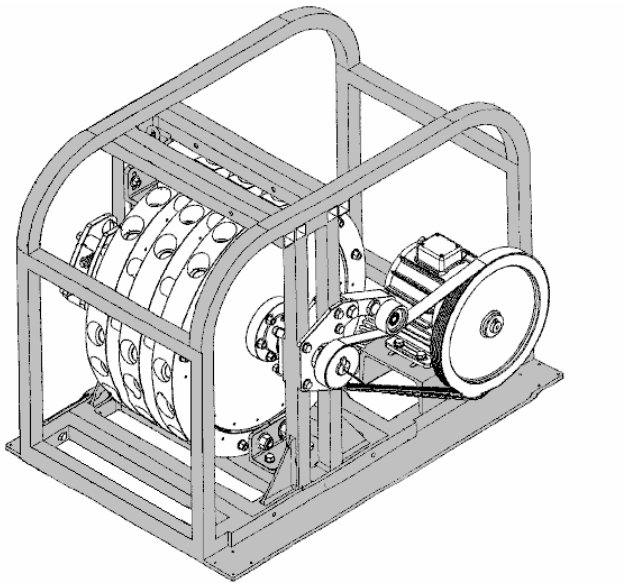


The operation is a simple strategy. Eight sets of magnets are mounted on rocker arms. These have two main positions. In the first position, the rocker magnets attract the magnets mounted on the rotor. When the rotor moves because of this attraction and reaches a point where there is about to be a backward drag on the rotor, the position of the rocker arms is altered so that the first set of rocker magnets are moved out of the way to a position where they have little effect due to their increased distance from the rotor magnets. This rocker movement also

moves magnets of the opposite polarity which push the rotor magnets on their way. In this design, the attraction and the push are applied to different sets of magnets. If the attraction is on magnets 1, 3, 5, etc. then the push is on magnets 2,4,6, etc. But, in spite of this, the pull and push are applied to every rotor magnet as it passes. The power needed to operate the electric motors is minimal as the power of the motor is provided by the magnets. Instead of two tiny motors, it would be possible to operate the rocker arms using small solenoids and if the motor is used to power an electrical generator, then the design could be made self-powered by using some of the electrical output to provide the necessary input power. The sketch above shows just one layer of the motor, but there can be as many layers as you like, each driving the single output shaft, and increasing it's power with every layer.

Mike Brady's "Perendev" Magnet Motor.

One of the most widely known permanent magnet motors is the "Perendev" motor, which catches the imagination of most people. It is said that dozens of these motors have been made and sold as motor/generators with an output of not less than 100 kilowatts. As far as I am aware, this has not been confirmed, nor have there been independent tests made on the motor other than a brief test by Sterling Allan. However, let me stress again that it is **very** difficult to get any permanent-magnet-only motor operating and it is much easier to start with one like the Adams motor shown in Chapter 2, or the Charles Flynn motor shown earlier in this chapter. Please notice as well, that the magnets used in this design are non-standard magnets and so will be difficult to get and probably very expensive because of that and specialised magnetic shielding is used.

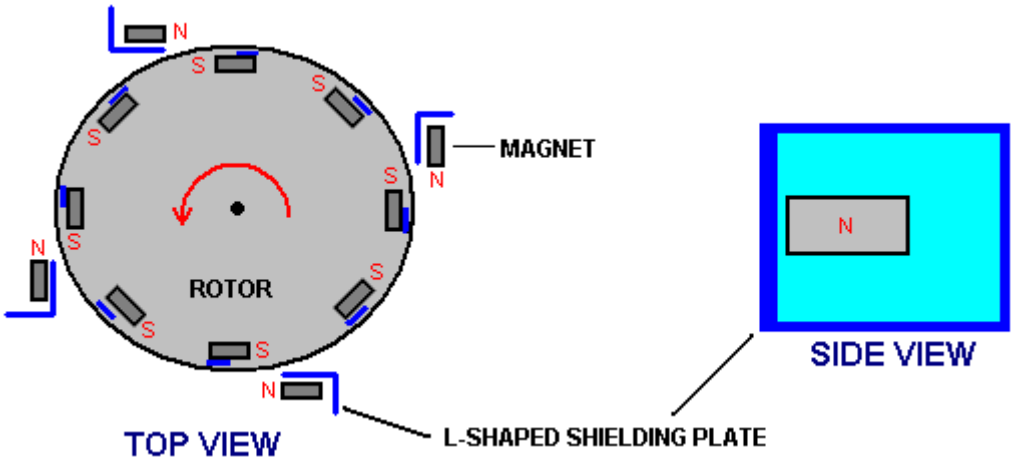


Mike's Patent Application WO 2006/045333 A1 dated 4th May 2006 is shown in the Appendix. In mid 2010, Mike had so much difficulty in getting his design into commercial production that his financial backers are most unhappy with the situation, and if Mike is having difficulty in replicating it (as did Howard Johnson with his magnet motor) then a newcomer to this field would be well advised to stick with magnet motors which use movement of the stator magnets, such as Don Kelly, Stephen Kundel and others, or magnet motors using mechanical or electrical shielding such as the Charles Flynn motor, the Robert Tracy motor, or the Jines motor.

Magnetic shielding from Pasi Mäkilä

A method of blocking a magnetic field using simple materials, comes form Pasi Mäkilä of Finland. His video showing this is at https://www.youtube.com/watch?v=14ayyu9PVSI and he concentrates on placing shielding around a cylindrical magnet:

However, when used as general shielding, a series of flat steel and aluminium layers can be used and while Pasi uses aluminium sheet 1.5 mm thick and zinc-plated steel which is 1 mm thick he suggests using thinner sheets. He suggests using four layers of steel with a sheet of aluminium between the steel sheets and perhaps one or more layers of aluminium on the outside. Pasi's main aim is to share this arrangement to allow people to make permanent magnet motors. One arrangement which may well be worth trying out is to use the shielding to block the backward drag of rotor magnets passing stator magnets, perhaps like this:



With this arrangement, the South poles of the rotor magnets are attracted to the exposed North poles of the stator magnets, causing the rotor to rotate. As soon as a rotor South passes the stator North pole, the stator shielding blocks the reverse pull which would normally slow the rotor down.

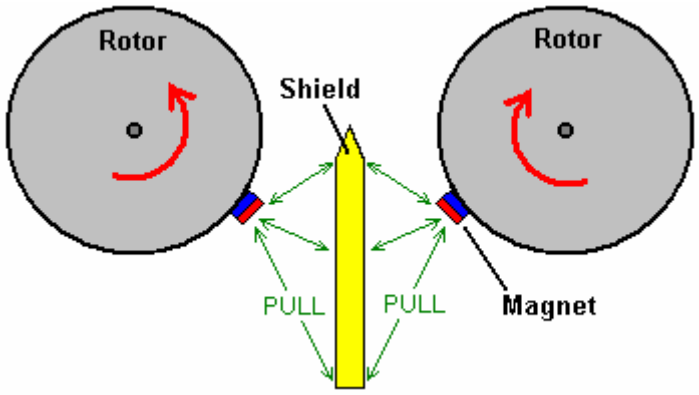
We then have the repulsion of the North pole of the stator magnet and the North pole of the rotor magnet. To block that, a short length of shielding is placed beside the north pole end of the rotor magnet. It would probably be an advantage to run the stator north pole shielding over the top and underside of the rotor magnet to cause major magnetic blocking.

This magnetic motor design is just a suggestion and has not yet been built and tested.

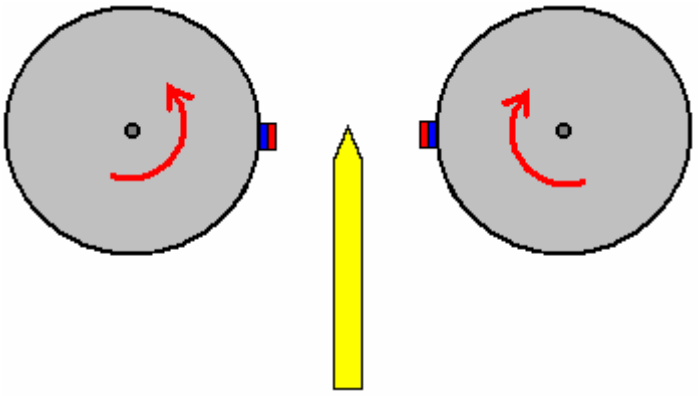
The Twin Rotor Suggestion

When you are considering shielding magnets using iron or steel, you need to remember that fridge magnets stick to refrigerators because the refrigerators are made of steel. This demonstrates the fact that there is an attraction between magnets and iron or steel. Consequently, if a magnet is shielded with steel so that it blocks the whole of the magnetic field of the magnet, a second magnet will be attracted to that metal shielding material. At http://www.youtube.com/watch?v=vUcWn1x3Tss there is, at the present time, a video by "magneticveil" where he proposes the use of this feature of simple shielding in the construction of a magnet motor.

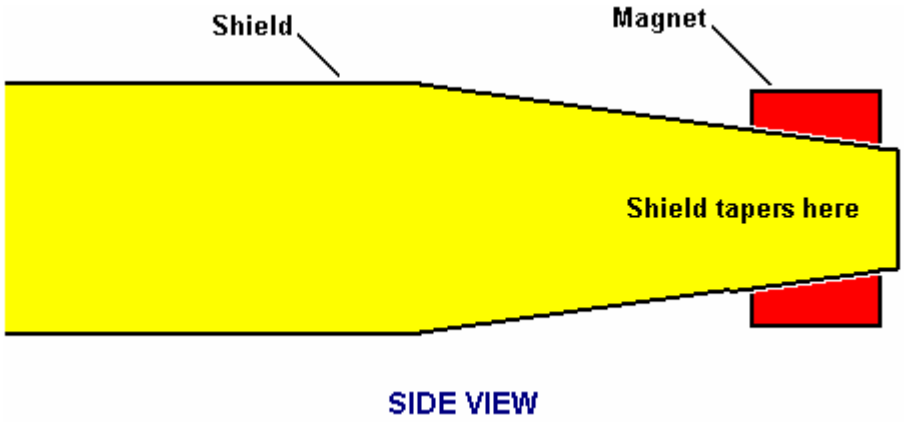
He suggests using two rotors geared together. The rotors have magnets on them, but for the purposes of explanation, just one pair of magnets are shown here:



Each magnet is attracted to the metal shield material between the rotors. This causes the rotors to rotate in the direction shown by the red arrows. The magnets are drawn to the nearest point to the shield which they can reach as shown here:

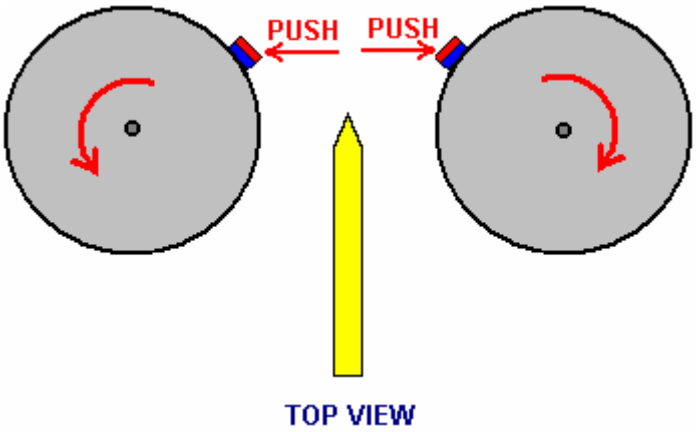


At this point you would expect the rotors to stop moving and lock into a stationary position. However, the interesting idea is to adjust the shape of the shield like this:



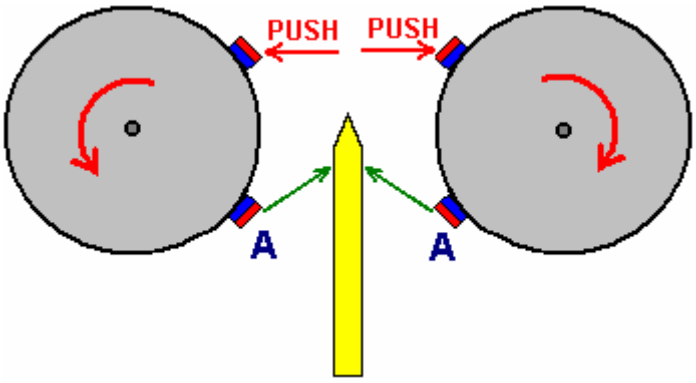
At the end of the shield, its width is reduced and tapered so that the magnetic field from the magnet behind it exactly matches the attraction of the magnet on the near side of the shield. This has the effect of giving a completely neutral zone at the tip of the shield, with neither an attraction or a repulsion in that region. The degree of tapering depends on the strength of the magnets, the thickness and material of the shield and the spacing between the magnets and the shield, and it needs to be discovered by experiment.

This neutral zone stops there being a major pull between the magnets and the shield, and so momentum carries the rotors on past the end of the shield. This produces a situation like this:



Here, the magnets have moved past the shield and are repelling each other strongly. They are beyond the axles of the rotors, so the repelling force produces a turning effect on each rotor. This is the situation with just one pair

of magnets, but each rotor will have many magnets on it. This produces an additional turning effect. Consider just one other pair of magnets, in the same position as our first diagram:



The pull between the magnets “A” and the shield, adds to the rotation caused by the push between the unshielded magnets. This arrangement of magnets and shield should allow continuous rotation of both rotors and the motor can be stopped by removing the shield.

It should be noted that this arrangement uses magnets in repulsion mode. That is, the outward-facing poles of the magnets on both rotors are the same. There have been reports of permanent magnet motors where the magnets were in repulsion mode, and while these motors ran well, it was found that after about three months, the magnets lost their magnetisation. If at all possible, magnets should be used in their attraction mode. This is not possible in the above twin-rotor arrangement, so if one is being constructed, it might be a good idea to arrange the physical construction in such a way that the rotor magnets can easily be removed. This allows remagnetisation of the magnets, or alternatively, their replacement if very cheap types are used.

The Permanent Magnet Motor of Victor Diduck

In US patent application number US2007/0296284 of 27th December 2007, there is shown a convincing design for a powerful permanent magnet motor. Here is one of the embodiments from that patent – one which looks reasonably easy to build.

Magnetic Motor

Abstract:
A magnetic motor having a magnetic drive assembly magnetically coupled to a magnetic slave assembly. The drive assembly has at least one drive magnet. In one embodiment the drive magnet is mounted on a cowling. In another embodiment the drive magnet is mounted on a drive wheel. The slave assembly has at least one slave wheel mounted on a slave shaft. At least one slave magnet is mounted on the slave wheel. In one embodiment slave magnets are mounted in grooves running diagonally across the face of the slave wheel. In another embodiment the slave magnets are mounted in notches cut into the slave wheel. The drive magnet is magnetically coupled to the slave magnet with the poles arranged in a like-faces-like orientation. The gap between the drive magnet and slave magnet can be adjusted in order to optimise the magnetic coupling the between them. The slave wheel and its slave shaft are caused to rotate by the magnetic coupling between the drive magnet and the slave magnet. The slave shaft can be coupled to an output device such as an electric generator.

BACKGROUND OF THE INVENTION
There have been a number of attempts to perfect magnetic motors; for instance, U.S. Pat. No. 4,151,431 issued to Howard Johnson. However, in most such devices no working models have been achieved. In order to make a permanent magnet motor operate it is necessary to accomplish a switching function equivalent to that accomplished in electric motors by brushes, commutators, alternating current, or other means. In permanent magnet motors magnetic leakage must be shielded so as to reduce energy lost as eddy-current energy. A proper combination of materials, geometry, and magnetic concentration is required in order to be able to construct a magnetic motor that can operate continuously.

SUMMARY OF THE INVENTION
A magnetic motor is provided comprising a magnetic drive assembly magnetically coupled to a magnetic slave assembly. The magnetic slave assembly includes a rotatable slave shaft upon which is mounted at least one rotatable slave wheel. Upon the slave wheel is mounted at least one slave magnet. The magnetic drive assembly

includes at least one drive magnet which is magnetically coupled to the slave magnet in a like-faces-like orientation. As a result of the magnetic coupling between the drive magnet and the slave magnet, magnetic forces produced between the coupled drive magnet and slave magnet drive the rotatable slave wheel, making it rotate and therefore causing the slave shaft to rotate. The slave shaft is coupled to an output device such as the armature of an electric generator.

The slave assembly is coupled to a frame. The slave wheels are fixed to the shaft so that the wheels rotate together. Each slave wheel has embedded in its surface a plurality of slave magnets set in indentations cut into the slave wheel. One pole of each slave magnet is exposed and facing outwards from the surface of the slave wheel, and the other magnet pole faces the slave wheel. Either the north pole or the south pole of the slave magnets may face outward, as long each magnet has the same pole facing outwards.

In one embodiment the indentations in the slave wheels for receiving the slave magnets form spaced apart, parallel grooves running from one side of the surface of the slave wheel to the other for receiving the slave magnets. The angle of each groove across the surface of the slave wheel is preferably about 35 degrees with respect to horizontal. The direction of orientation of the grooves of the other of the slave wheels is also about 35 degrees off of the horizontal, but in the opposite direction to that of the first wheel.

In another embodiment the indentations in the slave wheels for receiving the slave magnets are notches cut into the slave wheel at measured and equal intervals along the edges of the wheel, intervals of 45 degrees being preferred.

In this “cowling” embodiment of the invention, the magnetic drive assembly comprises a pair of non-magnetic cowlings surrounding and substantially enclosing each of the slave wheels. Each pair of cowlings forms a semi-circular surface having a diameter slightly larger than the diameter of its respective slave wheel. The concave curvature of the cowlings faces the slave wheels. Mounted on the convex surface of the cowlings are a plurality of permanent drive magnets. The drive magnets are mounted so that they present to the slave magnets the same pole as the slave magnets present to the drive magnets; i.e., like-faces-like: north-to-north or south-to-south. Neither the cowlings nor their drive magnets rotate.

In the various embodiments, the gap between the drive magnets and the slave magnets is adjustable.

BRIEF DESCRIPTION OF THE DRAWINGS

Further features and advantages of the invention will be apparent from the following detailed description taken in conjunction with the accompanying drawings, where:

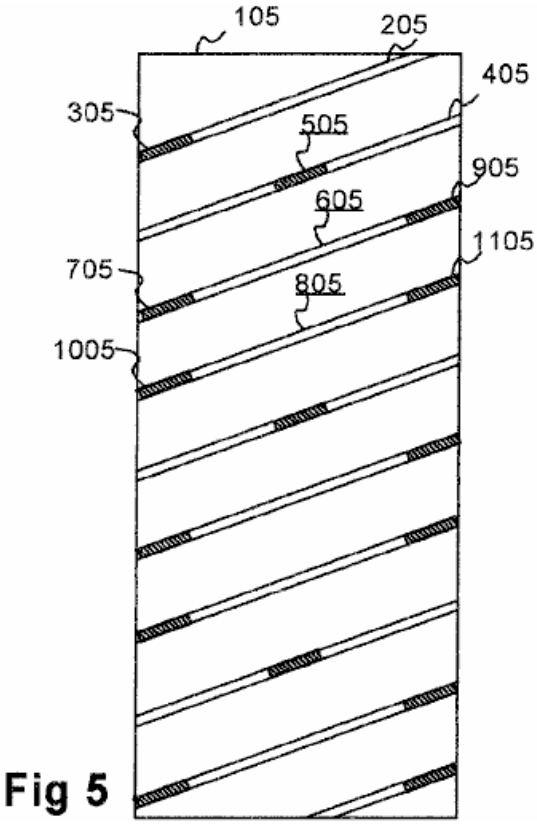

Fig 5

Fig.5 is a schematic diagram of another slave wheel of the cowlings embodiment showing the position of the permanent magnets.

DETAILED DESCRIPTION OF THE INVENTION

In the various embodiments of the invention there is generally provided a magnetic drive assembly and a magnetic slave assembly, with a magnetic field coupling the drive assembly to the slave assembly such that when the drive assembly rotates it causes the slave assembly to rotate. The coupling is entirely magnetic, where no chains, gears, pulleys, worm drives or other physical couplers are required.

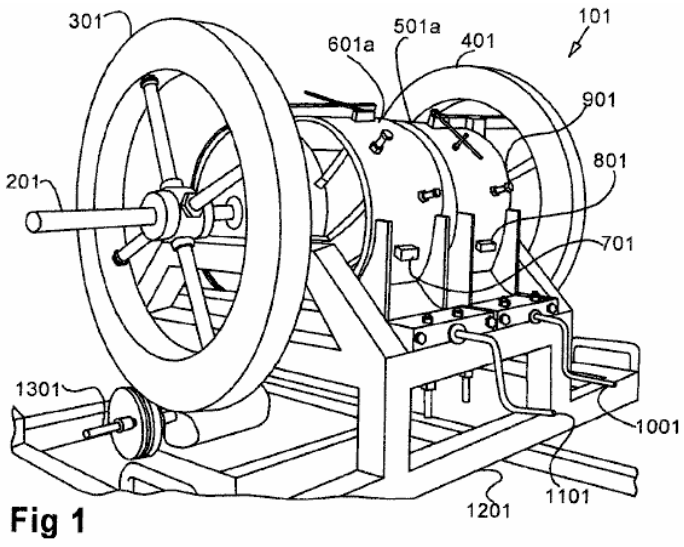

Fig 1

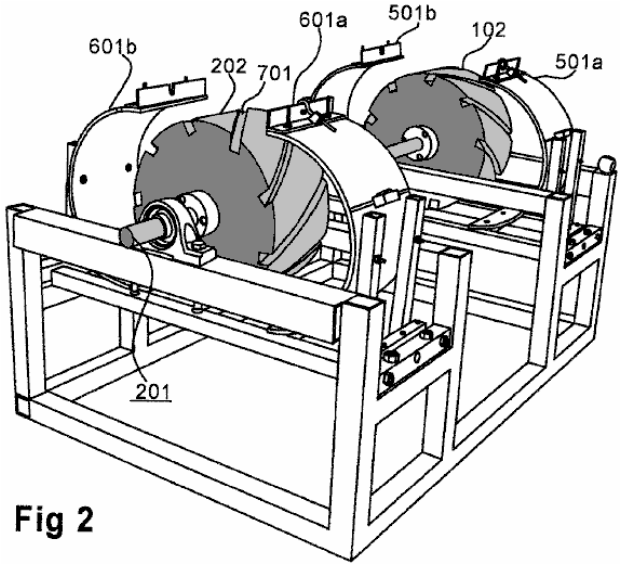

Fig 2

Fig.1 and **Fig.2** show a first embodiment of the invention, referred to herein as the "cowling" embodiment. In this embodiment the magnetic slave assembly of the magnetic motor **101** comprises two solid non-magnetic slave wheels **102** and **202**, most clearly seen in **Fig.2**. The slave wheels are mounted on a slave shaft **201**. **Fig.1** shows an embodiment in which optional fly-wheels **301**, **401** are mounted on slave shaft **201**. The fly-wheels may be conveniently mounted at or near the ends of the slave shaft. A device **1301** for generating electric current is provided that is directly coupled to the slave shaft, or indirectly coupled through a fly-wheel, as shown in **Fig.1**, or though some other element of the magnetic slave assembly.

Except for elements noted herein, the invention is constructed of a non-magnetic material. Pheotic plastic or ceramic materials are currently preferred for the slave wheels and drive wheels, but a wide variety of non-magnetic materials is acceptable so long as the material does not create or exacerbate eddy currents. The diameter of the slave wheels in currently operating models is approximately 10 inches (250 mm), and the width approximately 5 inches (125 mm). The optimum dimensions of the slave wheels will be determined by the specific application of the invention.

As seen in **Fig.2**, each slave wheel has a plurality of grooves running from one side to the other. One such groove is designated **701**. The grooves in one wheel are oriented at an angle of about 35 degrees to the slave wheel edge, while the grooves of the second wheel are oriented at about 35 degrees to the opposite edge, as can be seen clearly in **Fig.2**.

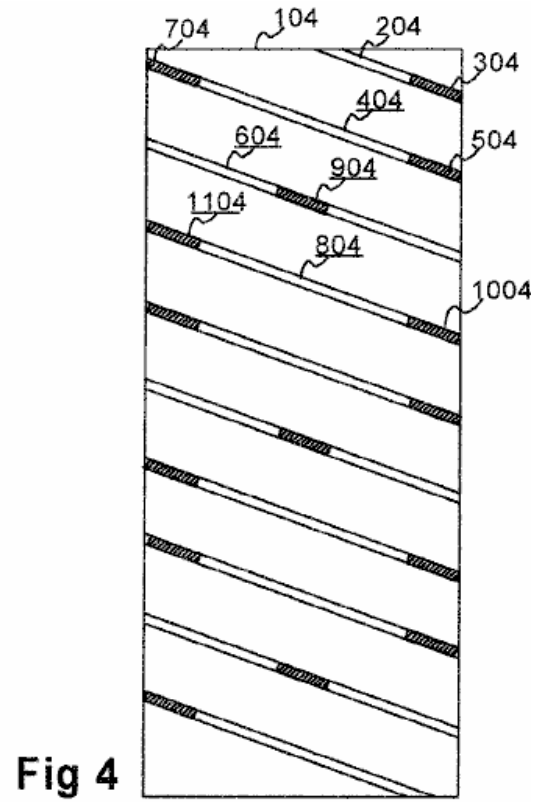

Fig 4

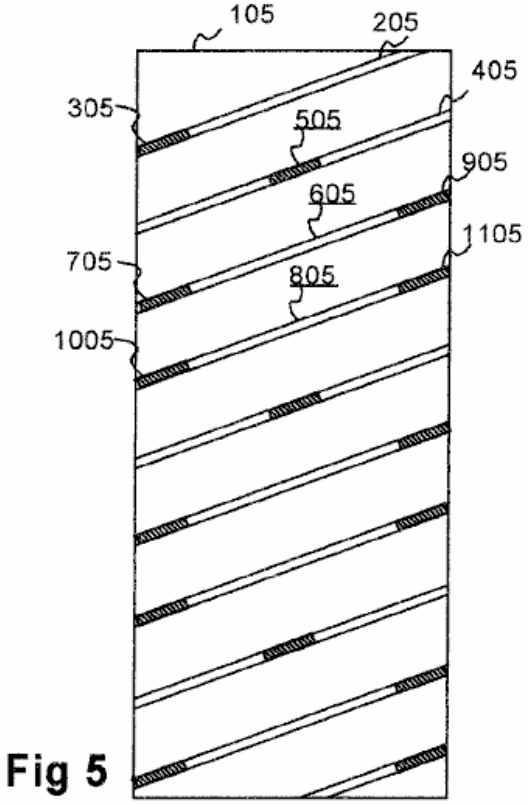

Fig 5

Fig.4 and **Fig.5** demonstrate the orientation of the grooves and the placement of the slave magnets. The rectangles **104** and **105** represent the surfaces of the slave wheels as if they were laid out flat. The grooves in slave wheel **104** slope downwards from left to right at an angle of about 35 degrees to the horizontal. The grooves in slave wheel **501** slope upward from left to right at an angle of about 35 degrees to the horizontal. In **Fig.4**, grooves **204**, **404**, **604**, and **804** are representative of the grooves in one slave wheel. Grooves **205**, **405**, **605**, and **805** of the slave wheel represented in **Fig.5** are representative of grooves in the other slave wheel.
Slave magnets are fitted into the grooves. In **Fig.4**, representative slave magnets are **304**, **504**, **704**, **904**, **1004**, and **1104**. The preferred position of the slave magnets is that two adjacent grooves have magnets positioned at their ends as shown with **304**, **504**, and **704** in grooves **204** and **404**. The next groove **604** has a single slave magnet **904** centrally placed. This pattern of two grooves with end magnets and the third with a central magnet is repeated. The preferred embodiment has a total of 9 grooves and 15 slave magnets per slave wheel. **Fig.5** shows that the same pattern is used in the second slave wheel, for instance in the manner in which slave magnets **305**, **505**, **706**, **905**, **1005**, and **1105** are positioned in grooves **205**, **405**, **605**, and **805**.

In the preferred embodiment, the north pole of each slave magnet faces outwards from the groove; however, having the south pole facing outwards produces equally satisfactory results. The magnets can be glued into place or otherwise firmly fixed so they do not shift. The attractive forces these magnets produce if opposite poles are allowed to make magnetic contact requires approximately 1200 ft. lbs. to overcome. Slave and drive magnets are permanent magnets and have the same pole facing outwards, producing repulsive forces on the order of a measured 38 gauss.

The magnetic drive assembly of the “cowling” embodiment comprises paired clam-shell cowlings **601*a***, **601*b*** and **501*a*, 501*b***, best seen in **Fig.2**, which shows the cowlings in an open position, exposing the slave wheels. **Fig.1** shows the cowlings in the closed position, in which the invention operates. Crank handles **1001**, **1101** operate worm-drives to provide for opening and closing the cowlings in order to adjust the gap between the cowlings and the slave wheels, and, hence, the gap between the drive magnets and the slave magnets.

Fig.1 also shows drive magnets **701**, **801** placed on the outer surface of cowlings **501*a*** and **601*a*** respectively. A plurality of ferro-magnetic bolts **901** penetrate the clam-shell cowling through threaded holes. These bolts modify the magnetic field and eliminate dead spots. The placing of the drive magnets and bolts is discussed below.

From **Fig.1** it can be seen that the combined curvature of the paired clam-shell cowlings results in them nearly surrounding their respective slave wheel when in the closed position. That is, each member of a cowling pair surrounds somewhat less than 180 degrees of the slave wheel's circumference so that when juxtaposed in the closed position, together they surround nearly 360 degrees of the slave wheel circumference.

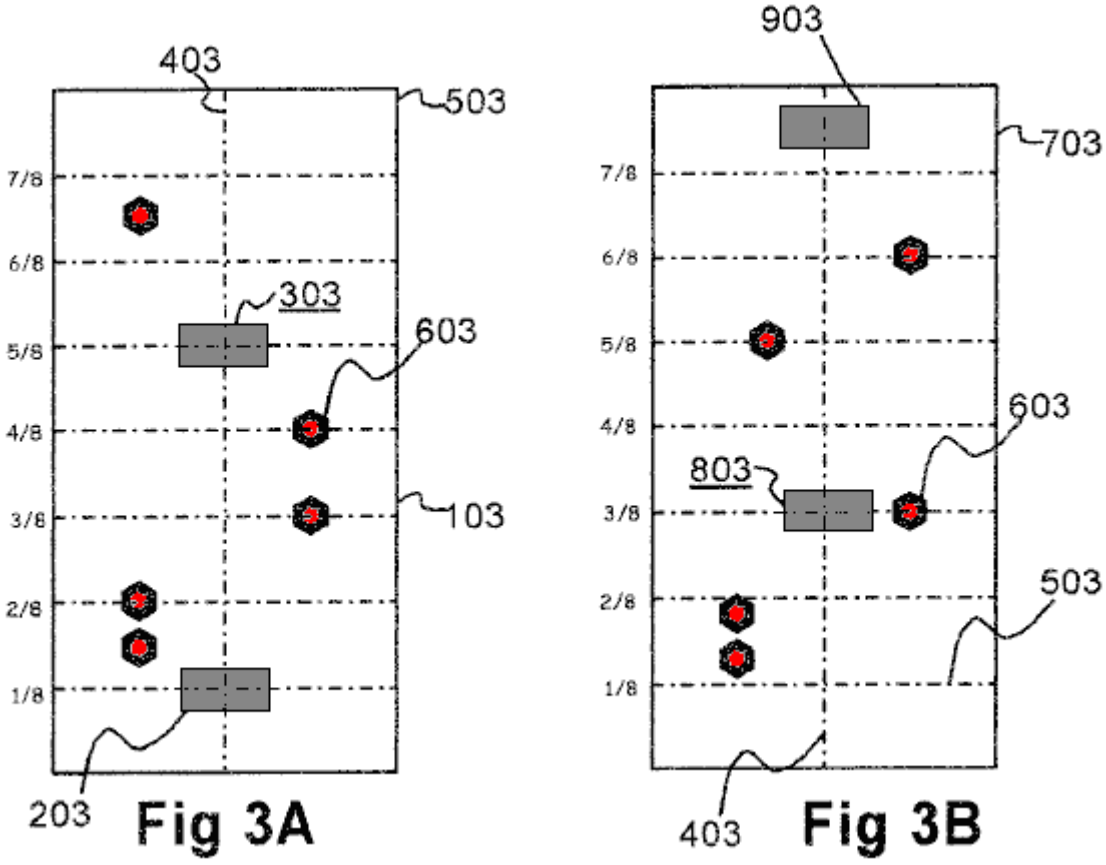

Fig.3A and **Fig.3B** represent a pattern for mounting the slave magnets on the outside, or convex, surface of one pair of cowlings. The figure represents the cowling-halves **103**, **703** as if they were laid flat. Guide lines are provided in the figure to indicate the longitudinal bisecting lines **403** and horizontal lines **503** dividing each cowling into eighths.

With respect to the cowling-half shown in **Fig.3A,** two permanent drive magnets, **203**, **303** are glued to the outside surface of the cowling on line **403** bisecting the cowling longitudinally. One drive magnet **203** is placed approximately one eighth of the way from one end. The second drive magnet **303** is placed three eighths of the way from the opposite end. Ferro-magnetic bolts **603** are inserted in the cowling through threaded holes. The purpose of the bolts is to modify the magnetic field to eliminate dead spots.

With respect to the cowling-half shown in **Fig.3B**, drive magnet **803** is placed three eighths of the way from one end, and drive magnet **903** is placed one eighth (one sixteenth ?) of the way from the other end. Again, ferro-magnetic bolts **603** are provided for eliminating dead spots in the magnetic field.

The diameter across each slave wheel is approximately 10 inches (250 mm). Measured from the bottom of groove **404** the diameter is 9 inches(225 mm). Consequently, the arc length from the bottom of one groove to the bottom of an adjacent groove is π inches (i.e., 3.14 inches or 80 mm).

The drive magnets are glued or otherwise firmly fixed to the outer or concave surfaces of the cowlings. Assuming that the slave magnets have been mounted in the grooves of the slave wheels with the north pole facing outwards, the north pole of each drive magnet is fixed against the cowling surface so that like poles face one another. As the cowlings are moved toward the slave wheels by turning the cranks **1101**, **1001** the drive magnets repel the slave magnets, causing the slave wheels to rotate.

Adjustment of the spacing between the cowlings and the slave wheels by means of cranks **1101**, **1001** adjusts the strength of the interaction of the fields of the drive magnets and slave magnets and, hence, the torque on the slave wheels.

As shown in **Fig.1**, fly-wheels **301**, **401** can optionally be mounted on the slave shaft. The preferred position is at or near the end of the shaft.

Slave shaft **201** thus turns as a result of the magnetic force from the cowlings being applied to the slave wheels. This shaft can be coupled to an output such as the armature of a generator **1301**, either directly or through a flywheel, as shown. Alternatively, the magnetic motor could itself drive a hydraulic pump of a transmission,

thereby reducing the number transmission components and the overall complexity of transmissions. Many different applications for this motor become obvious once it is realised that by using very strong permanent drive magnets useful power can be generated.

It is possible to vary the dimensions of the slave wheels. Presently, the preferred diameter is approximately 10 inches and a width of 5 inches. The motor can operate with the slave shaft **201** vertical or horizontal. While aluminium is a suitable material for the motor, the use of a hard plastic or ceramic materials have also been used with success. Pheotic plastic is presently preferred.

By using two slave wheels rather than just one, any dead spots in one wheel will be compensated for by the other wheel. The upper limit of the number of slave wheels is not yet known. The lower limit is one.

Chapter 2: Moving Pulsed Systems

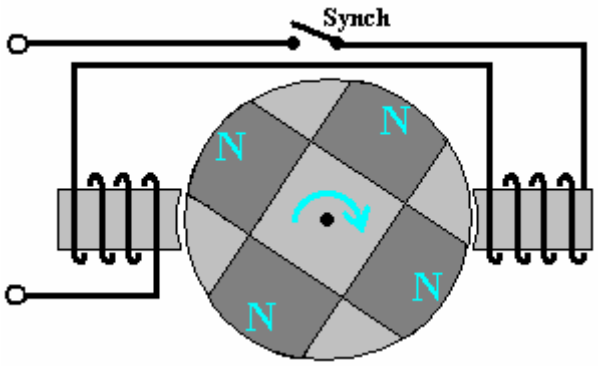
Note: If you are not at all familiar with basic electronics, you might find it easier to understand this chapter if you read chapter 12 first.

There are three categories of pulsed system and we will consider each in turn. These are drive-pulsed systems, energy-tapping pulsed systems and gravity free-energy pulsing systems. Here we will look at systems where an electrical pulse is used to cause the device to operate by creating a temporary magnetic field caused by electric current flowing through a coil or “electromagnet” as it is often called. Many of these systems are rather subtle in the way that they operate. One very well-known example of this is

The Motor/Generator of Robert Adams.

The late Robert Adams, an electrical engineer of New Zealand designed and built several varieties of electric motor using permanent magnets on the rotor and pulsed electromagnets on the frame of the motor (called the "stator" because it does not move). He found that if they were configured correctly, then the output from his motors exceeded their input power by a large margin (800%).

The diagram of his motor intended to show the basic operating principle is shown here:



If a motor is built like this, then it will most certainly work but it will never reach 100% efficiency let alone exceeding the 100% mark. It is only with a specific configuration which is hardly ever publicised that high performance figures can be achieved. While Robert has shown several different configurations, in order to avoid confusion I will describe and explain just one of them. I am indebted to several of Robert's friends and colleagues for the following information and I should like to express my thanks to them for their help and support in bringing you this information.

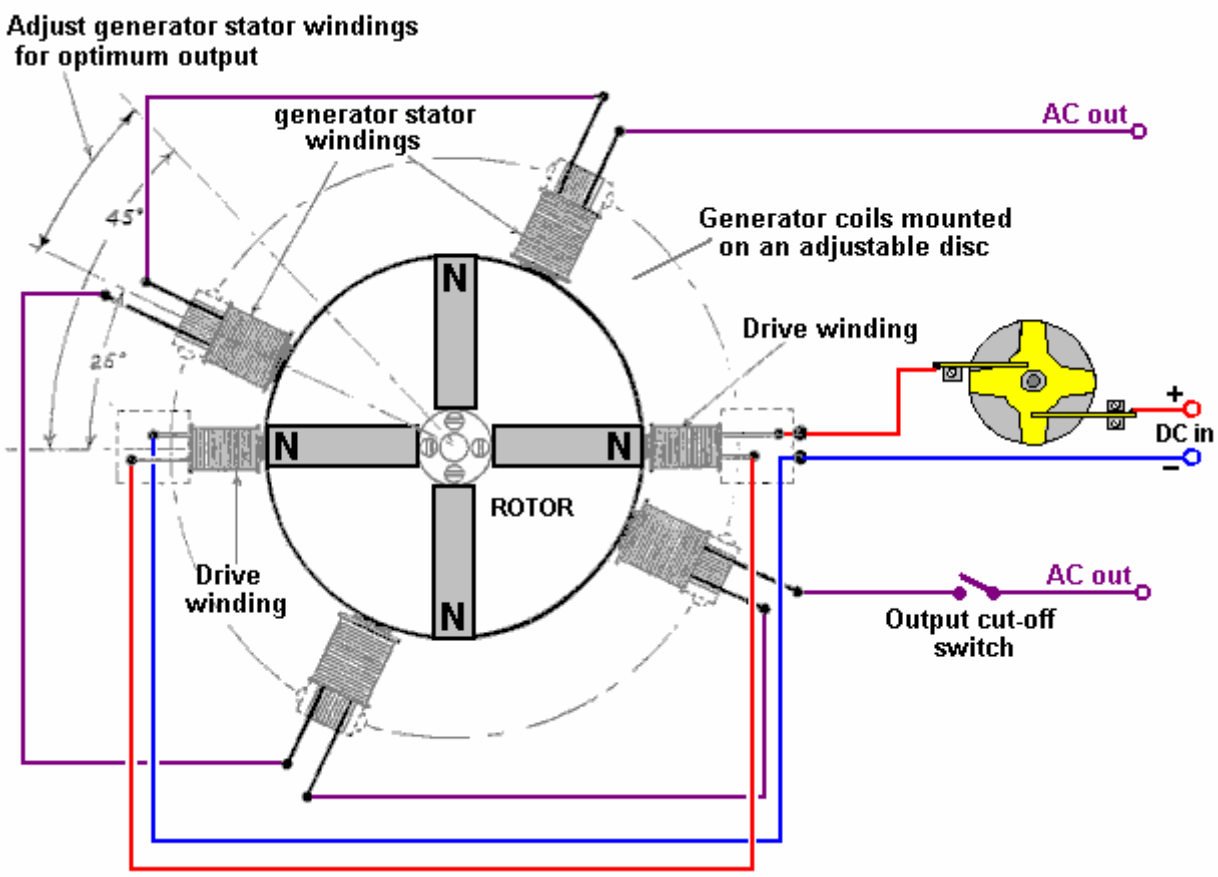
First and foremost, high performance can only be achieved with the clever use of power collection coils. These coils need to be positioned accurately and their power collection restricted to just a very short arc of operation by connecting them to, and disconnecting them from, the output circuit at just the right instant so that the back EMF generated when the current draw stops, actually contributes to the drive of the rotor, speeding it on it's way and raising the overall efficiency of the motor/generator as a whole.

Next, the shape of the magnets used is important as the length to width proportion of the magnet alters the pattern of it's magnetic fields. In direct opposition to the diagram shown above, the magnets need to be much longer than their width (or in the case of cylindrical magnets, much longer than their diameter).

Further, a good deal of experimentation has shown that the size and shape of the electromagnets and pick-up coils has a major influence on the performance. The cross-sectional area of the core of the pick-up coils should be four times that of the cross-sectional area of the permanent magnets in the rotor. The reverse is true for the cores of the drive coils as their cores should have a cross-sectional area of just one quarter of the rotor magnet cross-sectional area.

Another point which is almost never mentioned is the fact that big circuit gains will not be achieved unless the drive voltage is high. The minimum should be 48 volts but the higher the voltage, the greater the energy gain, so voltages in the 120 volts (rectified US mains voltage) to 230 volts (rectified mains voltage elsewhere) should be considered. Neodymium magnets are not recommended for drive voltages under 120 volts.

This is one of Robert's test circuits:

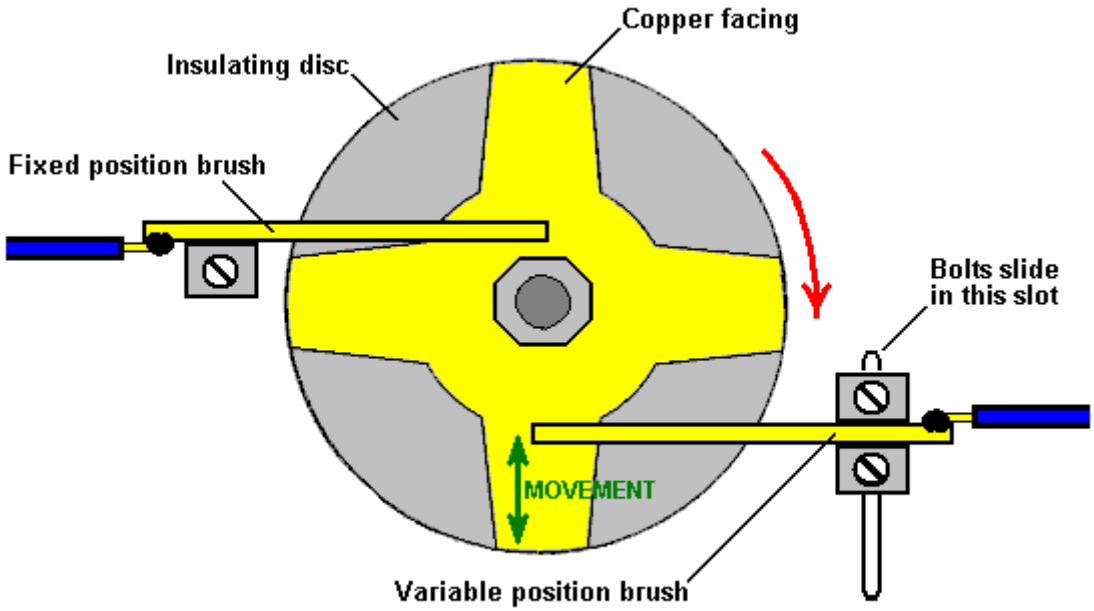


Notice that the cores of the "generator" pick-up coils are very much wider than the cores of the drive coils. Also notice the proportions of the magnets where the length is much greater than the width or diameter. The four generator windings are mounted on a single disc allowing them to be moved through an angle to find the optimum operating position before being locked in position and the two drive coils are mounted separately and held clear of the disc. Notice also that the power pick-up coils are much wider compared to their length than the drive coils are. This is a practical feature which is explained in greater detail later.

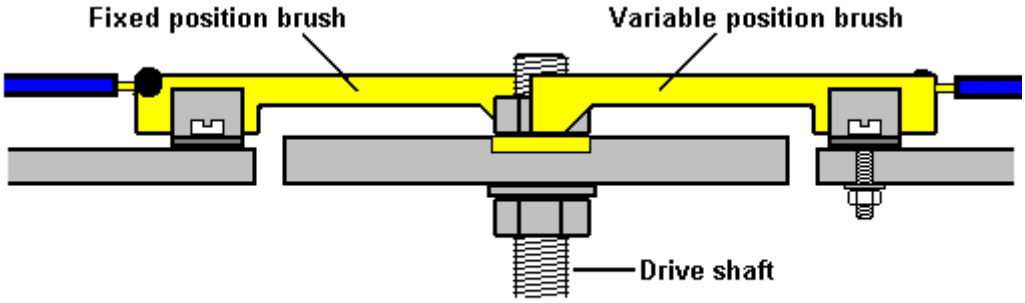
The DC input is shown passing through Robert's custom-made contactor switch which is mounted directly on the shaft of the motor/generator. This is a mechanical switch which allows an adjustable On / Off ratio, which is known as the "Mark/Space Ratio" or, if the "On" period is of particular interest, the "Duty Cycle". Robert Adams indicates that when the motor is running and has been adjusted to it's optimum performance, then the Mark/Space ratio should be adjusted to minimise the On period and ideally get it down to about 25% so that for three quarters of the time, the input power is actually switched off. There are various ways of achieving this switching while still having a very sharp turn on and turn off of the power.

Robert considered mechanical switching of the drive current to be a very good option although he was not opposed to using the contact to power a transistor to do the actual switching and so reduce the current through the mechanical contacts by a major factor. His reasons for his preference for mechanical switching are that it gives very sharp switching, needs no electrical power to make it operate and it allows current to flow in both

directions. The current flow in two directions is important because Robert produced various ways of getting the motor to feed current back into the driving battery, allowing it to drive the motor for long periods without lowering its voltage hardly at all. His preferred method of switching is shown here:



TIMING GEAR - TOP VIEW



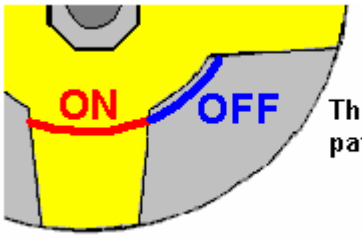
TIMING GEAR - SIDE VIEW

This switching gear operates as follows: The timing disk is bolted securely to the drive shaft of the motor and its position is set so that the electrical switch-on occurs when the rotor magnet is exactly aligned with the drive coil core. Adjustment of that timing is done by loosening the locking nut, rotating the disc very slightly and clamping the disc in position again. A spring washer is used to keep the assembly tight when the device is running. The disc has a star-shaped piece of copper sheet set into its surface and two silver-tipped, copper arm "brushes" slide across the surface of the copper star.

One of these two brushes is fixed in position and slides across the copper star near the drive shaft, making a permanent electrical connection to it. The second brush slides alternatively on the non-conducting surface of the disc and then over the conducting arm of the copper. The second brush is mounted so that its position can be adjusted and, because the copper arms taper, that alters the ratio of the "On" time to the "Off" time. The actual switching is achieved by current flowing through the first brush, through the copper arm and then through the second brush. The brush arms shown in the diagram above rely on the springiness of the copper arm to make a good brush-to-copper electrical connection. It might be preferred to use a rigid brush arm, pivot it and use a spring to ensure a very good contact between the brush and the copper star at all times.

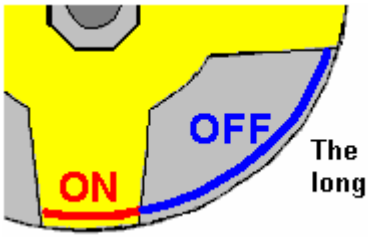
The adjustment of the On to Off time, or "Mark/Space Ratio" or "Duty Cycle" as the technical people describe it, could perhaps do with some description. If the moveable brush is positioned near the centre of the disc, then,

because of the tapering of the copper arms, the part of the non-conducting disc that it slides over is shorter and the part of the conducting copper arm with which it connects is longer, as the two sliding paths are about the same length, the current is on for about the same length as it is off, giving a Mark/Space ratio of about 50% as shown here:



The On path is about the same length as the Off path and so the Mark/Space ratio is about 50%

If, instead, the moveable brush is positioned near the outside edge of the disc, then because of the tapering of the copper arm, the On path is shorter and the non-conducting Off path is very much longer, being about three times as long as the On path, giving a Mark/Space ratio of about 25%. As the moveable brush can be positioned anywhere between these two extremes, the Mark/Space ratio can be set to any value from 25% to 50%.

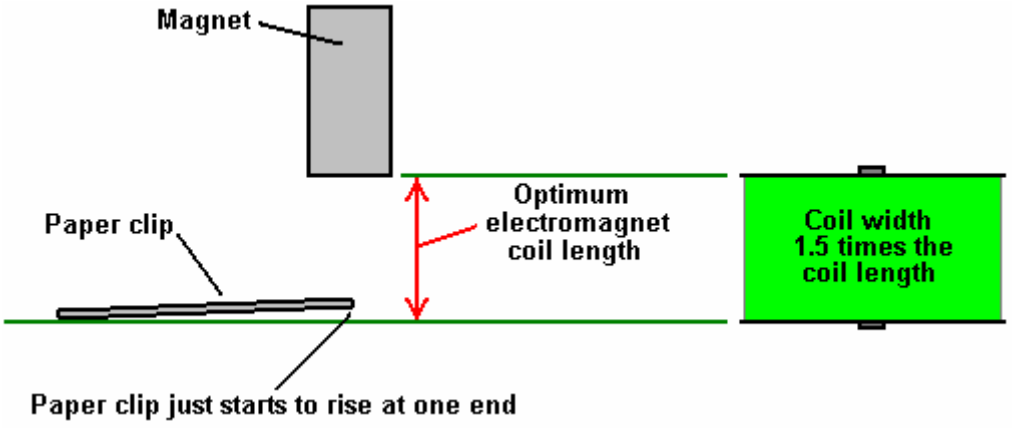


The On path is shorter and the Off path is much longer giving a Mark/Space ratio of about 25%

The two brushes can be on the same side of the drive shaft or on opposite sides as shown. One important feature is that the brushes touch in a position where the disc surface is always moving directly away from the brush mounting, causing any drag to be directly along the arm and giving no sideways loading on the brush. The diameter of the device is usually one inch (25 mm) or less.

You will also notice that the output is switched although the diagram does not give any indication of how or when that switching takes place. You will notice that the diagram has angles marked on it for the optimum positioning of the pick-up coils, well, an Adams Motor builder with a forum ID of "Maimariati" who achieved a Coefficient Of Performance of 1,223, found that the optimum switching for his motor is On at 42 degrees and Off at 44.7 degrees. That tiny 2.7 degree part of the rotor turn gives a substantial power output and cutting the output current off at that point causes the back EMF of the coils to give the rotor a substantial additional boost on its way. His input power is 27.6 watts and the output power is 33.78 kilowatts

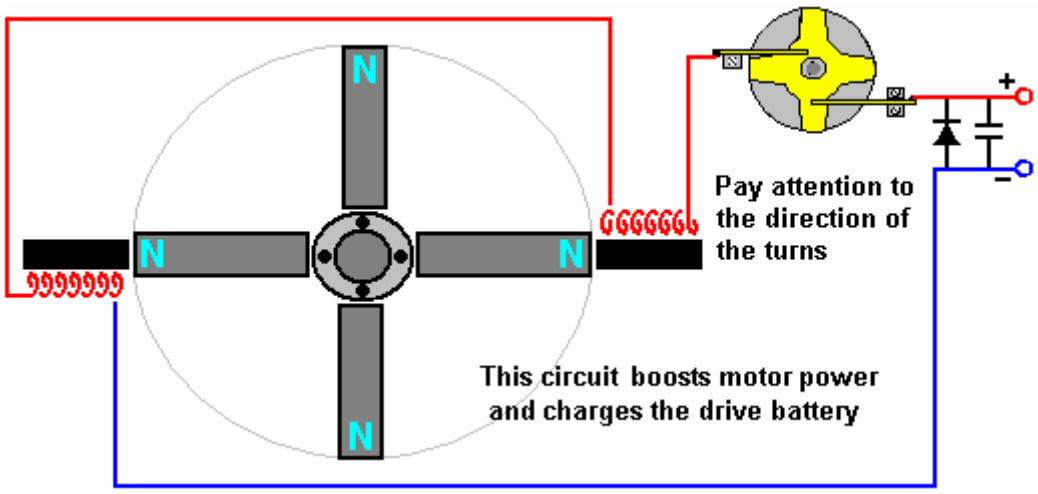
Now for some practical details. It is suggested that a good length for the power pick-up coils can be determined by using the “paper clip test”. This is done by taking one of the permanent magnets used in the rotor, and measuring the distance at which that magnet just begins to lift one end of a 32 mm (1.25 inch) paper clip off the table. The optimum length of each coil from end to end is exactly the same as the distance at which the paper clip starts to lift.



The core material used in the electromagnets can be of various different types including advanced materials and alloys such as ‘Somalloy’ or 'Metglas'. The power pick-up coil proportions are important as an electromagnet becomes less and less effective as its length increases, and eventually, the part furthest from the active end can actually be a hindrance to the effective operation. A good coil shape is one which you would not expect, with the coil width being, perhaps 50% greater than the coil length:

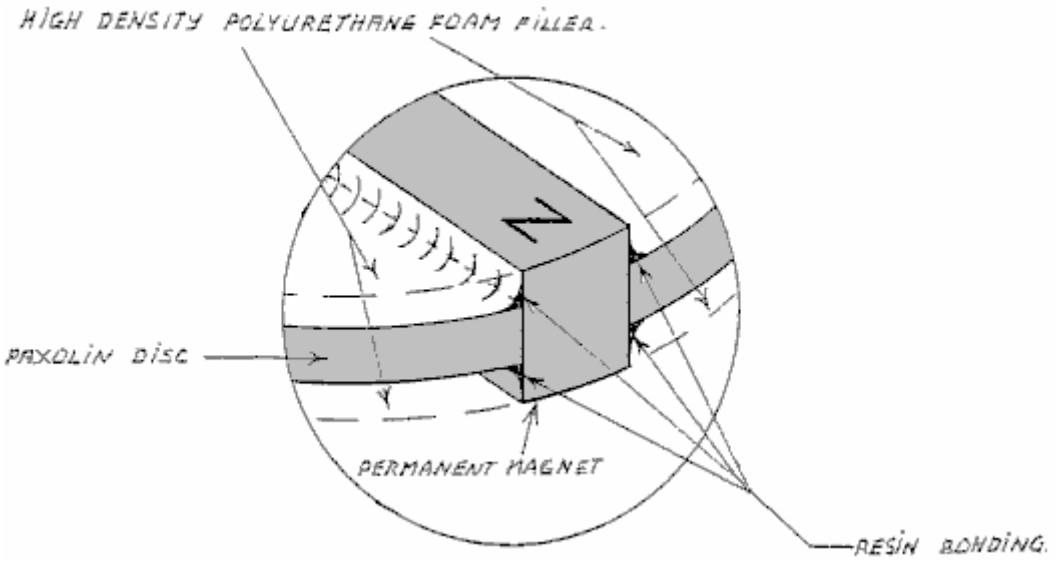
Contrary to what you would expect, the device draws in energy from the local environment better if the end of the pick-up coil farthest from the rotor is left unaffected by any other part of the device and the same applies to the magnet facing it. That is, the coil should have the rotor at one end and nothing at the other end, that is, no second rotor behind the coil. The speed at which the voltage is applied to, and removed from, the coils is very important. With very sharp voltage rises and falls, additional energy is drawn from the surrounding environmental energy field. If using transistor switching, then the IRF3205 FET has been found to be very good and a suitable driver for the FET is the MC34151.

If using a Hall-effect semiconductor to synchronise the timing, say the UGN3503U which is very reliable, then the life of the Hall-effect device is much improved if it is provided with a 470 ohm resistor between it and the positive supply line, and a similar 470 ohm resistor between it and the negative line. These resistors in series with the Hall-effect device effectively “float” it and protect it from supply-line spikes".



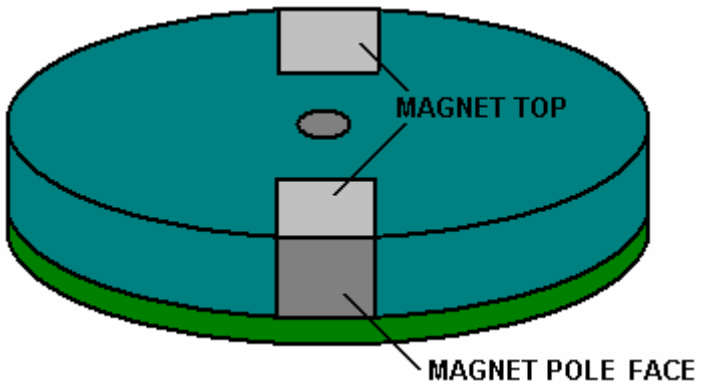
Here, two electromagnets are driven by the battery via Robert's 4-arm commutator which is mounted on the rotor shaft. Some of the recommendations given by Robert are the opposite of what you would expect. For example, he says that a single rotor construction tends to be more electrically efficient that one where several rotors are mounted on a single shaft. Robert is against the use of reed switches and he recommends making one of his commutators.

At one stage, Robert recommended the use of standard transformer shims for constructing the cores of the electromagnets. This has the advantage that matching bobbins for holding the coil windings are readily available and can still be used for pick-up coils. Later on, Robert swung towards the use of solid cores from the old PO Series 3000 telephone relays and eventually said that electromagnet cores should be solid iron.

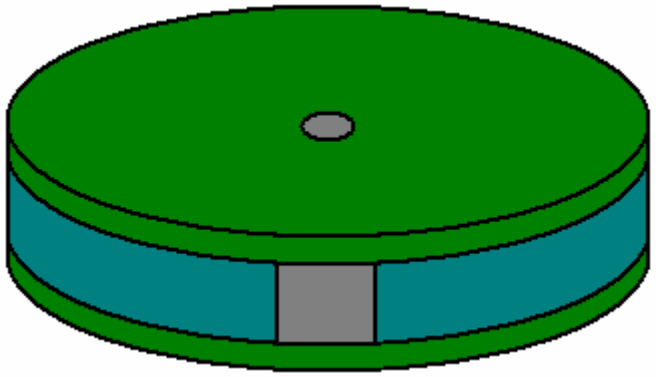


The diagrams presented by Robert show the magnets located on the rim of the rotor and pointing outwards. If this is done, then it is essential that the magnets in the rotor are firmly attached on at least five of their six faces and the possibility of using a ring of non magnetic material such as duct tape around the outside should be considered. That style of construction also lends itself to streamlining the rotor by having a completely solid construction, although it might be remarked that the motor would run better and more quietly if it were enclosed in a box which had the air pumped out of it. If that is done, then there will be no air resistance and because sound can't pass through a vacuum, quieter operation is bound to result.

While this may sound a bit complicated, there is no reason why it should be. All that is needed is two discs and one central disc which is the thickness of the magnets, with slots cut in it, the exact size of the magnets. The assembly starts with the lower disc, magnets and central disc. These are glued together, probably with epoxy resin, and that holds the magnets securely on four faces as shown here:



Here, the magnets are attached on the lower face, the right and left faces, and the unused pole face, and when the upper disc is attached, the upper faces are also secured and there is the minimum of air turbulence when the rotor spins:

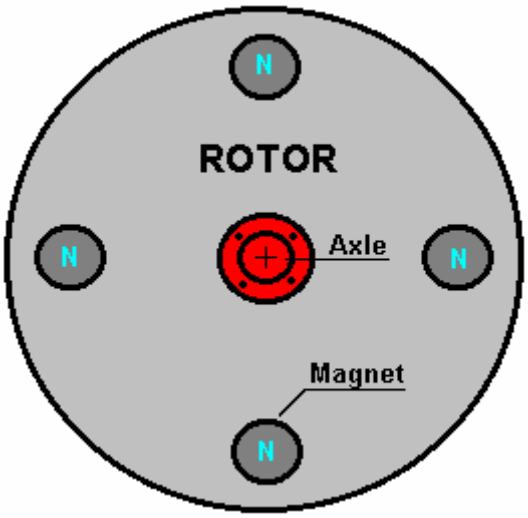


There is a "sweet spot" for the positioning of the power pick-up coils and it will usually be found that this is two or three millimetres away from the rotor. If that is the case, then there will be room for an outer band of duct tape on the rim of the rotor to provide additional protection against the failure of the magnet attachment method.

High-power versions of the motor/generator need to be enclosed in a metal box which is earthed as they are quite capable of generating a substantial amount of high frequency waves which can damage equipment such as oscilloscopes and create TV reception interference. There would probably be an improvement in performance as well as a reduction in sound if the box was airtight and had the air pumped out of it. If that is done, then there will be no air resistance as the rotor spins and since sound does not pass through a vacuum, quieter operation is possible.

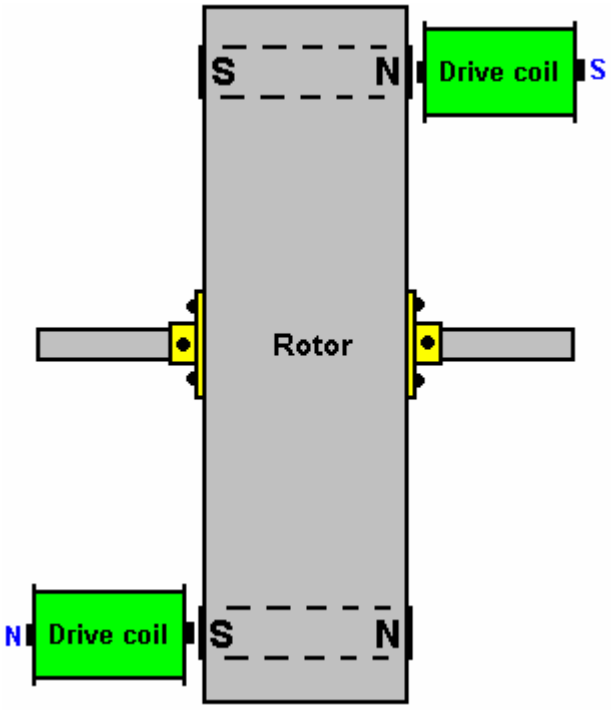
Experienced rotor builders do not like the radial magnets style of construction because of the stresses on the magnet attachments if high rotational speeds are reached. It should not need to be said, but it is obviously a major requirement to keep your hands well away from the rotor when the motor is running as it is perfectly possible to be injured by the high-speed movement if you are careless. Please remember that this presentation must not be considered to be a recommendation that you build or use any device of this nature and it must be stressed that this text, in common with the entire contents of this eBook, is intended to be for information purposes only and no representations or warranties are implied by this presentation. Should you decide to construct, test or use any device, then you do so entirely at your own risk and no liability attaches to anybody else if you sustain any kind of injury or property damage as a result of your own actions.

Because of the mechanical stresses caused during rotation, some experienced constructors feel that the magnets should be embedded in the rotor as shown here where they are kept well clear of the rim of a rotor which is made from a tough material. This is so that the outer strip of the material prevents the magnets breaking loose and becoming dangerous high-speed projectiles, which at best would destroy the electromagnets and at worst could injure someone quite badly:



It needs to be remembered that the proportions of the magnets are for the magnet length to be more than the diameter, so in cases like this where circular magnet faces are to be used, the magnets will be cylindrical and the rotor needs to have a significant thickness, which will depend on the magnets which are available locally. The magnets should be a tight push-fit in their holes and securely glued in place.

Robert Adams has used this construction style as well. However, if an arrangement like this is used, then there will be a substantial sideways pull on the rotor as it reaches the electromagnet core, tending to pull the magnets out of the rotor.



It is important that the rotor should be perfectly balanced and have the minimum amount of bearing friction possible. This calls for precision construction and either roller or ball bearings. The construction style shown above has the distinct advantage that it has an open end to both the magnet and the coils and this is believed to facilitate the inflow of environmental energy into the device.

It may be my ignorance showing here, but I have a problem with this version. The difficulty as I see it is that the magnet/core pull and the subsequent drive thrust when the coil is powered, form a "turning couple" as they both try to rotate the axle in the same direction. This places a substantial loading on the axle bearings, usually amplified by the radius of the rotor being greater than the distance from the rotor to the axle bearings. This load will be in the tens of kilograms range and will be applied and reversed perhaps forty times per second. To me, that appears like a vibration load and is directly opposed to the "perfectly balanced" rotor operation being sought. The radial magnet arrangement generally shown by Robert Adams does not have any of this kind of loading at all because the coils are exactly opposite each other and their loads cancel each other out exactly. The choice is, of course, up to the builder and his assessment of the advantages and disadvantages of the different styles of construction.

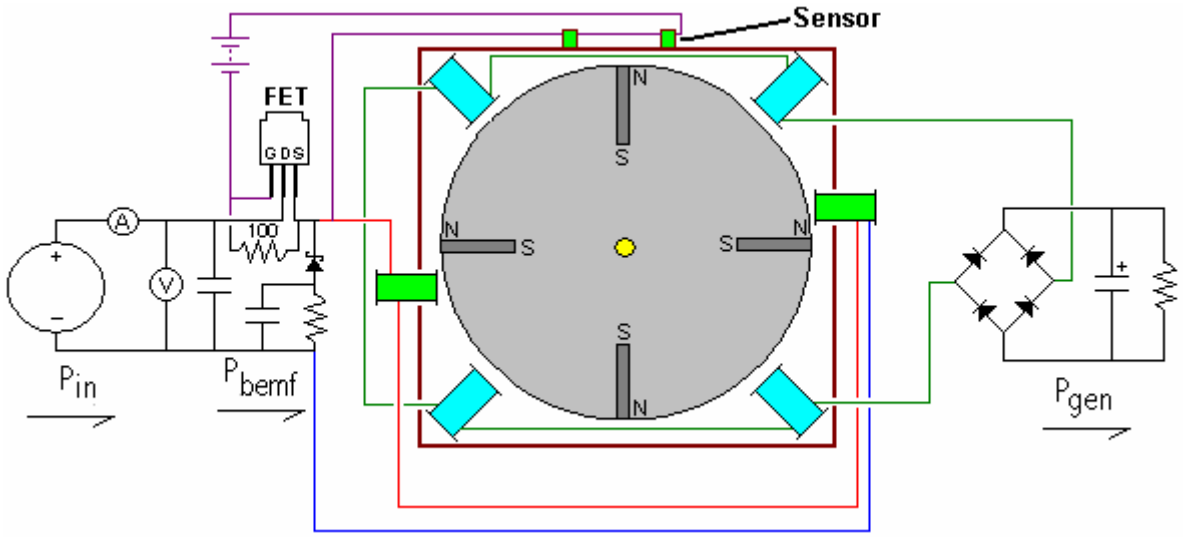
When getting ball-race bearings for an application like this, please be aware that "closed" bearings such as these are not suitable as supplied:

This is because this type of bearing is usually packed with dense grease which completely destroys its free motion, making it worse as a bearing than a simple hole-and-shaft arrangement. However, in spite of this, the

closed or "sealed" bearing is popular as the magnets tend to attract dirt and dust and if the device is not enclosed in a steel box as is necessary for the high power versions, then having the seal is considered to be an advantage. The way to deal with the grease packing is to soak the bearing in an isopropyal solvent cleaner to remove the manufacturer's grease, and then, when it has dried out, lubricate the bearing with two drops of a high quality thin oil. If it is intended to house the motor/generator in an earthed, sealed steel box then an alternative type of bearing which might be suitable is an open design like this:

especially if the air is removed from the box. Some constructors prefer to use ceramic bearings which are supposed to be immune to dirt. One supplier is http://www.bocabearings.com/main1.aspx?p=docs&id=16 but as with everything else, these choices have to be made by the builder and will be influenced by his opinions.

I'm not sure where it came from, but here is a circuit diagram showing a transistor drive and the return of the back EMF of the drive coils to the driving power supply. Using this method, about 95% of the drive current can be returned, lowering the current draw enormously:



The diode feeding the power back to the supply is a Shotky type because of it's high-speed operation. It needs to be able to handle the peak pulse power and so should be one of the more robust types. What this circuit does not have is the very important switching on the output coils circuit. Another strange item is the way that the FET sensor is arranged with two sensors rather than one and with an additional battery. While it must be admitted that the current draw of the FET gate should be very low, there still does not seem to be much reason to have a second power supply. One other peculiarity in this diagram is the positioning of the drive coils. With them offset as shown, it has the effect of them being at an angle relative to the rotor magnets. It is not at all clear if this is an advanced operating technique or just poor drawing - I am inclined to assume the latter although I have no evidence for this other than the circuit design and the low quality of the original drawing which had to be improved considerably to arrive at the diagram shown above.

The coil generator output should be fed into a capacitor before being passed to whatever equipment is to be powered by the device. This is because the energy is being drawn from the local environment and is not conventional energy. Storing it in a capacitor converts it to a more normal version of electrical power, a feature which has also been mentioned by Don Smith and by John Bedini although their devices are quite different in operation.

The DC resistance of the coil windings is an important factor. The overall resistance should be either 36 ohms or 72 ohms for a complete set of coils, whether they are drive coils or power pick-up coils. Coils can be wired in parallel or in series or in series/parallel. So, for 72 ohms with four coils, the DC resistance of each coil could be 18 ohms for series-connected, 288 ohms for parallel connected, or 72 ohms for connection in series/parallel where two pairs of coils in series are then wired in parallel.

To help with assessing the wire diameter and length which you could use, here is a table of some of the common sizes in both American Wire Gage and Standard Wire Gauge:

AWG	Dia mm	SWG	Dia mm	Max Amps	Ohms / 100 m
11	2.30	13	2.34	12	0.47
12	2.05	14	2.03	9.3	0.67
13	1.83	15	1.83	7.4	0.85
14	1.63	16	1.63	5.9	1.07
15	1.45	17	1.42	4.7	1.35
16	1.29	18	1.219	3.7	1.48
18	1.024	19	1.016	2.3	2.04
19	0.912	20	0.914	1.8	2.6

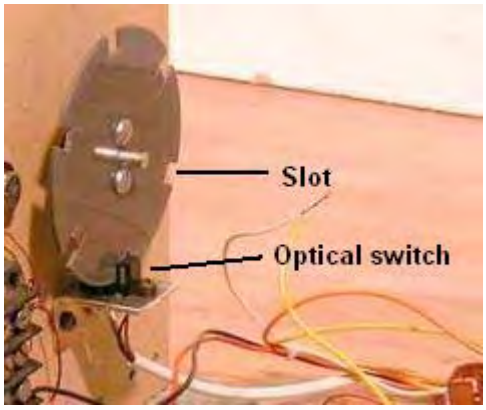
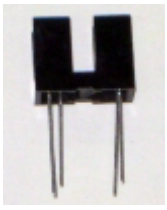
32	0.203	36	0.193	0.091	58.9
33	0.180	37	0.173	0.072	76.7
34	0.160	38	0.152	0.056	94.5
35	0.142	39	0.132	0.044	121.2

So far, we have not discussed the generation of the timing pulses. A popular choice for a timing system is to use a slotted disc mounted on the rotor axle and sensing the slots with an "optical" switch. The "optical" part of the switch is usually performed by UV transmission and reception and as ultra violet is not visible to the human eye, describing the switching mechanism as "optical" is not really correct. The actual sensing mechanism is very simple as commercial devices are readily available for performing the task. The sensor housing contains both a UV LED to create the transmission beam, and a UV dependent resistor to detect that transmitted beam.

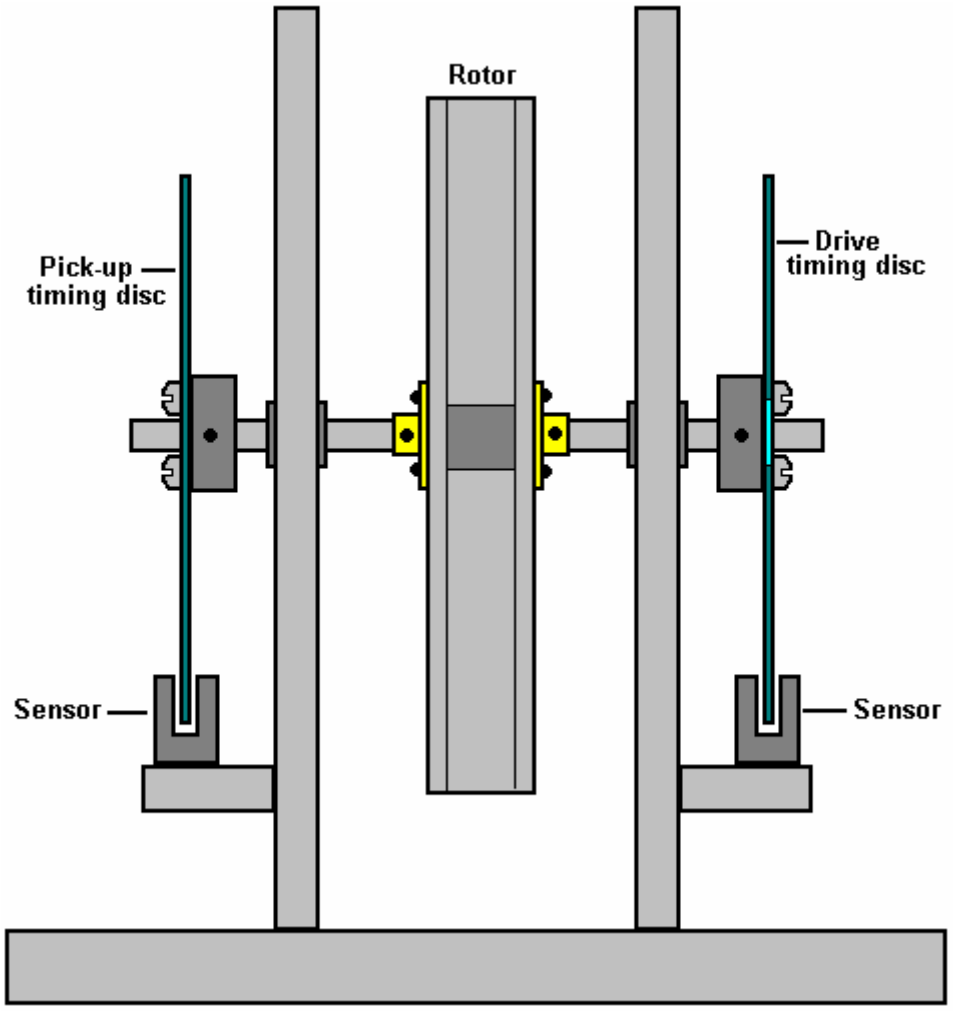
Here is an example of a neatly constructed timing mechanism made by Ron Pugh for his six-magnet rotor assembly:



and the switch/sensor:



This device happens to be one which is supplied by www.bayareaamusements.com under their product code number : OP-5490-14327-00. As the slotted disc rotates, one of the slots comes opposite the sensor and allows the UV beam to pass through to the sensor. That lowers the resistance of the sensor device and that change is then used to trigger the drive pulse for whatever length of time the slot leaves the sensor clear. You will notice the balanced attachment method used by Ron to avoid having an unbalanced rotor assembly. There can be two timing discs, one for the drive pulses and one for switching the power pickup coils in and out of the circuit. The slots in the power pick-up timing disk will be very narrow as the switch-on period is only about 2.7 degrees. For a six-inch diameter disc where 360 degrees represents a circumference length of 18.85 inches (478.78 mm) a 2.7 degree slot would be only 9/64 inch (3.6 mm) wide. The arrangement for an axial magnet rotor set-up could be like this:



So to recap, the things which are necessary for getting an Adams Motor output into the serious bracket are:

1. A performance of COP>1 can only be achieved if there are power pick-up coils.

2. The rotor magnets need to be longer than they are wide in order to ensure the correct magnetic field shape and the rotor must be perfectly balanced and have bearings as low-friction as possible.

3. The face area of the rotor magnets needs to be four times that of the drive coil cores and one quarter the area of the core of the power pick-up coils. This means that if they are circular, then the drive coil core diameter needs to be half the diameter of the magnet and the magnet diameter needs to be half the diameter of the power pick-up core. For example, if a circular rotor magnet is 10 mm across, then the drive core should be 5 mm across and the pick-up core 20 mm across.

4. The drive voltage needs to be a minimum of 48 volts and preferably, a good deal higher than that.

5. Do not use neodymium magnets if the drive voltage is less than 120 volts.

6. The drive coils should not be pulsed until they are exactly aligned with the rotor magnets even though this does not give the fastest rotor speed.

7. Each complete set of coils should have a DC resistance of either 36 ohms or 72 ohms and definitely 72 ohms if the drive voltage is 120 volts or higher.

8. Collect the output power in large capacitors before using it to power equipment.

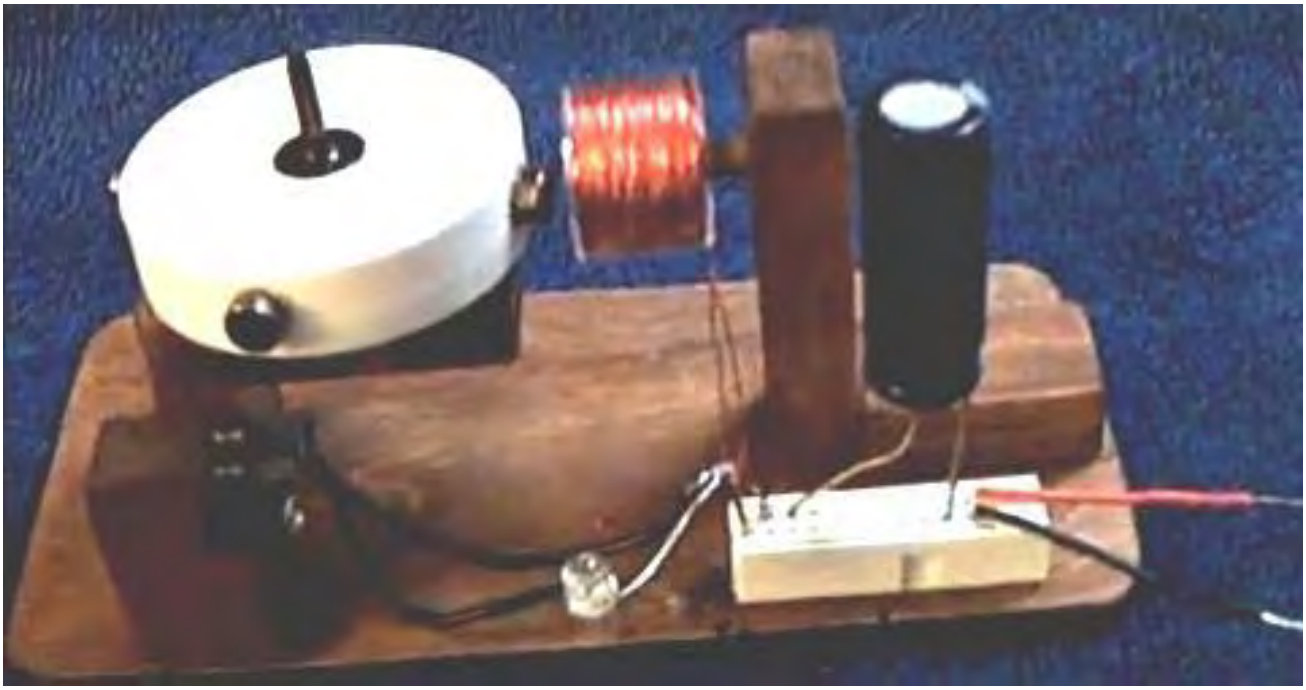
It may also be possible to boost the output power further, by using the Coil-Shorting technique shown in the section of this chapter on the RotoVerter.

If you want the original drawings and some explanation on the operation of the motor, then two publications from the late Robert Adams can be bought from www.nexusmagazine.com where the prices are quoted in Australian dollars, making the books look much more expensive than they actually are.

http://www.totallyamped.net/adams/index.html is a really impressive collection of well-informed practical material on building and using an Adams motor with details of sensors and how they work, core materials and their performances and how to locate the "sweet spot" - very highly recommended web site.

Lidmotor's Low-voltage Rotor

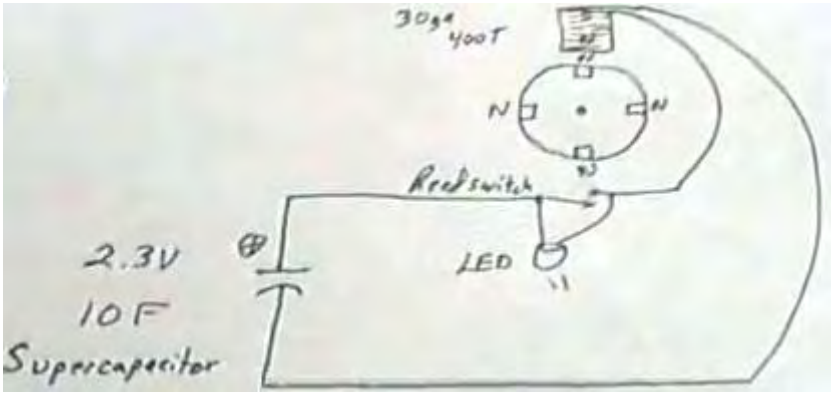
One very experienced developer whose YouTube ID is "Lidmotor" (because he makes motors from the lids of jars) has a short video at https://www.youtube.com/watch?v=SjWCprVXer8 showing a very simple rotor design with one of his jar lids mounted on a single bearing:



The white lid has four magnets attached to it spaced out evenly around the lid at ninety-degree intervals. Facing them is an air-core coil mounted on a non-magnetic support dowel and wound with 400 turns of '30-gauge' wire on a plastic spool. As 'Lidmotor' is American, the '30 gauge' wire is likely to be American Wire Gauge #30 with a diameter of 0.255 mm as opposed to the European Standard Wire Gauge size which has a 0.315 mm diameter.

An air-core coil has no effect on the passing rotor magnets IF it is not carrying current. An output coil will cause drag on the rotor if current is being drawn from the coil, and so timed output switching as used by Robert Adams would be needed to not just overcome the drag, but to push the rotor on its way as well.

There are two very important features of this rotor drive design. One is the fact that a supercap (10-Farad, 2.3V) is used to drive the rotor and when supplied with a charge of only 0.5V to 1.0V, can spin the rotor for up to thirty minutes. That very long time is likely to be a feature of the second important item which is that he has placed an LED across the reed switch used to power the coil. When the reed switch opens, a back-EMF voltage spike occurs and the LED feeds that voltage pulse back into the 100% efficient supercap, recovering most of the current used to drive the rotor. This is the same method as used by Robert Adams in his motor designs. Lidmotor presents his circuit like this:



While the circuit shows the magnet operating the reed switch as being 180 degrees around from the coil, the photograph indicates that the switching magnet is one 90 degrees away. Any of the other magnets can be used. The reed switch operation is adjusted to get the best performance. This is done by moving the switch backwards and forwards along the moving path of the magnet to make the switching occur earlier or later. The objective is to push the rotor magnet on its way by pulsing the coil very briefly just after the rotor magnet has passed the centre of the coil. The length of time that the reed switch is closed can be adjusted by moving the switch closer to the magnet for a longer switch-closed time, or further away for a shorter switch closure. It is also possible to alter the closed time by positioning the switch across the path of the magnet travel or parallel to it.

If you are not familiar with a reed switch, it is just a glass tube, filled with an inert gas, and with two overlapping metal strips inside the tube:

Reed switch

The external magnetic field magnetises the strips and they spring together due to magnetic attraction and spring apart again when the magnetic field moves away. These switches come in various sizes and the smallest version tends to be unreliable and has a very low maximum current capacity. The larger versions are much more robust.

Lidmotor's circuit is very simple and very effective, even though the rotor will have minimal weight and no significant drag. One wonders if adding a second coil and a diode feeding the supercapacitor, if the system could not become self-running.

Phemax's Inertial-Propulsion and Electrical Generation System.

Phemax Technologies, Inc. have developed what they describe as their 'sustainable transportation system' which is based on their inertial-propulsion generation wheel, which uses what they call '3-D Coraxial Hybrid Induction' (CHI), in which 'Coraxial' refers to their "combined radial-axial" technique where drive is provided by a radial pulsed magnet system and power extraction is achieved using an axially-orientated magnet/coil system.

Vice President and Chief Technology Officer, Michael Hsueh and Sales Manager, Sabrina Li

Taiwan inventor, Tajen (David) Chi, says that his company, "Phemax Technologies Inc." will be demonstrating their technology

in September 2010 at an expo, after which they will allow interested and qualified parties to come to their premises for licensing discussions.

Their device can take the place of the battery component of an electric vehicle or it can be used to supplement and recharge a battery bank in the vehicle. At the September exhibition, they will allow visitors to ride their 2 kW test car. David intends to put their test data on the Internet. With a rotational input of 1 NM at 500 rpm, a single inertial-propulsion generation wheel can produce 1 KW of axial generative power.

David also said that a 150W output from his motor actually produces between 180 and 200 watts of mechanical output, while a 1500W output produces a mechanical output of 1800 to 2000 watts (96 Volts at 20 Amps), as measured by a watt meter, speed meter, torque meter, and oscilloscopes. He says that these measurements were made by Michael Hseuh, Vice President and Chief Technology Officer.

Ceramic-based and carbon-based ultra-capacitors are used to return some of the output power to the input in order to keep the machine running continuously without the need for a power supply when the engine is running and providing it's output. When driving a vehicle powered by this device, the mechanical driving torque is provided via a continuously-variable transmission.

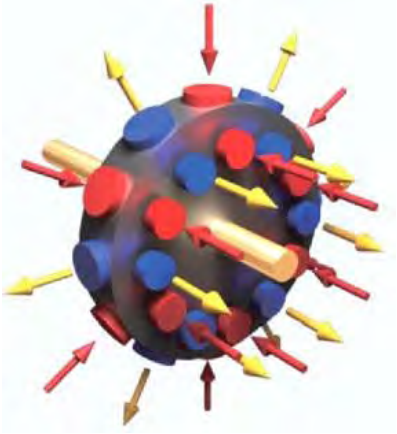
At this time, Phemax Technologies, Inc. have a 150-Watt and a 2 kW prototype which they plan to demonstrate in September 2010. He says that they generally run these prototypes for eight hours each day in their lab. The central principle of the Phemax Technologies Inc. process is what they call "CORAXIA" which stands for "combined radial-axial" hybrid induction, abbreviated to "CHI", which is David's surname. They also call this the "3-D Coaxial Hybrid Induction" system. They state that their electromagnetic 3-D arrangement enables the wheel to have both radial flux propulsion and axial flux generation with just a single rotor and two separate stators. As the radial electric drive rotates, the mechanical energy due to the inertia of the wheel and the ground power transmission mechanism enables the wheels of a vehicle to generate electricity as they rotate.

There are two videos showing the device generating electricity, located here:
http://www.youtube.com/watch?v=W_IzhpZxxcQ and
http://www.youtube.com/watch?v=O8frdR-fnO here.

Another application is where the electrical output from the device is being used to produce a hydrogen/oxygen gas mix from water using an underwater plasma arc:

David says he is self-taught in this area. He has three patents: Taiwan patent M352472, M372891 and M382655 (which are not in English). From his search of the patent index, the Internet and YouTube, David said he has not yet seen a patent or experimental set-up similar to what they have developed.

This motor/generator is unusual in that it uses pulsed rotor drive on magnets mounted on the circumference of the rotor and simultaneously, it picks up electrical energy from a coil/magnet arrangement mounted on the side faces of the rotor as shown here:



The basic drive/generator unit can be replicated on a single shaft to give increased power, still without increased frictional losses between the drive and the power generation:

It is unusual to see this technique used as it can be difficult to avoid interaction between the different magnetic fields. However, David has been entirely successful in doing this and the arrangement has no transmission losses between the drive motor and the generator as these are integral components of the system.

This system is capable of driving a self-powered air-conditioning unit and a 5 kW proof-of-concept prototype is shown here:

This device is also capable of driving electric lighting and with a 5 kilowatt output self-powered output, it can power most household needs. A typical washing machine has a 2.25 kilowatt maximum electrical draw as does the average tumble-dryer. Most fan-heaters are 3 kilowatts or less when on full output.

If a wind-power generator is already in place, then using the mechanical power of the generator to spin the axle of one of these CHI generators results in a very high-power electricity generation system.

Raymond Kromrey's Electrical Generator.

Where the objective is to produce electricity from a rotating magnetic field, there has always been a search for some method of either reducing, or eliminating altogether, the drag on the rotor when electric current is drawn from the generator. One design which claims to have very limited drag caused by current draw is the Kromrey design. The main characteristics of this design are said to be:

1. It has almost constant electrical power output even when the rotor speed is altered by as much as 35%.

2. It can continue to operate with it's electrical output short-circuited, without heating the rotor or causing a braking effect.

3. The production efficiency (electrical output divided by the driving force) is high.

4. The frequency of it's AC output power can be adjusted to that required by the equipment which it powers.

5. The rotor can be spun at any rate from 800 rpm to 1,600 rpm.

6. The simple construction allows manufacturing costs to be about 30% less than other generators.

7. This generator is recommended for supplying power at or above the 1 kilowatt level.

Here is the patent for this device:

Patent US 3,374,376 **19th March 1968** **Inventor: Raymond Kromrey**

ELECTRIC GENERATOR

My present invention relates to an electric generator which converts magnetic energy into electric energy using two components which can rotate relative to each other, i.e. a stator and a rotor, one having electromagnets or permanent magnets which induce a voltage in a winding which forms part of an output circuit mounted on the other component.

Conventional generators of this type use a winding which whose conductors form loops in different axial planes so that opposite parts of each loop pass through the field of each pole pair, twice per revolution. If the loops are open circuit, then no current flows in the winding and no reaction torque is developed, leaving the rotor free to turn at the maximum speed of its driving unit. As soon as the output winding is connected across a load or is short-circuited, the resulting current flow tends to retard the motion of the rotor to an extent which depends on the intensity of the current and this makes it necessary to include compensating speed-regulating devices if it is necessary to maintain a reasonably constant output voltage. Also, the variable reaction torque subjects the rotor and its transmission to considerable mechanical stresses and possible damage.

It is therefore the general object of this invention to provide an electric generator which has none of the above disadvantages. Another object is to provide a generator whose rotor speed varies very little in speed between open circuit operation and current delivery operation. Another objective is to provide a generator whose output voltage is not greatly affected by fluctuations in its rotor speed.

I have found that these objectives can be achieved by rotating an elongated ferromagnetic element, such as a bar-shaped soft-iron armature, and a pair of pole pieces which create an air gap containing a magnetic field. Each of the outer extremities of the armature carries a winding, ideally, these windings are connected in series, and these coils form part of a power output circuit used to drive a load. As the armature rotates relative to the air gap, the magnetic circuit is intermittently completed and the armature experiences periodic remagnetisations with successive reversals of polarity.

When the output circuit is open, the mechanical energy applied to the rotor (less a small amount needed to overcome the friction of the rotating shaft) is absorbed by the work of magnetisation, which in turn, is dissipated as heat. In actual practice however, the resulting rise in temperature of the armature is hardly noticeable, particularly if the armature is part of the continuously air-cooled rotor assembly. When the output circuit is closed, part of this work is converted into electrical energy as the current flow through the winding opposes the magnetising action of the field and increases the apparent magnetic reluctance of the armature, and so the speed of the generator remains substantially unchanged if the output circuit is open or closed.

As the armature approaches its position of alignment with the gap, the constant magnetic field tends to accelerate the rotation of the armature, aiding the applied driving force. After the armature passes through the gap there is a retarding effect. When the rotor picks up speed, the flywheel effect of its mass overcomes these fluctuations in the applied torque and a smooth rotation is experienced.

In a practical embodiment of this invention, the magnetic flux path includes two axially spaced magnetic fields traversing the rotor axis and substantially at right angles to it. These fields are generated by respective pole pairs co-operating with two axially spaced armatures of the type already described. It is convenient to arrange these two armatures so that they lie in a common axial plane and similarly, the two field-producing pole pairs also lie in a single plane. The armatures should be laminated to minimise eddy currents, so they are made of highly permeable (typically, soft-iron) foils whose principle dimension is perpendicular to the rotor axis. The foils can be held together by rivets or any other suitable method.

If the ferromagnetic elements are part of the rotor, then the output circuit will include the usual current-collecting means, such as slip-rings or commutator segments, depending on whether AC or DC current output is desired. The source of coercive force in the stator includes, advantageously, a pair of oppositely positioned, yoke-shaped magnets of the permanent or electrically energised type, whose extremities constitute the pole pieces mentioned above. If electromagnets are used in the magnetic circuit, then they may be energised by an external source or by direct current from the output circuit of the generator itself.

I have found that the terminal voltage of the output circuit does not vary proportionately to the rotor speed as might be expected, but instead, it drops at a considerably slower rate with decreasing rotor speed. So, in a particular tested unit, this voltage fell to only about half its original value when the rotor speed was dropped to one

third. This non-linear relationship between terminal voltage and driving rate produces a substantially constant load current and therefore, electric output over a wide speed range, at least under certain load conditions, inasmuch as the inductive reactance of the winding is proportional to frequency (and consequently, to rotor speed) so as to drop off more rapidly than the terminal voltage, in the event of a speed reduction, with a resulting improvement in the power factor of the load circuit.

If the magnetic circuit contains only a single pole pair per air gap, the flux induced in the rotating armature will change its direction twice per revolution so that each revolution produces one complete cycle of 360 electrical degrees. In general, the number of electrical degrees per revolution will equal 360 times the number of pole pairs, it being apparent that this number ought to be odd since with even numbers it would not be possible to have poles alternating in polarity along the path of the armature and at the same time to have the North and South poles of each pair at diametrically opposite locations. In any case, it is important to dimension the curved facing faces of the pole pairs in such a manner so as to avoid allowing the armature to bridge between adjoining poles, so it is necessary to make the sum of the arcs spanned by these faces (in the plane of rotation) equal to considerably less than 360 degrees electrical.

The invention will now be described in more detail, reference being made to the accompanying drawings in which:

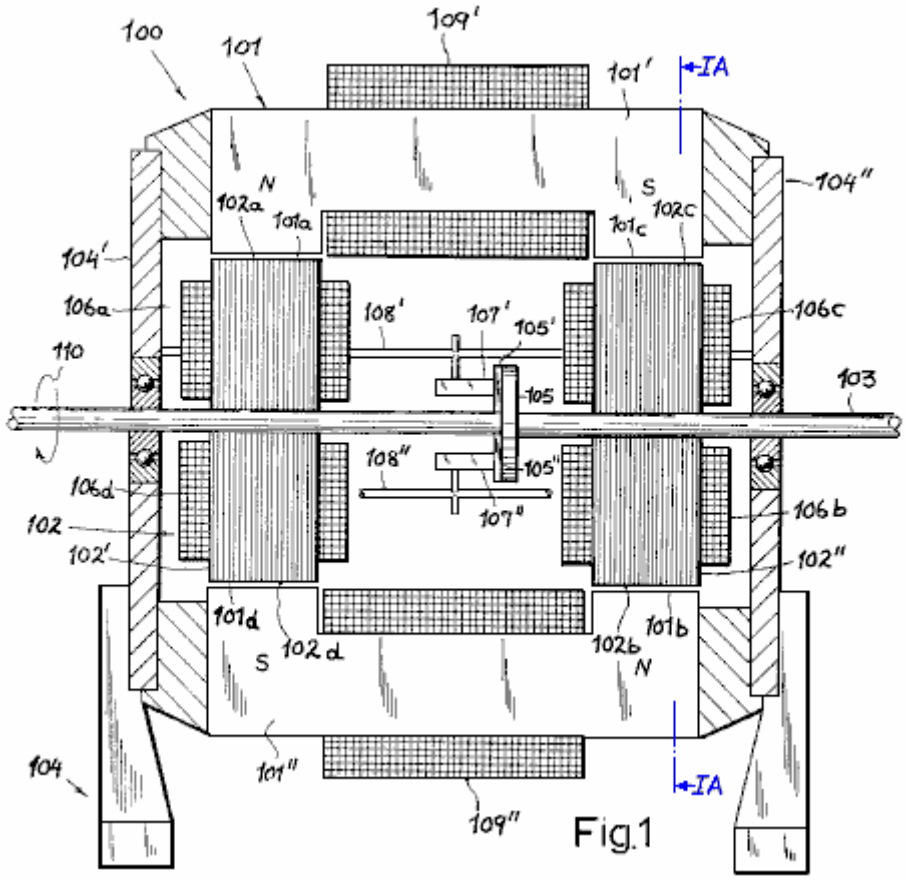

Fig.1

Fig.1 and **Fig1A**. illustrate a first embodiment of my invention, shown in axial section and in a cross-sectional view taken on line IA - IA of Fig.1 respectively.

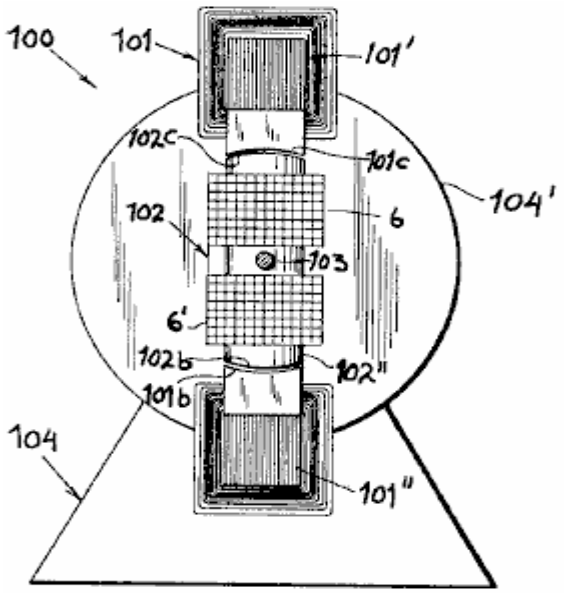

Fig.1A

Fig.2 and **Fig.3** are perspective views illustrating two other embodiments.

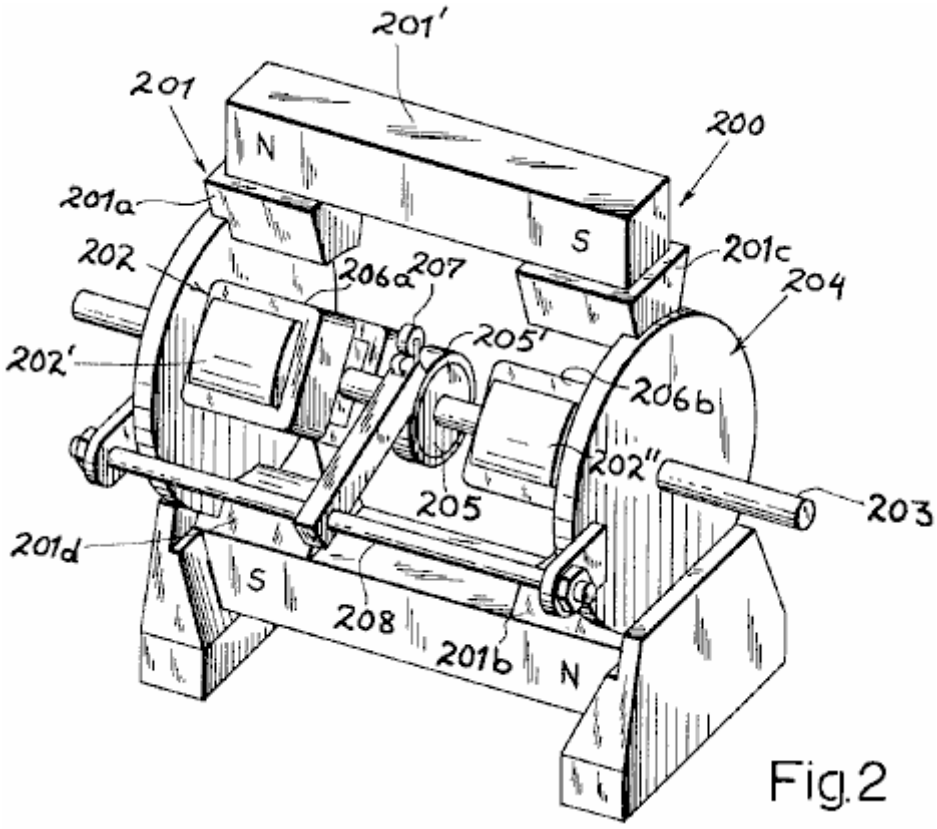

Fig.2

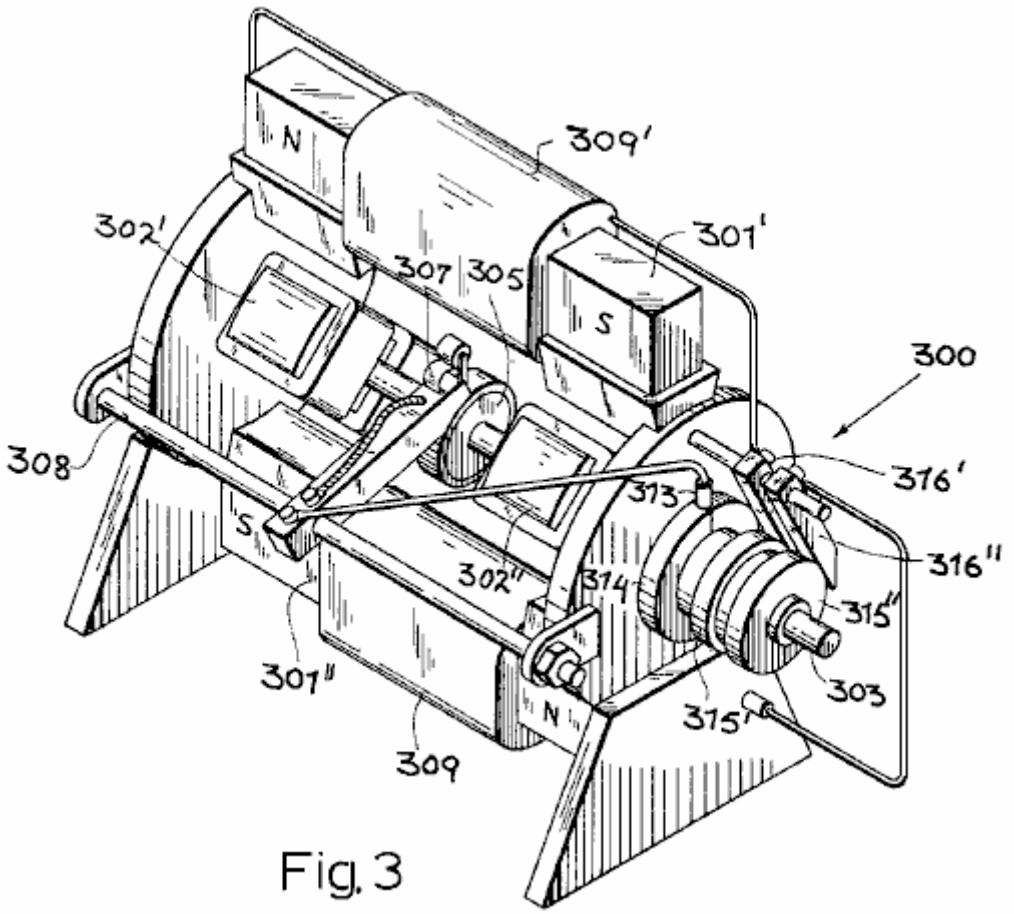

Fig. 3

Fig.4 and **Fig.5** illustrate diagrammatically, two output circuit arrangements, one for a DC output and one for an AC output.

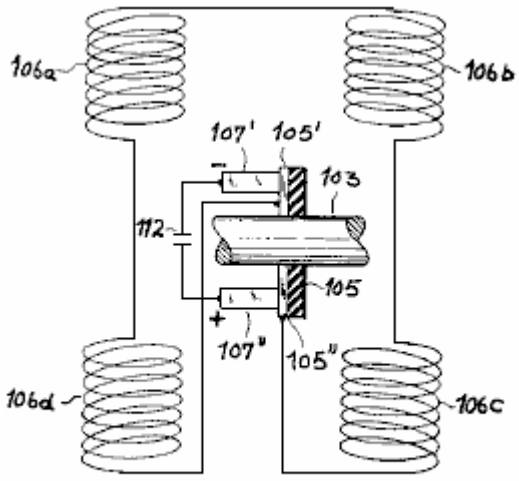

Fig. 4

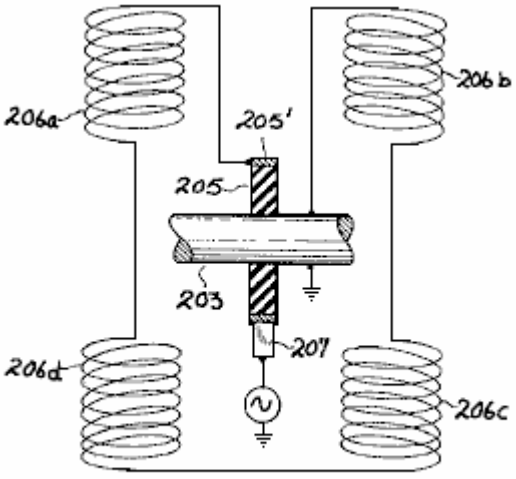

Fig. 5

Fig.6 is a somewhat diagrammatic illustration of an arrangement for comparing the outputs of a conventional generator and a generator according to this invention.

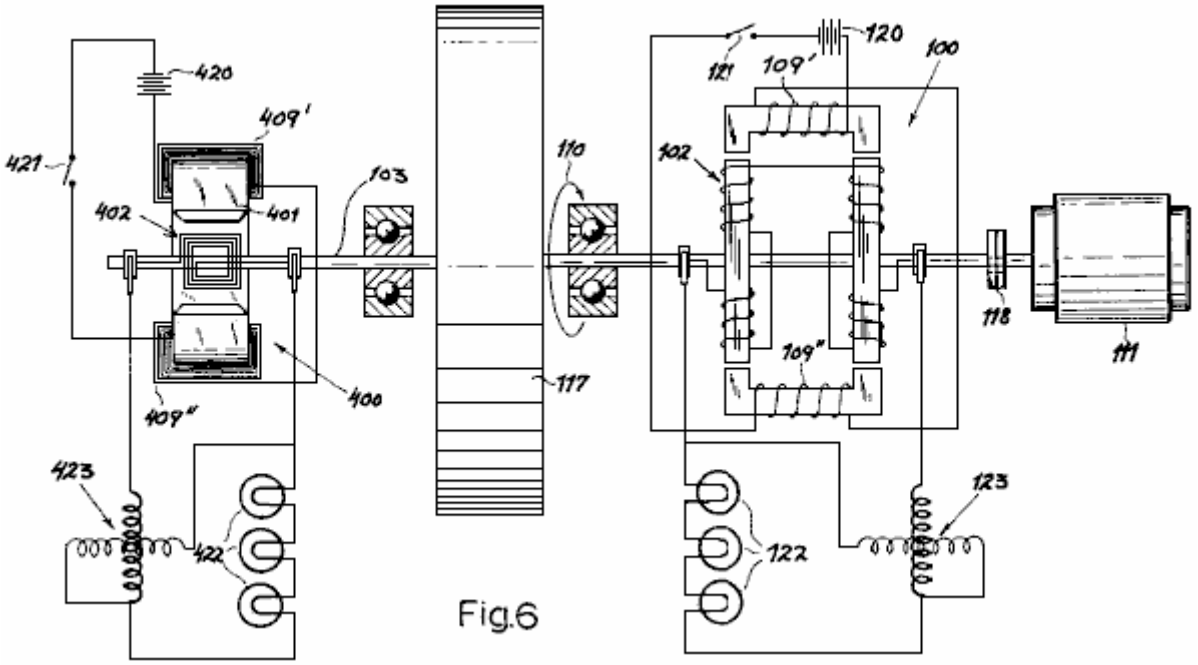

Fig.6

The generator **100** shown in **Fig.1** and **Fig.1A** comprises a stator **101** and a rotor **102** which has a pair of laminated armatures **102'** and **102"**, carried on a shaft **103** which is free to rotate in bearings mounted in the end plates **104'** and **104"**, of a generator housing **104** which is made from non-magnetic material (e.g. aluminium) which is rigidly attached to the stator.

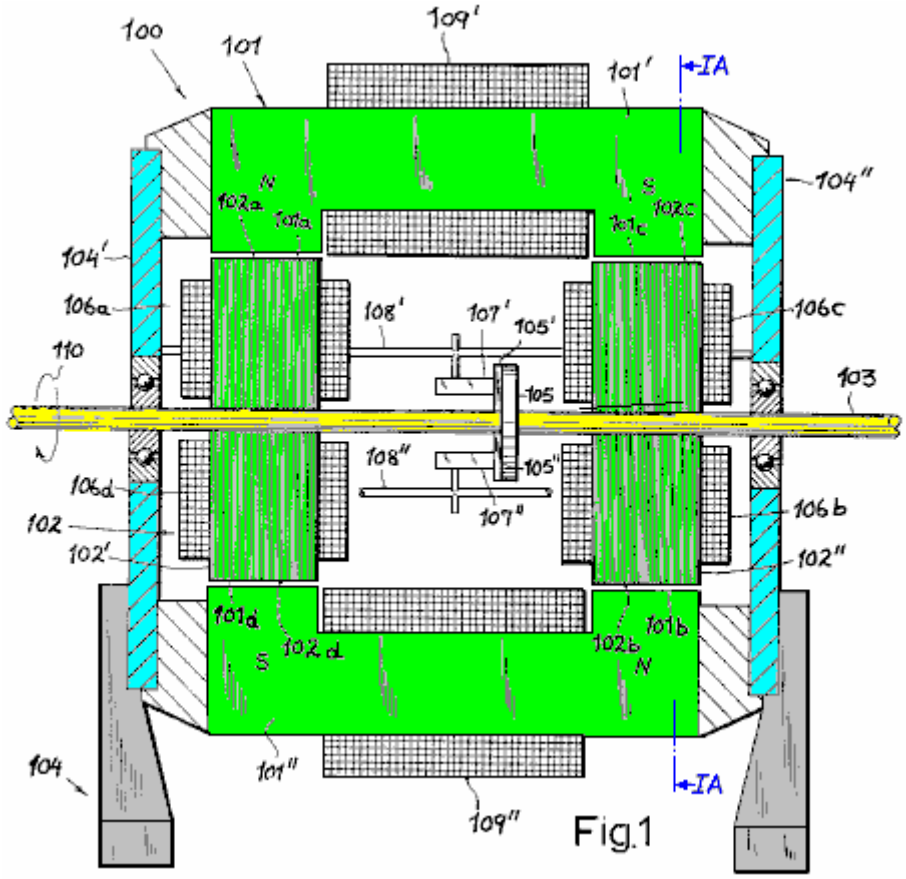

Fig.1

Shaft **103** is coupled to a source of driving power indicated diagrammatically by an arrow **110**. The stator **101** includes a pair of yoke-shaped laminated electromagnets **101'** and **101"** whose extremities form two pairs of co-planar pole pieces, designated respectively **101a, 101b** (North magnetic pole) and **101c, 101d** (South magnetic pole). The pole pieces have concave faces, facing towards the complimentary convex faces **102a, 102d** of armature **102'** and **102b, 102c** of armature **102"**. These faces whose concavities are all centred on the axis of

shaft **103**, extend over arcs of approximately 20^{O} to 25^{O} each in the plane of rotation (**Fig.1A**) so that the sum of these arcs adds up to about 90^{O} geometrically and electrically.

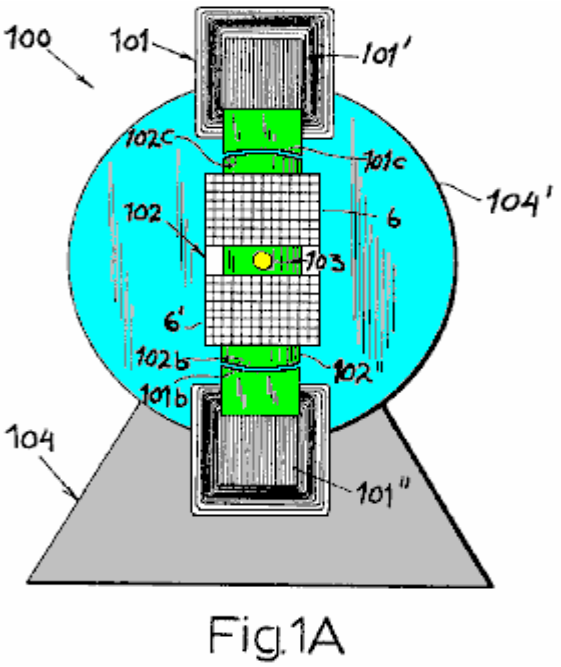

Fig.1A

The stator magnets **101', 101"** are surrounded by energising windings **109', 109"** which are connected across a suitable source of constant direct current (not shown). Similar windings, each composed of two series-connected coils **106a, 106d** and **106b, 106c**, surround the rotor armatures **102'** and **102"**, respectively. These coils form part of an output circuit which further includes a pair of brushes **107', 107"** which are carried by arms **108', 108"** on housing **104** with mutual insulation brushes **107', 107"** co-operate with a pair of commuter segments **105', 105"** (see also **Fig.4**) which are supported by a disc of insulating material **105**, mounted on shaft **103**.

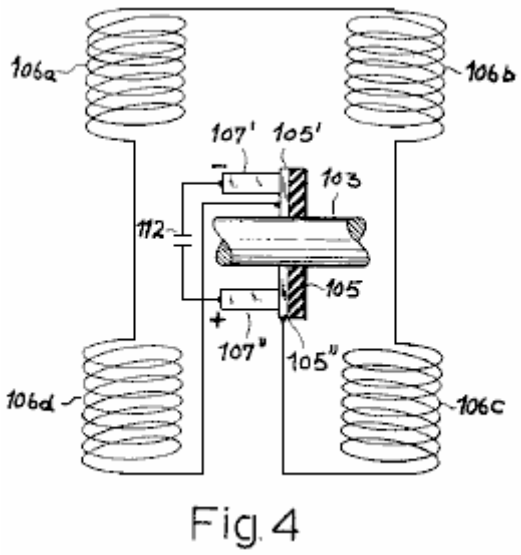

Fig.4

By virtue of the series-connection of coils **106a-106d** between the segments **105'** and **105"**, as illustrated in **Fig.4**, the alternating voltage induced in these coils gives rise to a rectified output voltage at brushes **107'** and **107"**. The unidirectional current delivered by these brushes to a load (not shown) may be smoothed by conventional means, represented by capacitor **112** in **Fig.4**.

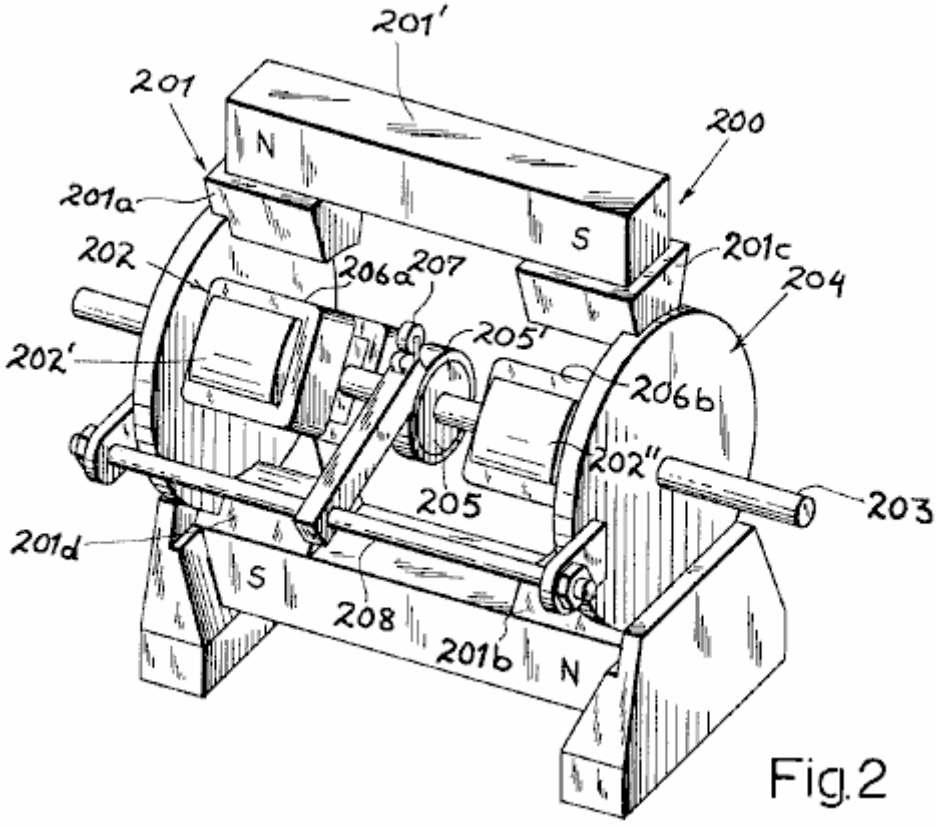

Fig.2

Fig.2, shows a modified generator **200**, whose housing **204**, supports a stator **201** essentially consisting of two permanent bar magnets **201'** and **201"**, extending parallel to the drive shaft **203** (on opposite side of it), each of these magnets being rigid and each having a pair of sole shoes **201a, 201c** and **201b, 201d** respectively. Rotor **202** is a pair of laminated armatures **202'** and **202"**,similar to those of the previous embodiment, whose output coils **206a, 206b, 206c** and **206d** are serially connected between a slip-ring **205'**, supported on shaft **203** through the intermediary of an insulating disc **205**, and another terminal here represented by the grounded shaft **203** itself. Slip-ring **205'** is contacted by brush **207** on holder **208**, the output of this brush being an alternating current of a frequency determined by the rotor speed.

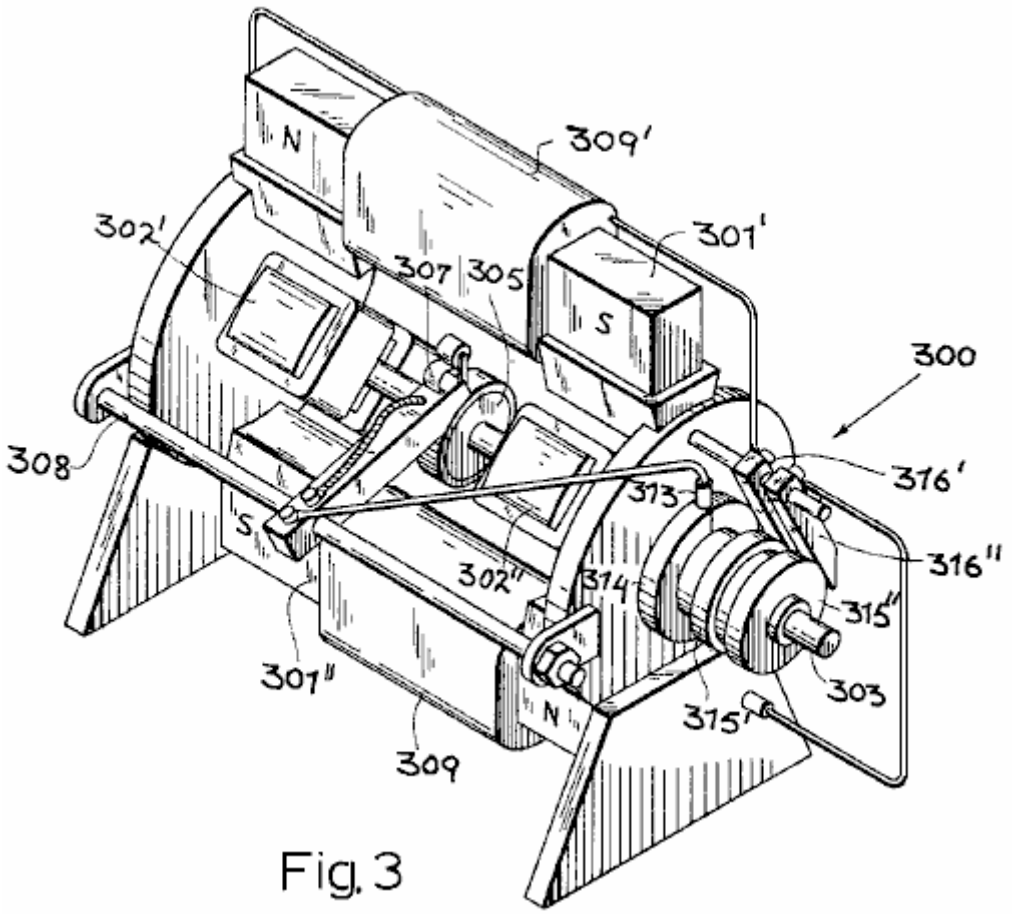

Fig. 3

Fig.3 shows a generator **300** which is basically similar to the generator **100** shown in **Fig.1** and **Fig.1A**. It's shaft **303** carries a pair of laminated soft-iron armatures **302', 302"** which can rotate in the air gaps of a pair of electromagnets **301', 301"** which have windings **309'** and **309"**. The commutator **305** again co-operates with a pair of brushes **307**, only one of which is visible in **Fig.3**. This brush, carried on an arm **308**, is electrically connected to a brush **313** which engages with a slip-ring **314** positioned on an extremity of shaft **303** which also carries two further slip-rings **315', 315"** which are in conductive contact with ring **314** but are insulated from the shaft. Two further brushes **316', 316"** contact the rings **315', 315"** and respectively are connected to windings **309'** and **309"**. The other ends of these windings are connected to an analogous system of brushes and slip-rings on the extremity of the opposite shaft, and arranged so that the two commutator brushes are effectively bridged across the windings **309'** and **309"** in parallel. Therefore, in this embodiment, the stator magnets are energised from the generator output itself, it being understood that the magnets **301'** and **301"** (made, for example, of steel rather than soft iron) will have a residual coercive force sufficient to induce an initial output voltage. Naturally, the circuits leading from the brushes **307** to the windings **309', 309"** may include filtering as described in connection with **Fig.4**.

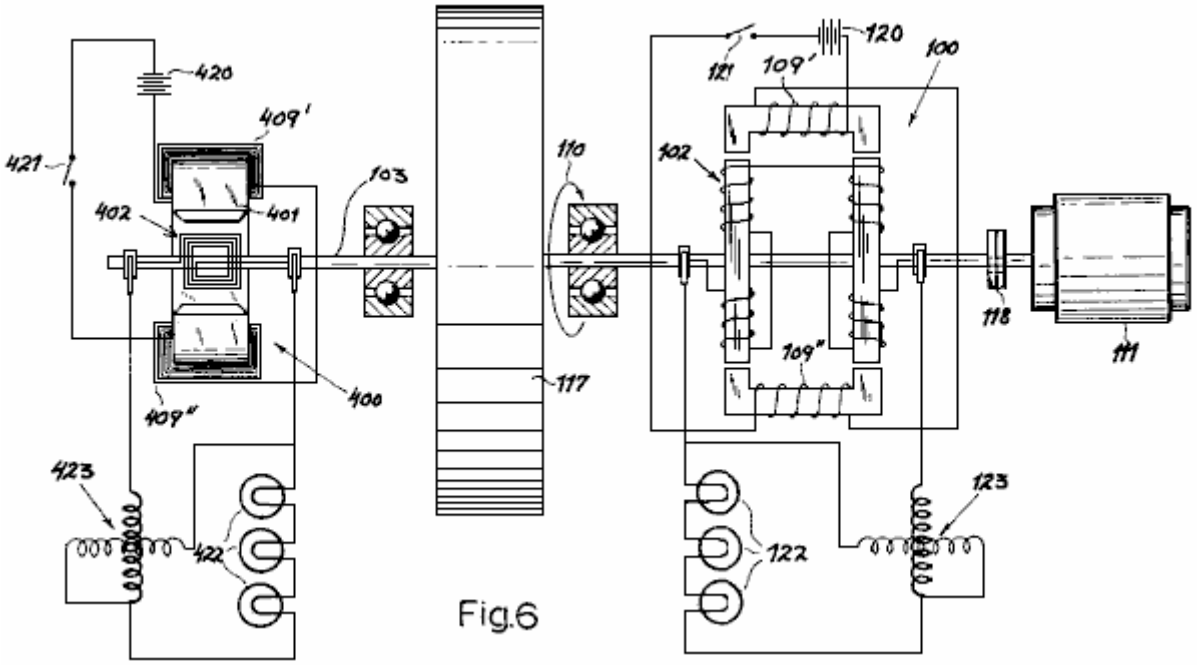

Fig.6

Fig.6 shows a test circuit designed to compare the outputs of a generator of this design, such as the unit **100** of **Fig.1** and **Fig.1A**, with a conventional generator **400** of the type having a looped armature **402** which rotates in the gap of a stator magnet **401** which is fitted with energising windings **409', 409"**. The two generators are interconnected by a common shaft **103** which carries a flywheel **117**. This shaft is coupled through a clutch **118** to a drive motor **111** which drives the rotors **402** and **102** of both generators in unison, as indicated by arrow **110**. Two batteries **120** and **420**, in series with switches **121** and **421**, represent the method of supplying direct current to the stator windings **109', 109"** and **409', 409"** of the two generators.

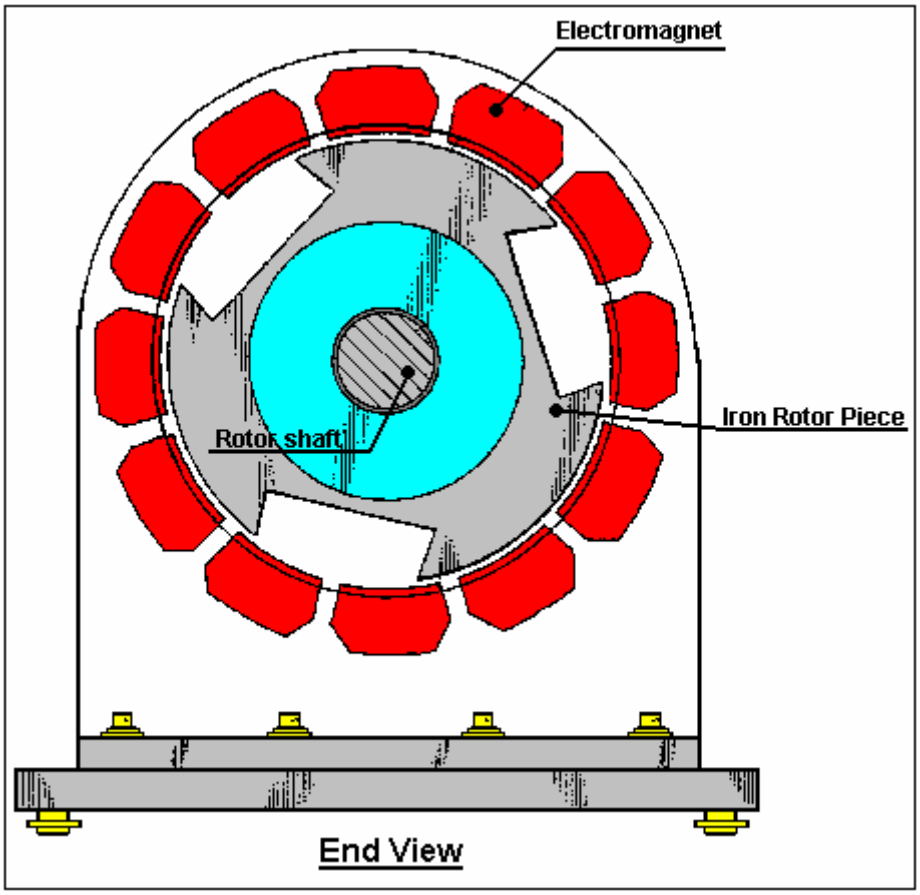
The rectified output of generator **100** is delivered to a load **122**, shown here as three incandescent lamps connected in series, and with a combined consumption of 500 watts. Generator **400**, provides current into an identical load **422**. Two watt meters **123** and **423** have their voltage and current windings connected respectively in shunt and in series with their associated loads **122** and **422**, to measure the electric power delivered by each generator.

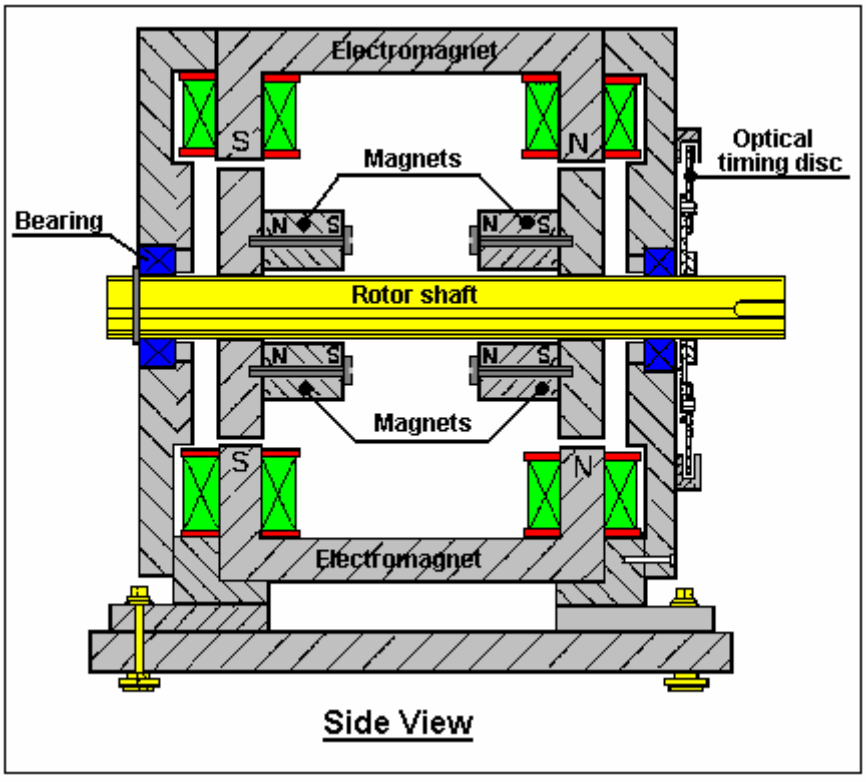
When clutch **118** is engaged, shaft **113** with it's flywheel **117** is brought to an initial driving speed of 1,200 rpm. at which point, the switch **421** in the energising circuit of the conventional generator **400**, is closed. The lamps **422** light immediately and the corresponding wattmeter **423** shows an initial output of 500 watts. However, this output drops immediately as the flywheel **117** is decelerated by the braking effect of the magnetic field on armature **402**.

Next, the procedure is repeated but with switch **421** open and switch **121** closed. This energises generator **100** and the lamps **122** light up, wattmeter **123** showing an output of 500 watts, which remains constant for an indefinite period of time , there being no appreciable deceleration of flywheel **117**. When the clutch **118** is released and the rotor speed gradually decreases, the output of generator **100** is still substantially 500 watts at a speed of 900 rpm. and remains as high as 360 watts when the speed dropped further to 600 rpm. In a similar test with a generator of the permanent magnet type, such as the one shown at **200** in **Fig.2**, a substantially constant output was observed over a range of 1600 to 640 rpm.

Teruo Kawai's COP=1.6 Magnetic Motor.

In July 1995, a patent was granted to Teruo Kawai for an electric motor. In the patent, Teruo states that a measured electrical input 19.55 watts produced an output of 62.16 watts, and that is a COP of 3.18. The main sections of that patent are included in the Appendix.





In this motor, a series of electromagnets are placed in a ring to form the active stator. The rotor shaft has two iron discs mounted on it. These discs have permanent magnets bolted to them and they have wide slots cut in them to alter their magnetic effect. The electromagnets are pulsed with the pulsing controlled via an optical disc arrangement mounted on the shaft. The result is a very efficient electric motor whose output has been measured as being in excess of its input.

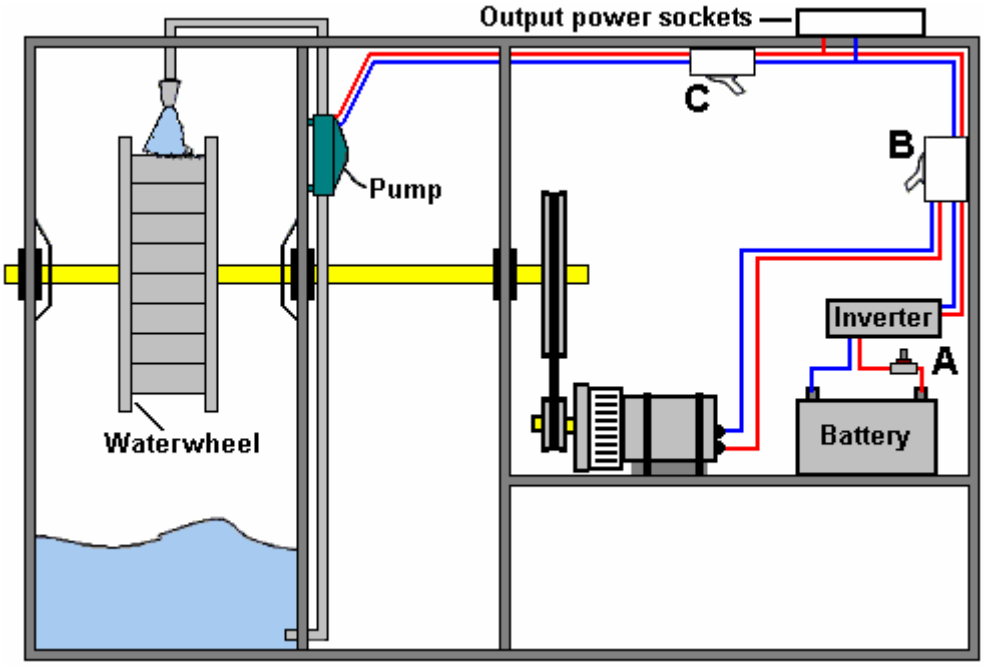
James Hardy's Self-Powered Water-Pump Generator.
There is a video on Google which shows an interesting self-powered water-pump driven, electrical generator at:
http://www.youtube.com/watch?v=IGpXA6qhH_Q

This is a very simple device where the jet of water from the pump is directed at a simple water-wheel which in turn, spins an electrical alternator, powering both the pump and an electric light bulb, demonstrating free-energy.

Initially, the generator is got up to speed, driven by the mains electrical supply. Then, when it is running normally, the mains connection is removed and the motor/generator sustains itself and is also able to power at least one light bulb. The generator output is normal mains current from a standard off-the-shelf alternator.

James has Patent Application US 2007/0018461 A1 published in 2007 on his design. In that application he points out that a major advantage of his design is the low noise level produced when the generator is running. In the video and the pictures above, the demonstration has the housing opened up in order to show how the generator system works, but during normal use, the compartments are completely sealed.

In his document, James shows the overall system like this:



The housing is divided into three separate compartments. The first compartment has a strong axle shaft running through it, supported on ball or roller bearings – possibly ceramic for this environment. The bearings are protected by being covered by splash guards which keep the water (or other liquid) off them. A waterwheel of almost any type is mounted on the shaft and a high-capacity water pump directs a stream of liquid on to the waterwheel, striking the paddles at right angles in order to provide the maximum impact.

This first compartment is sealed in order to contain all of the liquid inside it and the bottom is effectively a sump for the liquid. A pipe located near the bottom of the compartment feeds the liquid to the pump which is located in the second compartment. The pump boosts the liquid through a nozzle, directing it at the waterwheel. While almost any nozzle will work, it is usual to choose one which produces a concentrated jet of liquid in order to generate the largest possible impact. One would expect that the larger the diameter of the waterwheel, the more powerful the system would be. However, that is not necessarily the case as other factors such as the overall weight of the rotating members might affect the performance. Experimentation should show the most effective combination for any given pump.

The rotating shaft is given a third bearing supported by the side of the final compartment. The shaft then has a large diameter belt pulley mounted on it, the belt driving a much smaller pulley mounted on the shaft of the generator. This raises the rate at which the generator shaft is rotated. If the pump operates on AC mains voltage, then the generator will be one which generates mains voltage AC. If the pump operates on, say, 12 volts, then the generator will be one which generates 12 volts DC. The diagram above, shows the arrangement for a mains voltage system as that is probably the most convenient. If a 12-volt system is chosen, then the inverter can be omitted.

The generator is started by pressing the 'normally open' press-button switch marked "**A**" in the diagram. This passes the battery power through to the 1-kilowatt inverter which then generates AC mains voltage. The switch marked "**B**" is a "changeover" switch, and for starting, it is set so that it passes the AC power through switch "**A**" to the pump. This causes the pump to turn on and direct a powerful jet of liquid at the waterwheel, forcing it around and so powering the generator. When the generator gets up to full speed, switch "**B**" is flipped over, disconnecting the inverter and feeding the generator power through to the pump, keeping it running and supplying additional power to the output power sockets mounted on top of the housing. The press-button switch is released, disconnecting the battery which is no longer needed. Switch "**C**" is an ordinary On/Off mains switch which is needed if you want to turn the generator off.

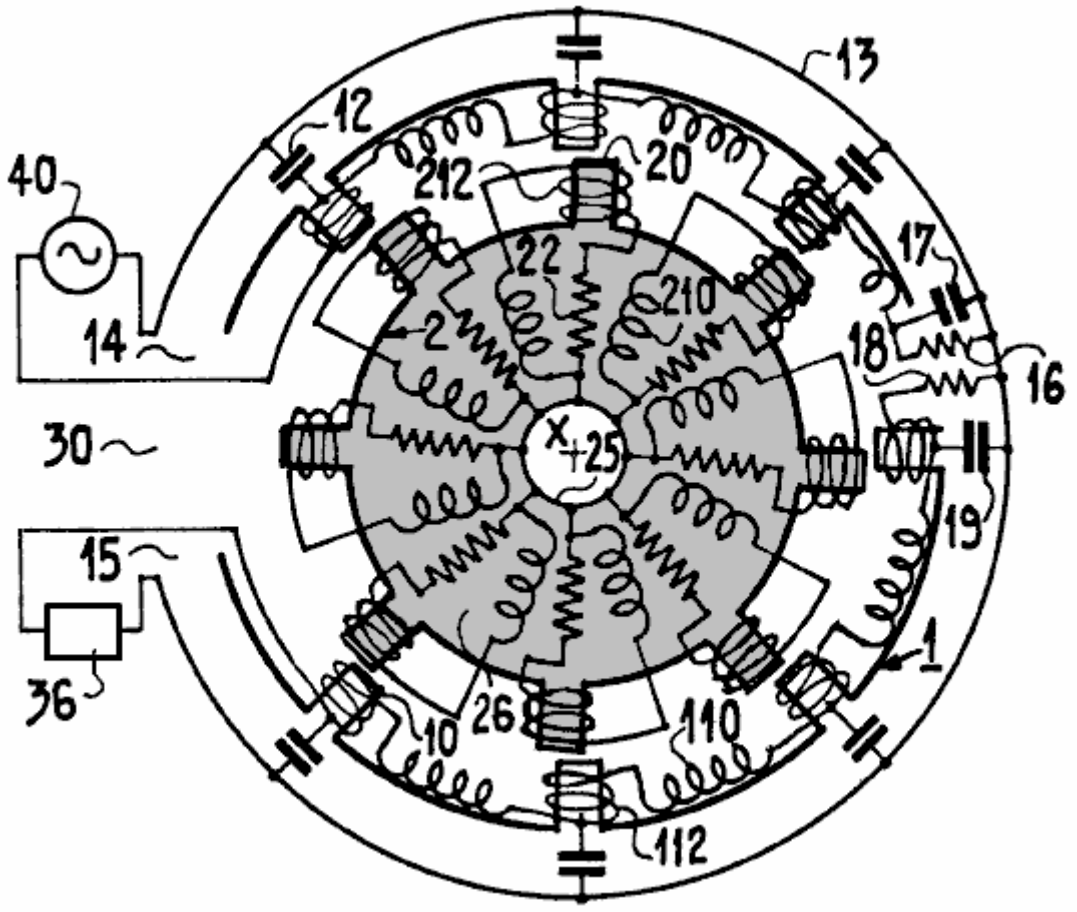
A major advantage of this generator system is that the main components can be bought ready-made and so only very simple constructional skills and readily available materials are needed. Another advantage is that what is happening can be seen. If the pump is not working, then it is a simple task to discover why. If the generator is not spinning, then you can see that and sort the problem. Every component is simple and straightforward.

James suggests that a suitable pump is the 10,000 gallons per hour "Torpedo Pump" from Cal Pump, web site: http://www.calpumpstore.com/products/productdetail/part_number=T10000/416.0.1.1:

Georges Mourier's COP=10,000 Motor/Generator Patent.
This patent from Frenchman Georges Mourier is quite remarkable in that it states clearly in the patent that it has a Coefficient Of Performance of 10,000 with an input power of just 10 watts producing an output of 100 kilowatts, which, considering the massive opposition of the US Patent Office to any claim of output power being greater than the input needed to produce that output, is little short of amazing. This patent contains a fair amount of mathematics where Georges goes about showing why there is a power amplification. This can be ignored by most people as the point to concentrate on is how to build a power-amplifying motor/generator.

US Patent 4,189,654 19th February 1980 Inventor: Georges Mourier

Electrical machine operating as a generator or as an amplifier



Abstract
The invention relates to an electrical machine. The stator **1** is a delay line, in the form of a low-pass filter in the example, formed by inductance **11** and capacitors **12** connected between these inductances and the common conductor **13**. The rotor **2** comprises dissipating elements **22** incorporated in circuits **26**, separate in the example,

and having a common point **25**. It is put in movement by a motor. The machine operates as a high-gain amplifier having a wide band of high-frequency signals applied to the input **14** of the stator, separated from the output **15** by the decoupling zone **30**. High powers are obtainable. Application to installations for testing vibration of industrial equipment and to high-power long wave radio transmission.

Description

The invention relates to an electrical machine capable of operating as a generator and as an amplifier. The machine comprises a fixed part, or stator, in which moves a moving part designated hereinafter by the term “rotor”, by analogy with the case of machines of the prior art in which the movement in question is a movement of rotation, although this movement may be other than a rotation and in particular a rectilinear translation in the case of the invention.

The stator consists of a line having two conductors which have two input terminals and two output terminals; it’s rotor comprises resistive elements under conditions which will be described in detail later.

In operation, a wave is propagated between the input terminals and the output terminals in question in this line. Electrical machines are known from U.S. Patent 3,875,484, in which the stator comprises inductances and capacitances incorporated in a transmission line, as in the machines of this invention, along which there is propagated, in operation, an electric wave, but contrary to the case of the invention, this line has only one pair of terminals to which those of the alternating current source are connected. The application of the voltage of this source between these terminals causes the rotation of the rotor of the machine which, as it is operating as a motor, does not have an output. Owing to the structure, a brief indication of which has been given above, the machine of this invention is intended, on the contrary, to operate as a generator or as an amplifier; it has an output constituted by the other pair of terminals of the stator, the rotor being driven by an exterior motor.

A better understanding of the invention will be had from the ensuing description with reference to the accompanying Figures which represent:

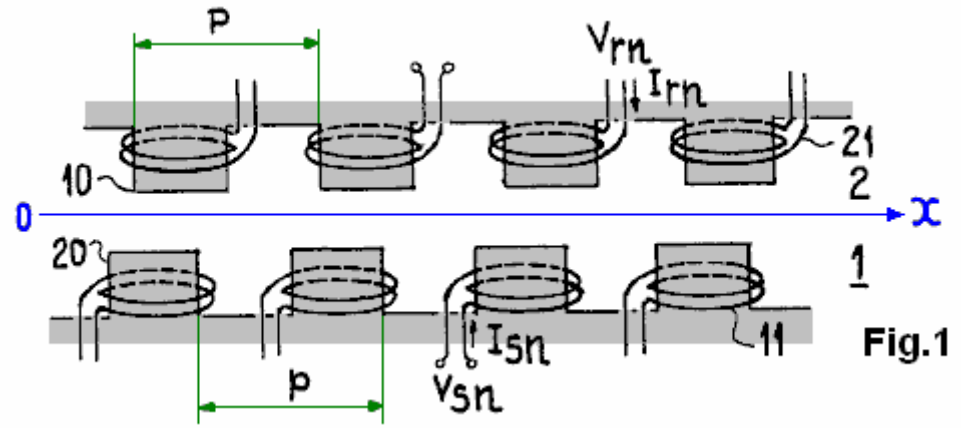


FIG.1, diagrammatically, the stator assembly and the rotor of a machine to which the invention is applied;

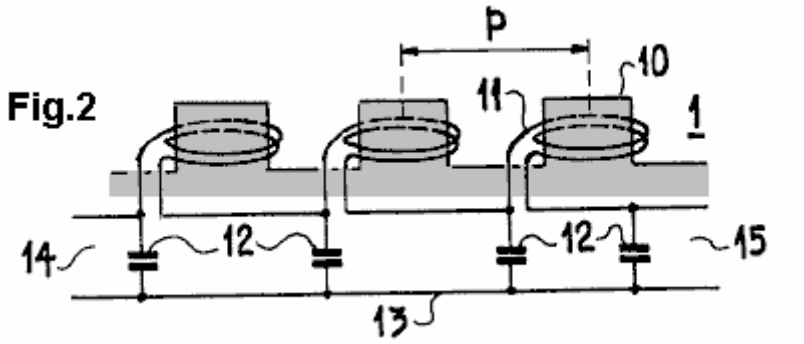

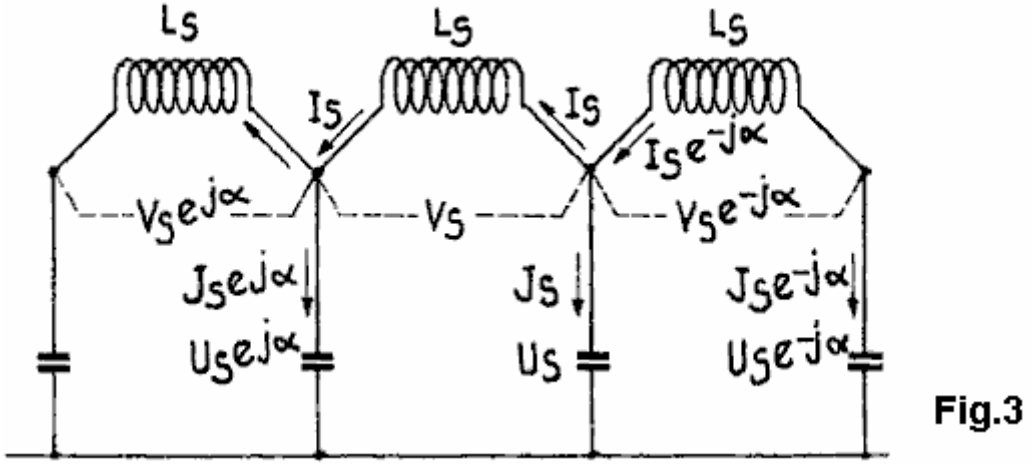

Fig.3

Fig.2 and **Fig.3**, diagrammatically, an embodiment of an electrical circuit of the stator of a machine of the invention and the corresponding diagram;

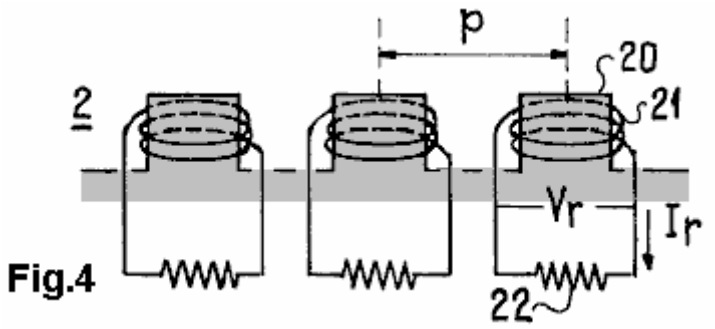

Fig.4

Fig.4, diagrammatically, a rotor structure of the machines of the invention;

Fig.5

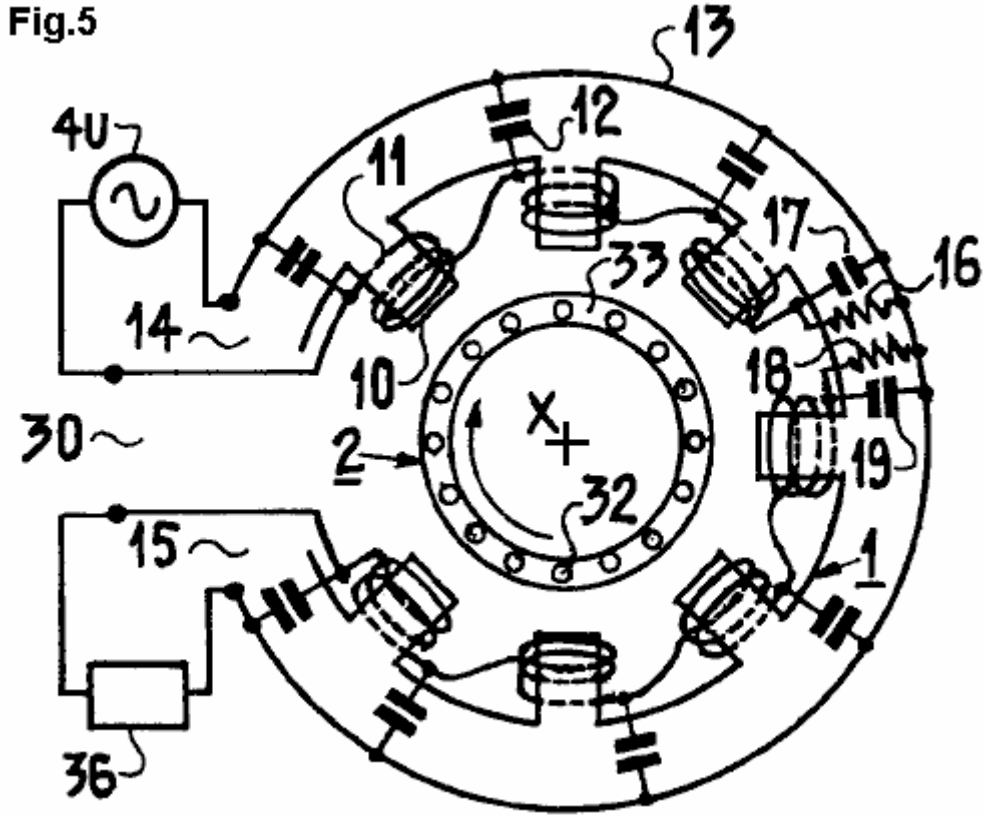

Fig.5, a diagrammatic view of a variant embodiment of the machine of the invention having a stator according to the design of **Fig.2**;

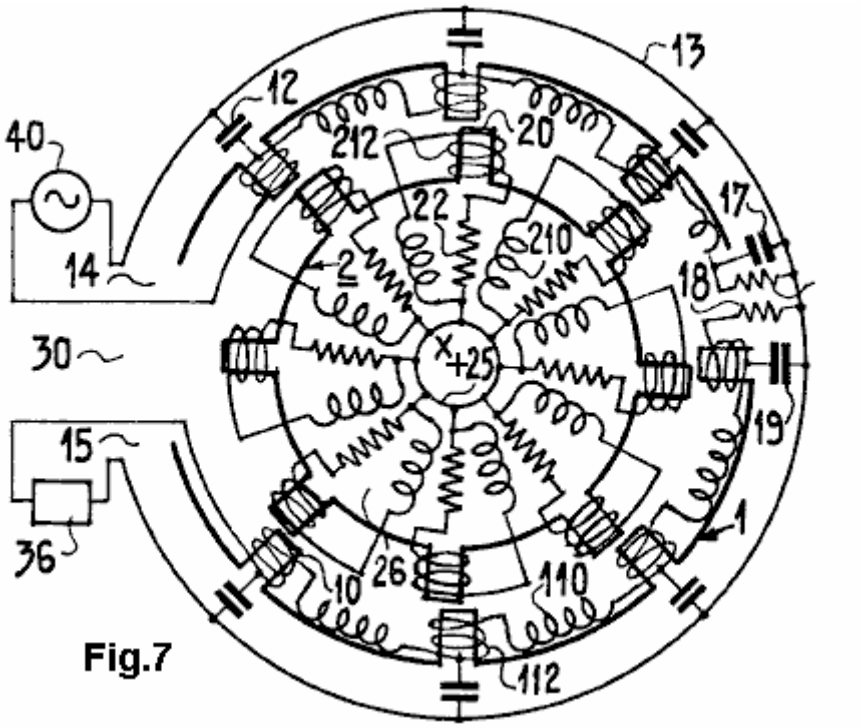

Fig.7

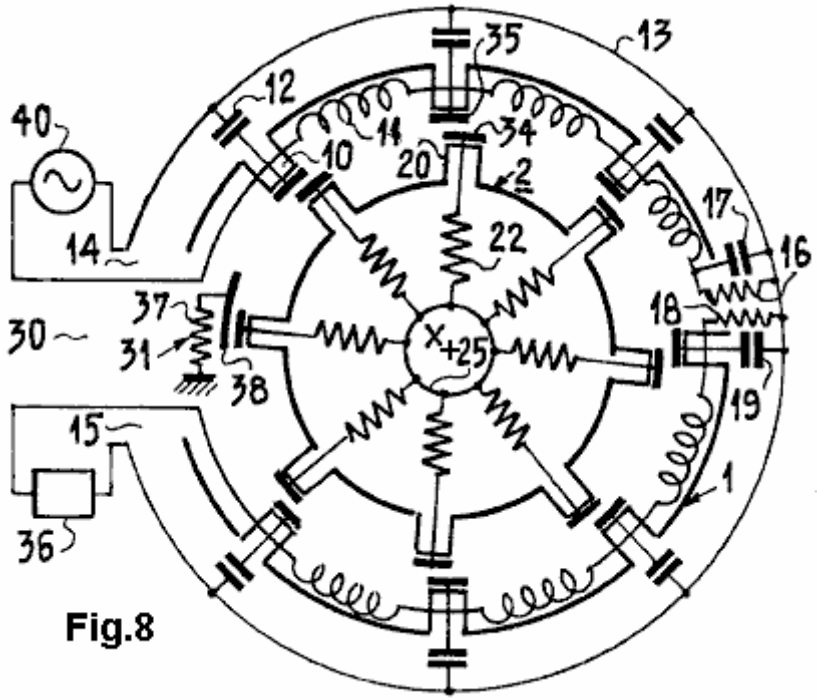

Fig.8

Fig.7 and **Fig.8**, diagrammatic views of two variant embodiments of the machine of the invention operating as amplifiers;

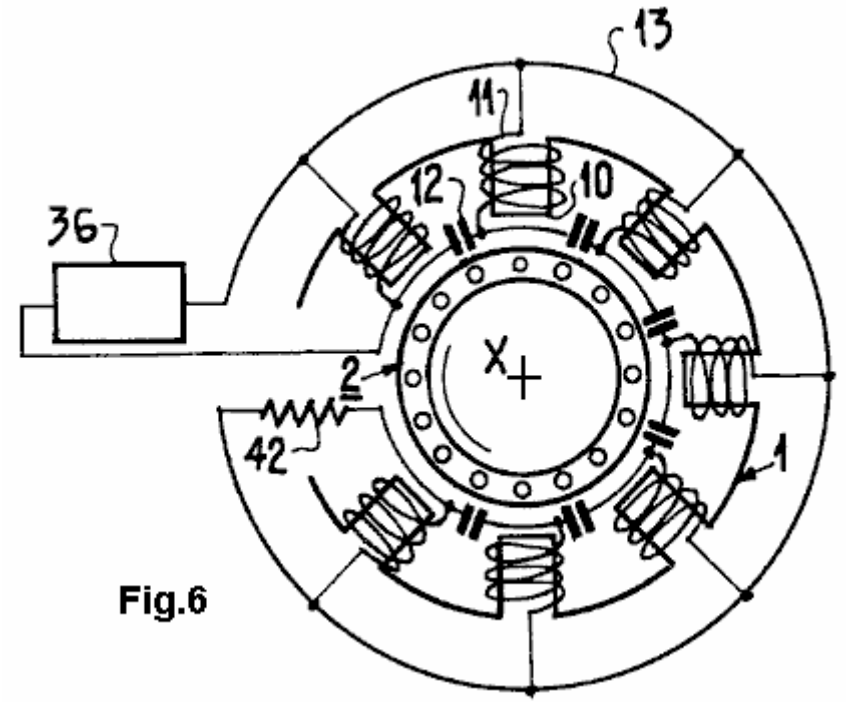

Fig.6

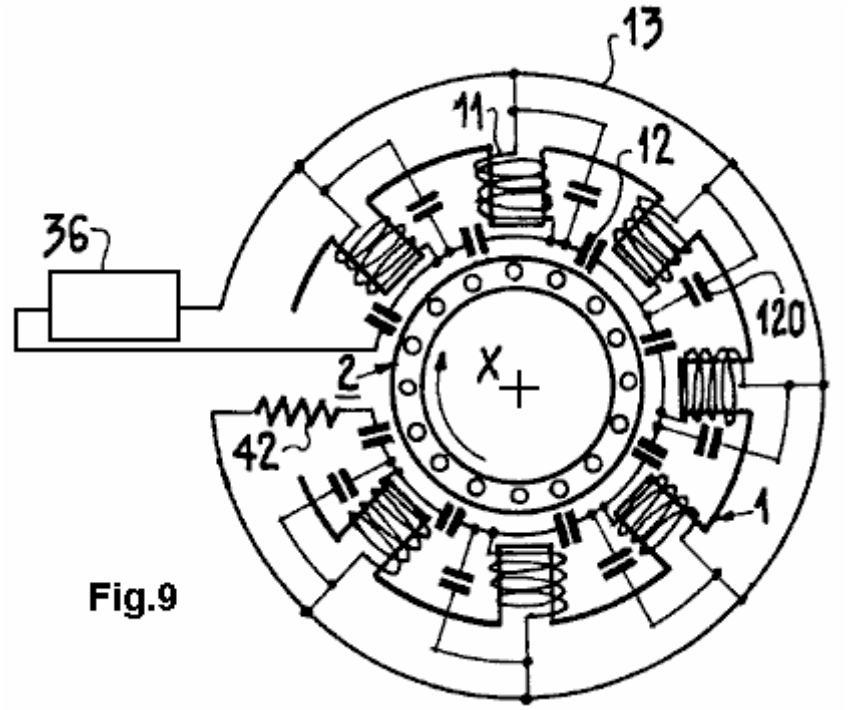

Fig.9

Fig.6 and **Fig.9**, two modifications of the machine of the invention operating as generators.

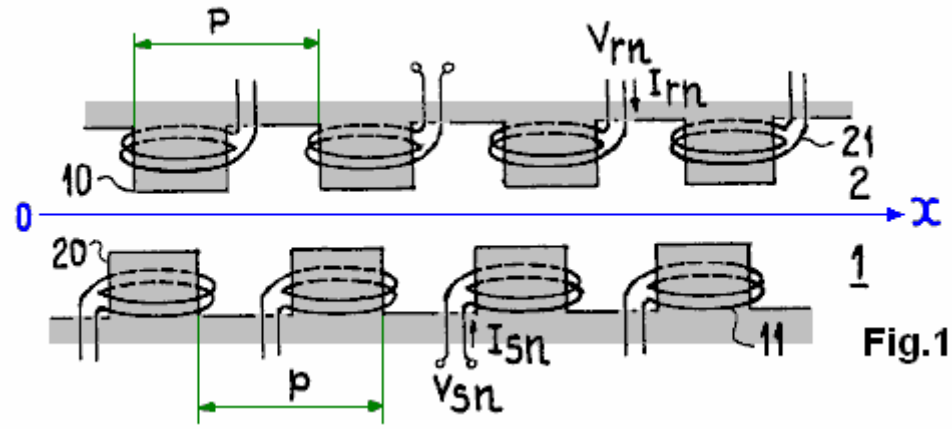

Fig.1

Fig.1 shows diagrammatically, a machine structure to which the invention is applied, in which the stator **1** and the rotor **2** comprise poles aligned in the direction o → x along which the rotor movement occurs. These poles are marked as **10** and **20** and are repeated with the same horizontal spacing or pitch **p** in both the rotor and the stator. References **11** and **21** are the inductive windings through which the coupling occurs between a pole of the rotor and a pole of the stator when they align in the course of their movement.

V_{sn} and V_{rn} are the instantaneous values of the voltages at the ends of these windings, and I_{sn} and I_{rn} are the currents in those coils at the moment of this alignment, n being the number assigned to the pole in each part of the machine. In order to simplify the notations, this index number 'n' will be omitted when mentioning the voltages and currents in question. φ designates the magnetic flux and M the coefficient of mutual inductances of this coupling. There are then obtained the following known equations:

$$\phi_s = L_s I_s + M I_r \quad \ldots\ldots\ldots\ldots (1)$$
$$\phi_r = M I_s + L_r I_r \quad \ldots\ldots\ldots\ldots (2)$$
$$V_s = j\omega L_s I_s + j\omega M I_r \quad \ldots\ldots\ldots\ldots (3)$$
$$V_r = j\omega' M I_s + j\omega' L_r I_r \quad \ldots\ldots\ldots\ldots (4)$$

where $\mathbf{L_s}$ and $\mathbf{L_r}$ are the values of inductances **11** and **21** and $\boldsymbol{\varphi_s}$ and $\boldsymbol{\varphi_r}$ the magnetic flux in these windings.

In these equations, the quantities **ω** and **ω'** are the angular frequencies of the currents in the stator and the rotor respectively; **ω** = 2πf, where **f** is the corresponding frequency. For equal phase differences between two successive poles of the stator and rotor, the pulses **ω** and **ω'** in the relation:

$$\omega' = \omega - \beta u \quad \ldots\ldots (5)$$

where **β** is in accordance with the usual definition the constant of propagation of the magnetic field wave along the stator, and **u** is the speed at which the rotor moves in front of the stator in the direction of the reference axis o – x in the case of the machine of the embodiment of **Fig.1**.

$$\beta = \frac{2\pi}{\Lambda} = \frac{\omega}{v_\phi}$$

if **Λ** and **vφ** respectively are the wavelength and the phase velocity in the stator.

In the embodiment of the machine of this invention having a stator in the form of a low-pass filter transmission line with an input **14** and an output **15**, and the inductances **11**, charge-accumulating elements **12** mounted between these inductances, and a common conductor **13** as shown in **Fig.2** and **Fig.3**, there is added to the foregoing equations the following equation:

$$\frac{V_s}{I_s} = -\frac{2}{jC_s\omega}(1 - \cos\alpha) \quad \ldots\ldots\ldots\ldots (6)$$

where **α** is equal to $\boldsymbol{\beta_p}$ and $\mathbf{C_s}$ is the value of the capacitors **12** (**Fig.2**) included in the construction of the filter, it being observed that there is obtained with the notations of **Fig.3**:

$$I_s = \frac{-J_s}{1 - \exp(-j\alpha)} \quad \text{and} \quad V_s = U_s(1 - \exp(j\alpha)), \text{ with } U_s = -j\frac{J_s}{C_s\omega}$$

There is also added:

$$V_r + R_r I_r = 0 \quad \ldots\ldots\ldots\ldots (7)$$

the equation for a rotor constructed, as shown in **Fig.4**, by separate resistive circuits each of which comprises, in addition to the foregoing, coupling inductance **21**, a resistor **22** of value R_r.

By eliminating the magnitudes of flux, voltage and current between the homogeneous equations (1), (2), (3), (4), (6) and (7) and by replacing **ω'** with it's expression taken from equation (5), there is obtained an equation in **β** whose roots have an imaginary part, whence it results that the variation with respect to time of the wave propagated along the stator in the direction **o --- x** of **Fig.1**, **whose amplitude** is proportional, in accordance with the conventional notation, to **exp j(ωt-βx)**, **undergoes an amplification in the course of this propagation**.

The equation in question is:

$$(\beta - \frac{\omega}{u} + \frac{j}{u\frac{L_r}{R_r}})(\beta^2 \quad \beta^2 1) = j\frac{\beta^2 1}{u\frac{L_r}{R_r}} \quad \frac{\frac{M^2}{L_r L_s}}{1 - \frac{M^2}{L_r L_s}} \quad \ldots\ldots (8)$$

$$\text{with} \quad \beta^2 1 = \omega^2 C_s L_s \frac{1}{p^2}(1 - \frac{M^2}{L_4 L_s})$$

and assuming that **α** is small, that is to say, that the machine has a large number of phases in the electro-technical sense of the word, the roots of which will be calculated by their relative difference **z** from a reference value chosen to be equal to **ω / u**, which is but little different, under the conditions of operation of the machines of the invention, from the quantity β_1 defined above; there is obtained:

$$z = \frac{\beta - \beta_1}{\beta_1} \text{ and } \beta = \beta_1(1+z) \quad \ldots\ldots\ldots (9)$$

The foregoing ratio **ω/u** is none other than the value of **β** in synchronous machines, in which **ω'** is null (equation 5). In the machines of this invention, **ω'** is non-zero: these machines operate in the asynchronous manner.

The equation in **z** is written:

$$z^2 + 2j\gamma z - j\gamma = 0 \quad \ldots\ldots\ldots (8')$$

in the particular case of a coupling coefficient

$$\mu = \frac{M^2}{L_r L_s} \; de \; \frac{1}{2}$$

It has two roots having an imaginary part. **The machine is capable of amplifying a signal applied to the input of the stator**. The order of magnitude of this amplification is shown below as an example. The expression of these roots is:

$$z\pm = -j\gamma \pm j\sqrt{\gamma^2 - j\gamma} \quad \ldots\ldots\ldots (10)$$

with:

$$z\pm = \frac{R_r}{L_r} \quad \frac{1}{2u\beta_1'}$$

to which the following numerical values correspond for a certain number of values of **γ**. The amplified wave corresponds to the root **Z+**.

	0.01	0.03	0.1	0.3	1
Z+	0.0703 + 0.610	0.120 + 0.094j	0.212 + 0.135j	0.334 + 0.149j	0.455 + 0.098j

The gain "**g**" in power per unit length of the stator is, according to equation (9) is:

$$g\ \mathrm{db/m} = 8.7\beta_1\text{-(imaginary part of z)}$$

In the given example, this gain reaches it's maximum value for the wave corresponding to **z+**, for **γ** between 0.1 and 0.3. The imaginary part of **z** is then in the neighbourhood of 0.15, which gives for **g**, in respect of a stator whose length is 5 wavelengths (x = 5), about 40 decibels. It will be observed that the corresponding propagation constant **β** differs only slightly in absolute value from the constant **ω/u** corresponding to synchronous operation. The machine of this invention operates under conditions which differ only slightly from synchronous operating conditions.

The wave passing through the stator is amplified in the manner of an electromagnetic wave which is propagated along the delay line of wave propagating tubes employed in hyper frequency described, among others, by J. R. Pierce in "Travelling Wave Tubes", Van Nostrand Co, 1950. The amplification occurs, as for these tubes, in a wide band around the central frequency.

In the foregoing, the rotor has been represented, for ease of description, with a structure having poles (reference **20** in the Figures). With the scope of the invention the rotor could be in the form of the well-known squirrel-cage structure of asynchronous machines. The above calculations remain valid in giving to the notion of resistance and to the notion of inductance the signification they have in this case.

The foregoing properties have been established by means of simplifying hypotheses which permit a clearer presentation. These properties apply generally to all machines whose stator and rotor would have the indicated electrical structure, even in the case of an operation which would differ slightly from these hypotheses in the neighbourhood of synchronous frequency. Moreover, the case was considered of a coupling by inductance between the rotor and the stator with a mutual coefficient **M**. Within the scope of the invention, this coupling could also be of an electrostatic nature between the conductors of the stator and rotor; similar equations would be obtained by substituting for the coefficient **M** the coefficient of electrostatic influence between the conductors in question, for the quantity $\mathbf{L_r}$ that, **Cr**, of the capacitance of each circuit of the rotor and, after interversion between $\mathbf{L_s}$ and $\mathbf{C_s}$. In this case $\mathbf{V_r}$ (equation 7) represents the voltage drop at the terminals of the capacitance of the rotor. The machine of this invention is also capable of operating as a generator, as will be seen below. A few embodiments of the structure of the machine of this invention will be given here.

Fig.5

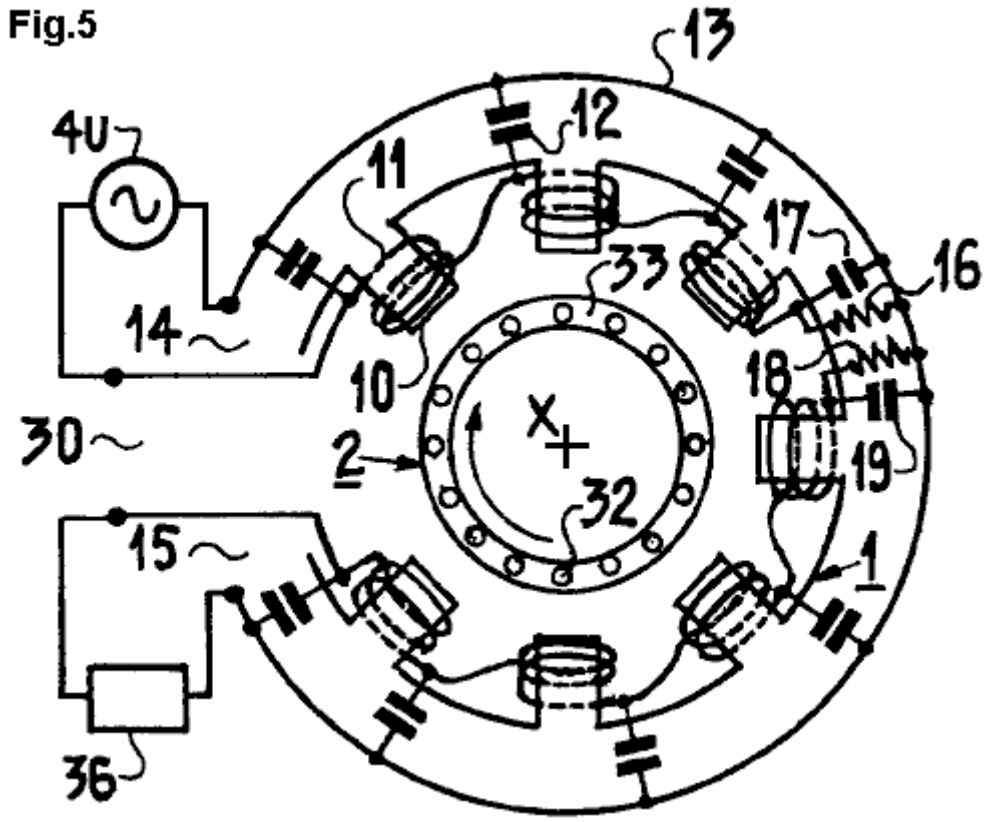

Fig.5 shows a first modification of this structure comprising a stator in accordance with the low-pass filter diagram of **Fig.2**. The rotor is a squirrel-cage, the reference numerals **32** and **33** are the bars and the end faces. In operation, it is driven by a rotor (not shown) which rotates it in the direction of the arrow about axis **X** which is common to the rotor and the stator of the machine. A source of alternating voltage **40** is applied to input **14** of the

stator, and applied to the output **15** is a load **36**, the impedance of which is equal to the characteristic impedance of the line of which the stator is part. In this arrangement of revolution about the axis **X**, a decoupling zone **30** separates the input and output of the stator. Further, in this zone, and in order to avoid any risk of coupling between input and output of the stator by the circuits of the rotor, there is provided any damping device considered necessary, an embodiment of which is given below.

The different elements of the filter constituting the stator are damped by the resistors **16**, and **18** which are connected as shown in the Figure between the windings **11** and the conductor **13** common to the terminals of the capacitors **17** and **19**.

Such a machine operates as an amplifier of the signal applied to the input of the stator with a gain which is of the order of 40 db in the numerical example given above. Such machines may be used as supply sources for high-power vibrators for the testing of industrial equipment of all kinds. They have the advantage over presently-known installations of this type of avoiding the steep leading edges and the high frequencies which result in their spectrum. Output powers of 100 kilowatts may be obtained with 10 watts applied at the input, with frequencies ranging up to 50 kHz. The same machine may be used as a high-power amplifier in radio broadcasting.

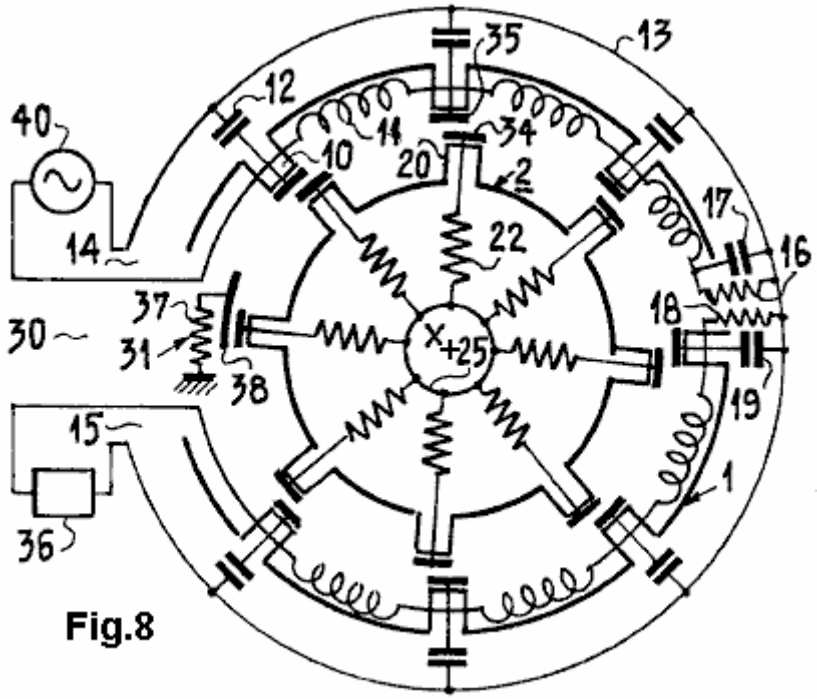

Fig.8

Fig.7 and **Fig.8** give two other modifications of the arrangement of the circuits of the rotor in which the same reference numbers indicate the same components as in the preceding Figures. In **Fig.8**, the coupling between the rotor and stator is electrostatic. It occurs between conductors **34** and **35** when they face each other in the course of the rotation of the rotor.

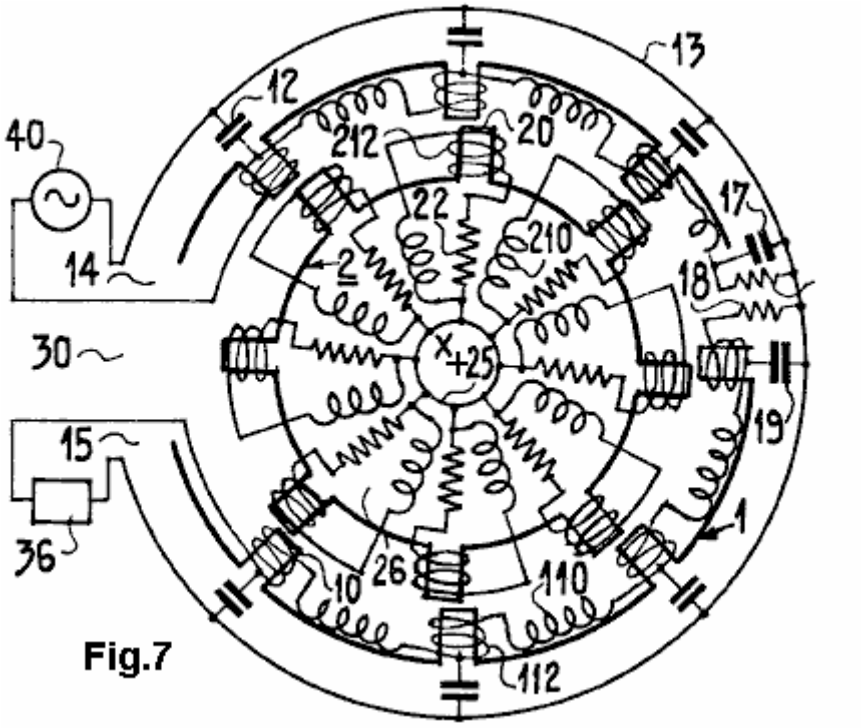

Fig.7

In **Fig.7, 110** and **112** designate the two constituent parts of the self-inductances associated with each one of the poles **10** of the stator, and **210** and **212** the parts of the self-inductances of each pole **20** of the rotor. In both **Fig.7** and **Fig.8**, **25** is a common conductor and **26** indicates all of the elements associated with each pole of the rotor. In the modification of **Fig.8**, an example is given of the construction of the damping device **31** in the zone **30**. A rail **38** is earthed through resistor **37** and through a contact (not shown) of the circuits of the rotor out along this rail **38** when they pass through the zone **30**.

The same machine is capable of operating as a generator (**Fig.6** and **Fig.9**).

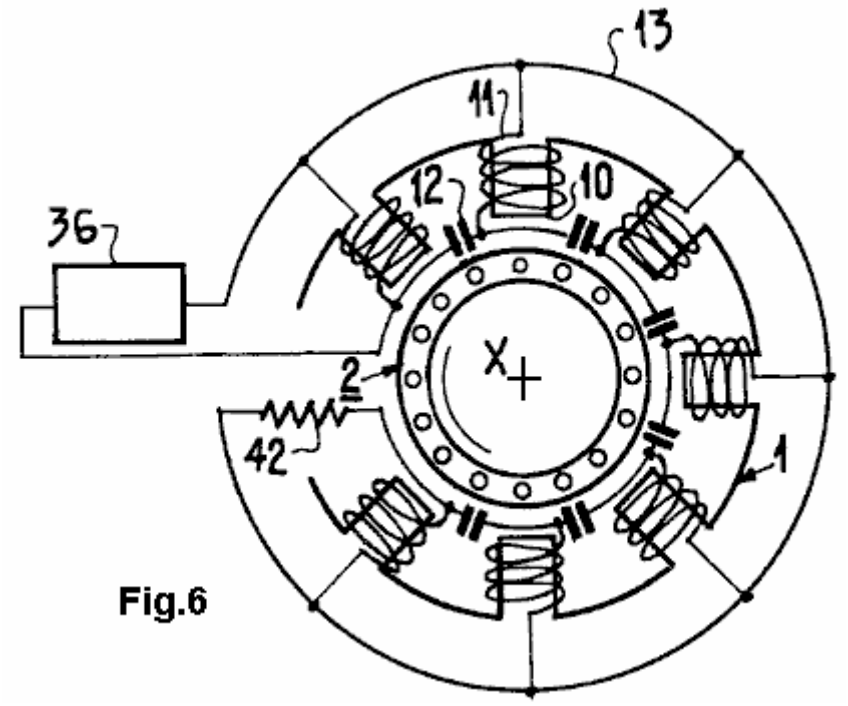

Fig.6

Fig.6 represents a machine whose stator is connected as a high-pass filter: each pole winding is connected at one end to the common conductor **13** and at the other end to two capacitors **12**, as shown above. The filter thus constructed has a phase velocity which varies very rapidly with the frequency and in the direction opposed to that of the flux of electrical energy (inverse wave). The rotor has a velocity rather close to that of the phase velocity whereas the energy flows back to the load **36** in the opposite direction. The upstream side (for the energy) of the filter terminates on the characteristic impedance **42** of the filter. A generator is obtained in this way having a

frequency which is determined within a wide band by the speed of rotation of the rotor. In the example shown in the Figure, the rotor has a squirrel-cage structure.

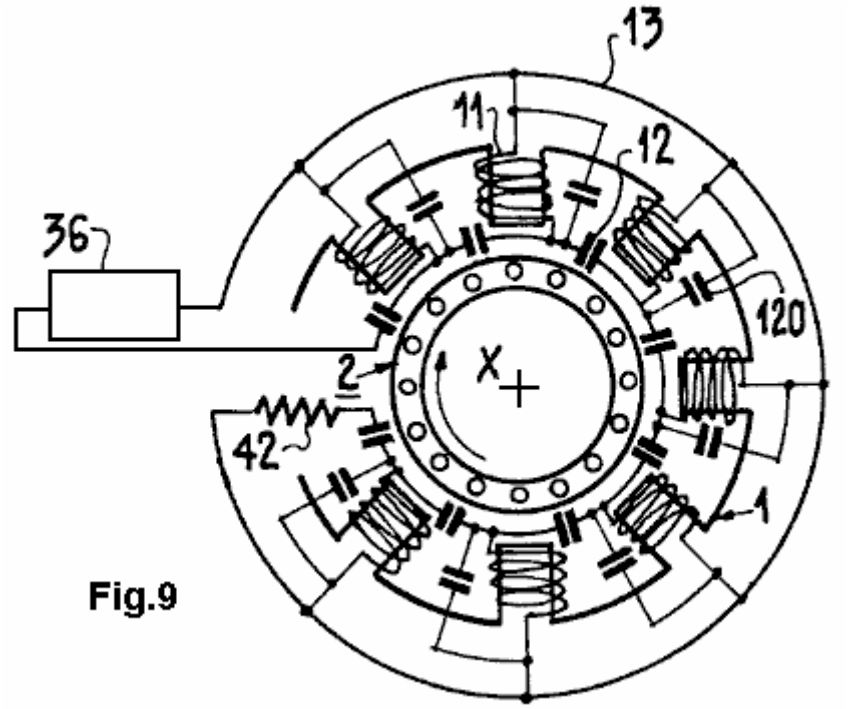

Fig.9

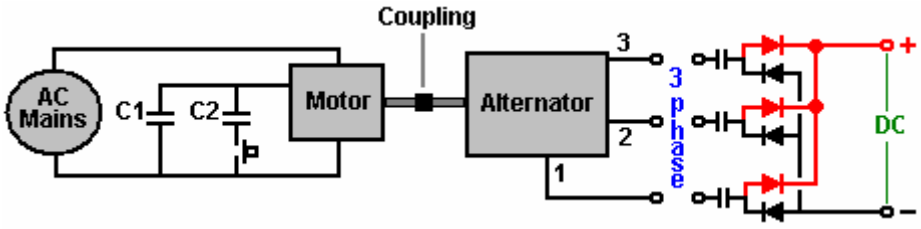
The machine of **Fig.9** differs from that of **Fig.6** by the addition of supplementary capacitors **120** arranged in parallel with the inductances **11**. The circuit thus obtained is an inverse wave band-pass filter. The width of its band-pass is determined by the respective values of the capacitors **12** and **120**. The phase velocity remains rapidly variable as a function of the frequency. The machine operates as a generator, the frequency of which, depends only very slightly on the velocity of rotation of the rotor.

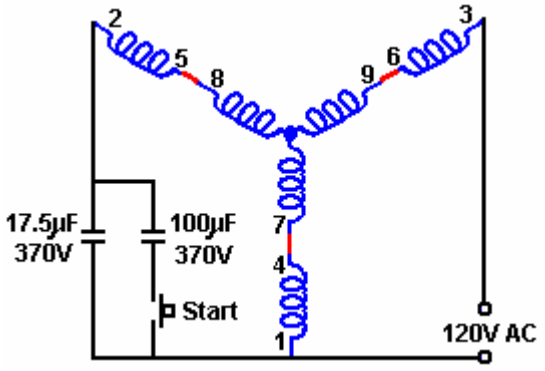
The "RotoVerter" Power Amplification System.

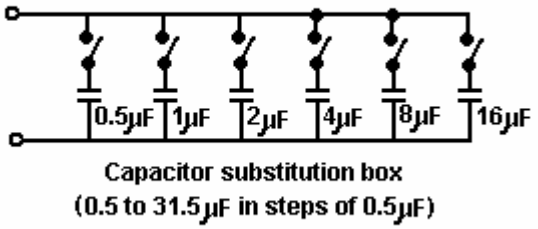
Not all pulsed-drive systems use permanent magnets as part of their drive mechanism. For example, the RotoVerter, designed by Hector D Peres Torres of Puerto Rico, and which has been reproduced by several independent researchers, producing at least 10 times more output power than the input power, uses standard three-phase electric motors instead of magnets.

This system has been reproduced by several independent researchers and it produces a substantial power gain when driving devices which need an electrical motor to operate. At this time, the web site: http://panacea-bocaf.org/rotoverter.htm has considerable details on how to construct the device as do the http://www.scribd.com/doc/2965018/HighEfficiencyForElectricMotors and the http://www.scribd.com/doc/26347817/RV-Energy-Saving-X documents. The outline details are as follows:



The output device is an alternator which is driven by a three-phase mains-powered, 3 HP to 7.5 HP motor (both of these devices can be standard 'asynchronous squirrel-cage' motors). The drive motor is operated in a highly non-standard manner. It is a 240V motor with six windings as shown below. These windings are connected in series to make an arrangement which should require 480 volts to drive it, but instead, it is fed with 120 volts of single-phase AC. The input voltage for the motor, should always be a quarter of its rated operational voltage. A virtual third phase is created by using a capacitor which creates a 90-degree phase-shift between the applied voltage and the current.





Capacitor substitution box
(0.5 to 31.5µF in steps of 0.5µF)

The objective is to tune the motor windings to give resonant operation. A start-up capacitor is connected into the circuit using the press-button switch shown, to get the motor up to speed, at which point the switch is released, allowing the motor to run with a much smaller capacitor in place. Although the running capacitor is shown as a fixed value, in practice, that capacitor needs to be adjusted while the motor is running, to give resonant operation. For this, a bank of capacitors is usually constructed, each capacitor having its own ON/OFF switch, so that different combinations of switch closures give a wide range of different overall values of capacitance. With the six capacitors shown above, any value from 0.5 microfarad to 31.5 microfarad can be rapidly switched to find the correct resonant value. These values allow combined values of 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, ...by selecting the appropriate switches to be ON or OFF. Should you need a value greater than this, then wire a 32 microfarad capacitor in place and connect the substitution box across it to test higher values step by step to find the optimum value of capacitor to use. The capacitors need to be powerful, oil-filled units with a high voltage rating - in other words, large, heavy and expensive. The power being handled in one of these systems is large and setting one up is not without a certain degree of physical danger. These systems have been set to be self-powered but this is not recommended, presumably because of the possibility of runaway with the output power building up rapidly and boosting the input power until the motor burns out.

The Yahoo EVGRAY Group at http://groups.yahoo.com/group/EVGRAY has a large number of members many of whom are very willing to offer advice and assistance. A unique jargon has built up on this forum, where the motor is not called a motor but is referred to as a “Prime Mover” or “PM” for short, which can cause confusion as “PM” usually stands for “Permanent Magnet”. RotoVerter is abbreviated to “RV” while “DCPMRV” stands for “Direct Current Permanent Magnet RotoVerter” and “trafo” is a non-standard abbreviation for “transformer”. Some of the postings in this Group may be difficult to understand due to their highly technical nature and the extensive use of abbreviations, but help is always available there.

To move to some more practical construction details for this system. The motor (and alternator) considered to be the best for this application is the “Baldor EM3770T” 7.5 horsepower unit. The specification number is 07H002X790, and it is a 230/460 volts 60Hz 3-phase, 19/9.5 amp, 1770 rpm, power factor 81, device.

The Baldor web site is www.baldor.com and the following details should be considered carefully before trying any adaption of an expensive motor. The following constructional photographs are presented here by kind permission of Ashweth of the EVGRAY Group.

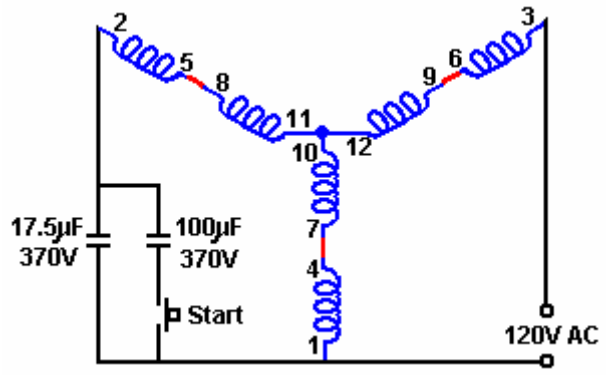
The end plate of the drive motor needs to be removed and the rotor lifted out. Considerable care is needed when doing this as the rotor is heavy and it must **not** be dragged across the stator windings as doing that would damage them.

The second end-plate is then removed and placed on the opposite end of the stator housing:

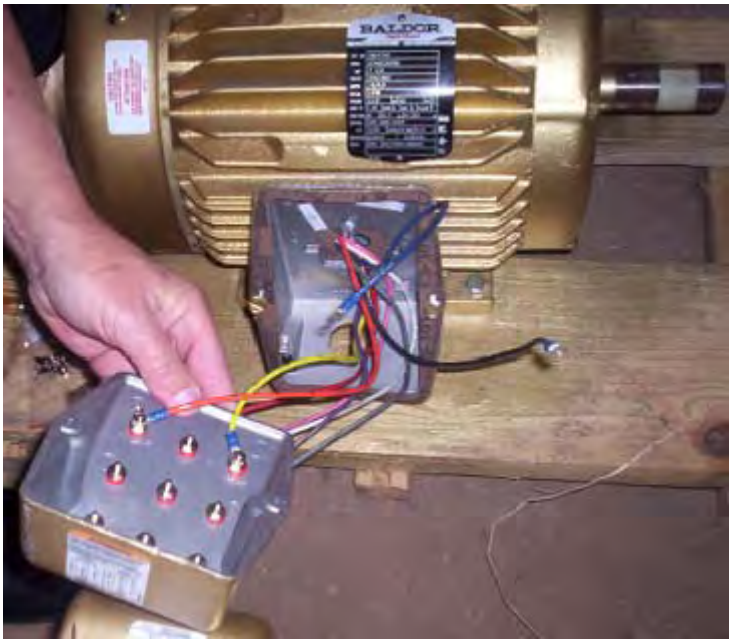
The fan is removed as it is not needed and just causes unnecessary drag, and the rotor is inserted the opposite way round to the way it was removed. That is, the housing is now the other way round relative to the rotor, since the rotor has been turned through 180 degrees before being replaced. The same part of the shaft of the rotor passes through the same end plate as before as the end plates have also been swapped over. The end plates are bolted in position and the rotor shaft spun to confirm that it still rotates as freely as before.

To reduce friction to an absolute minimum, the motor bearings need to be cleaned to an exceptional level. There are various ways of doing this. One of the best is to use a carburettor cleaner spray from your local car accessories shop. Spray inside the bearings to wash out all of the packed grease. The spray evaporates if left for a few minutes. Repeat this until the shaft spins perfectly, then put one (and only one) drop of light oil on each bearing and do not use WD40 as it leaves a residue film. The result should be a shaft which spins absolutely perfectly.

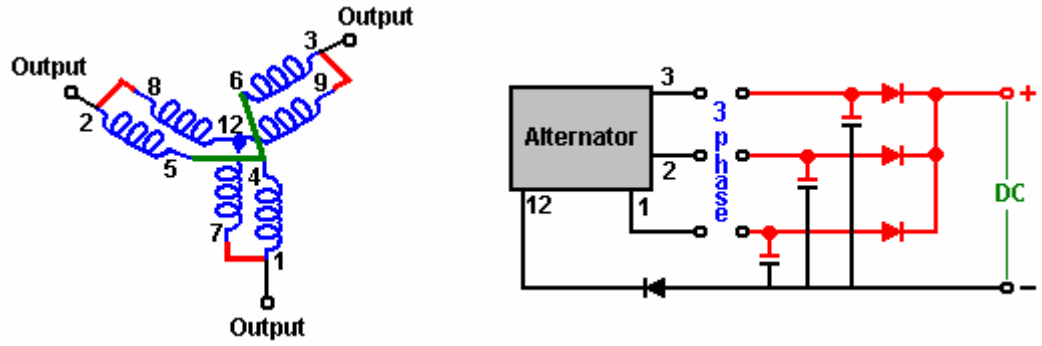
The next step is to connect the windings of the two units. The motor (the “Prime Mover”) is wired for 480 volt operation. This is done by connecting winding terminals 4 to 7, 5 to 8 and 6 to 9 as shown below. The diagram shows 120 volts AC as being the power supply. This is because the RotoVerter design makes the motor operate at a much lower input than the motor designers intended. If this motor were operated in the standard way, a 480 volt 3-phase supply would be connected to terminals 1, 2 and 3 and there would be no capacitors in the circuit.



It is suggested that the jumpering of the motor windings is more neatly done by removing the junction box cover and drilling through it to carry the connections outside to external connectors, jumpered neatly to show clearly how the connections have been made for each unit, and to allow easy alterations should it be decided to change the jumpering for any reason.



The same is done for the unit which is to be used as the alternator. To increase the allowable current draw, the unit windings are connected to give the lower voltage with the windings connected in parallel as shown below with terminals 4,5 and 6 strapped together, 1 connected to 7, 2 connected to 8 and 3 connected to 9. This gives a three-phase output on terminals 1, 2 and 3. This can be used as a 3-phase AC output or as three single-phase AC outputs, or as a DC output by wiring it as shown here:



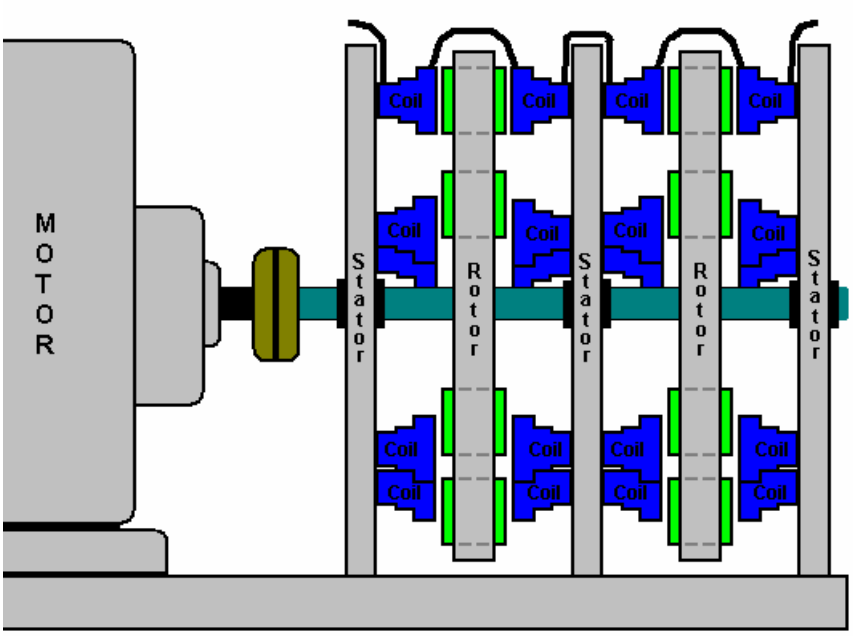
The motor and the alternator are then mounted securely in exact alignment and coupled together. The switching of the direction of the housing on the drive motor allows all of the jumpering to be on the same side of the two units when they are coupled together, facing each other:

The input drive may be from an inverter driven from a battery charged via a solar panel. The system how needs to be 'tuned' and tested. This involves finding the best 'starting' capacitor which will be switched into the circuit for a few seconds at start-up, and the best 'running' capacitor.

To summarise: This device takes a low-power 110 Volt AC input and produces a much higher-power electrical output which can be used for powering much greater loads than the input could power. The output power is much higher than the input power. This is free-energy under whatever name you like to apply to it. One advantage which should be stressed, is that very little in the way of construction is needed, and off-the-shelf motors are used. Also, no knowledge of electronics is needed, which makes this one of the easiest to construct free-energy devices available at the present time. One slight disadvantage is that the tuning of the "Prime Mover" motor depends on its loading and most loads have different levels of power requirement from time to time. A 220 Volt AC motor can also be used if that is the local supply voltage.

If an alternator is being driven by the RotoVerter motor (the "Prime Mover") but although the shaft is being rotated rapidly there is no output voltage, then it is likely that the alternator has been sitting around unused for a long time and has lost the magnetic properties which it needs at start-up. To fix this, connect each of the three output windings, one at a time, across a car battery for about five seconds to develop some magnetism and the alternator will then work. This is a one-off thing only needed after a long period of inactivity.

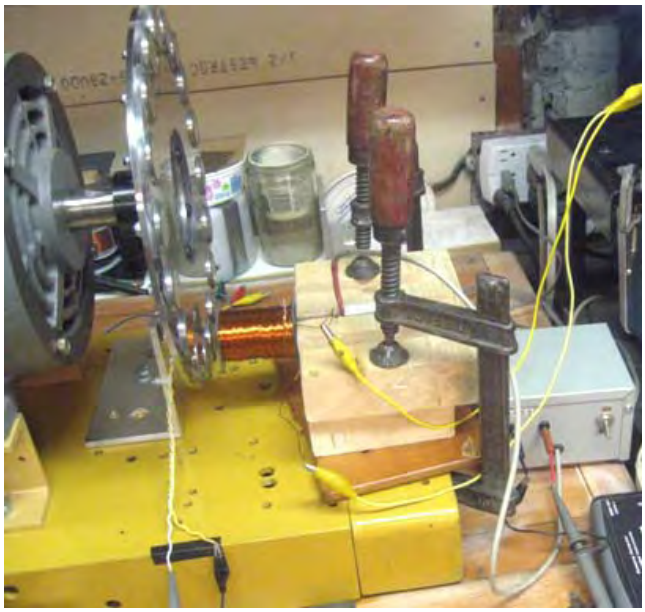
It is not essential to construct the RotoVerter exactly as shown above, although that is the most common form of construction. The Muller Motor mentioned earlier, can have a 35 kilowatt output when precision-constructed as Bill Muller did. One option therefore, is to use one Baldor motor jumpered as the "Prime Mover" drive motor and have it drive one or more Muller Motor style rotors to generate the output power:



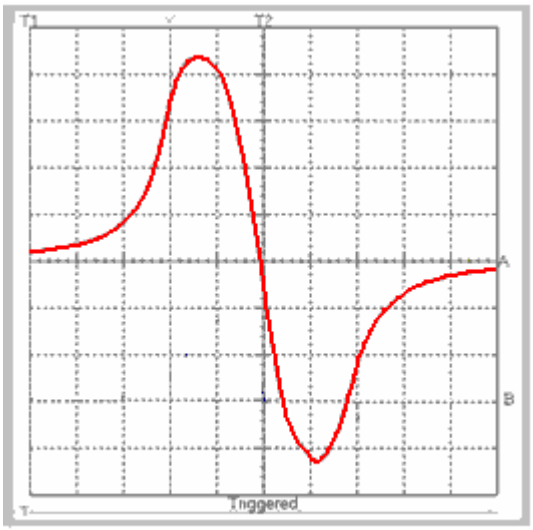
Power Boosting Through Coil Short-Circuiting.

The RotoVerter output and the Muller Motor/Generator output (and possibly, the Adams Motor output) can be increased very substantially by a technique developed by "Kone" the moderator of the EVGRAY Yahoo forum already mentioned. The technique is to place a dead short-circuit across each output coil, just as the magnetic field of that coil reaches a maximum. This is done five times in rapid succession and can boost the output power by an estimated factor of 100 times.

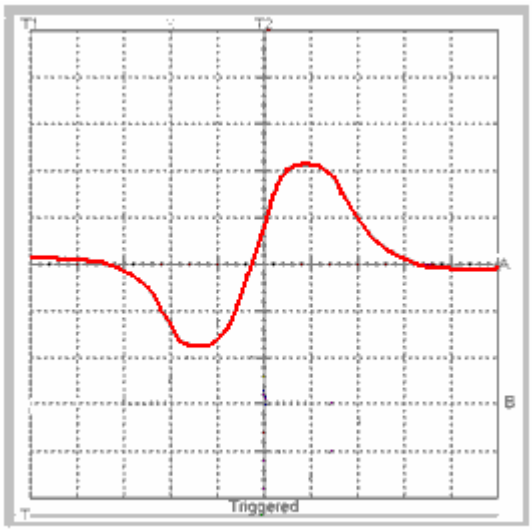
On the surface, it appears complete madness to place a short-circuit across the very output which you are generating as the whole point of the exercise. However, it is not as mad as it seems. At the peak point, the coil itself contains a large amount of energy and when a short-circuit is placed across it, the result is quite unusual. The effect of short-circuiting an iron-cored coil has been demonstrated by Ron Pugh of Canada with a bench test using this equipment:



Here, a device for measuring magnetic fields is sensing the magnetic field of the coil as the rotor magnets move past the coil. The measurement is done with the coil operating normally and then again, with the coil short-circuited. The results are shown in these oscilloscope displays:

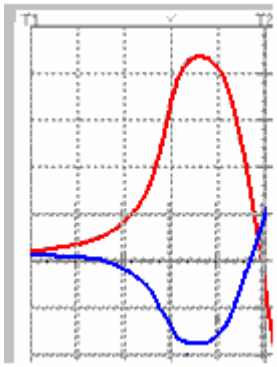


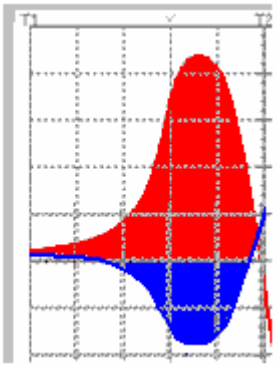
OPEN COIL



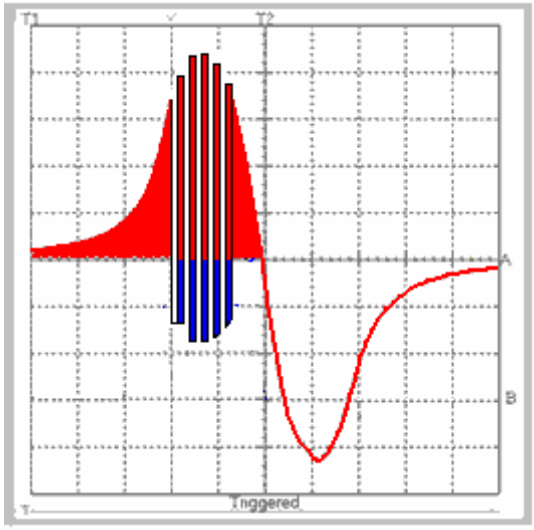
SHORT–CIRCUITED COIL

Quite surprisingly, the magnetic field is reversed by the short-circuit. If we consider just the first half of the cycle:





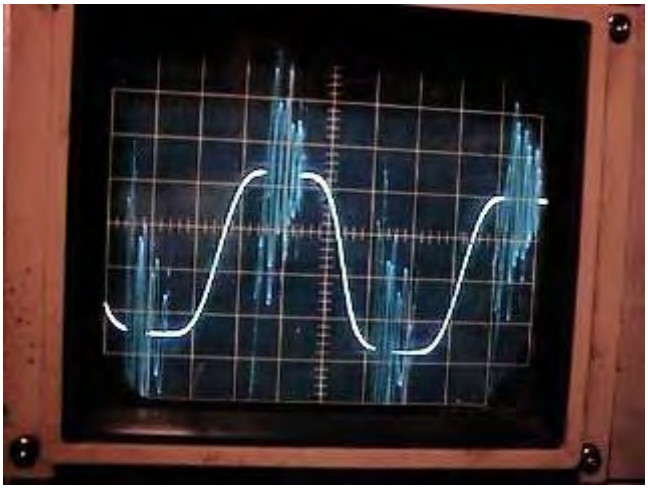
You will notice that when the open coil has a very strong positive position (relative to a North magnetic pole), the short-circuited coil has a strong reading of the opposite polarity. Therefore, at any given instance near the peak, there is the potential for a major magnetic reversal if the coil were to be switched from the red area into the blue area and back again. You might imagine that if the coil short-circuiting were performed very rapidly, that there would be a result like this:



However, this is not really possible with an iron-cored coil as it is not able to reverse it's magnetisation rapidly enough to produce this effect. Coils with iron cores might get up to 3,000 reversals per second although 1,000

would probably be a more realistic figure. For higher frequencies, a ferrite core could be used and for yet higher frequencies again, an iron-dust epoxy-encapsulated core is needed. For unlimited frequencies, an air-core coil is used.

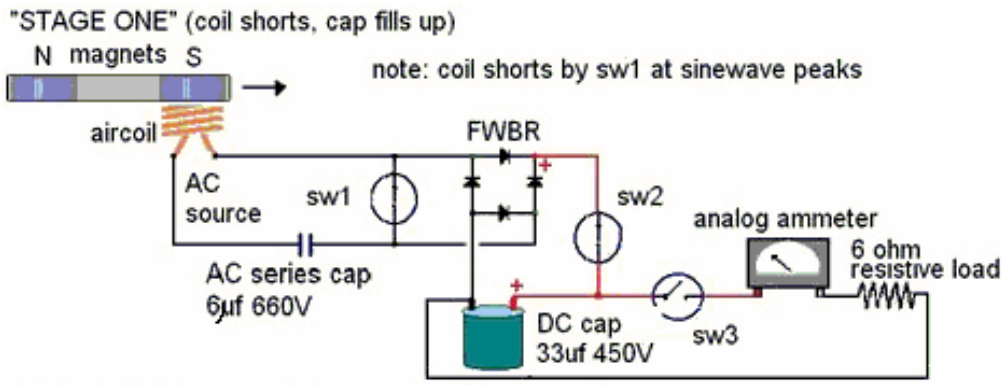
In the RotoVerter / Muller Motor example where Kone has demonstrated major energy gains, the arrangement is different to Ron Pugh's bench-test example. Firstly, the magnets on the rotor present two poles to the coil as they pass by, giving a full, even sine wave output. Secondly, Kone uses an air-core coil and he has the fast switching implemented to take advantage of that coil type:



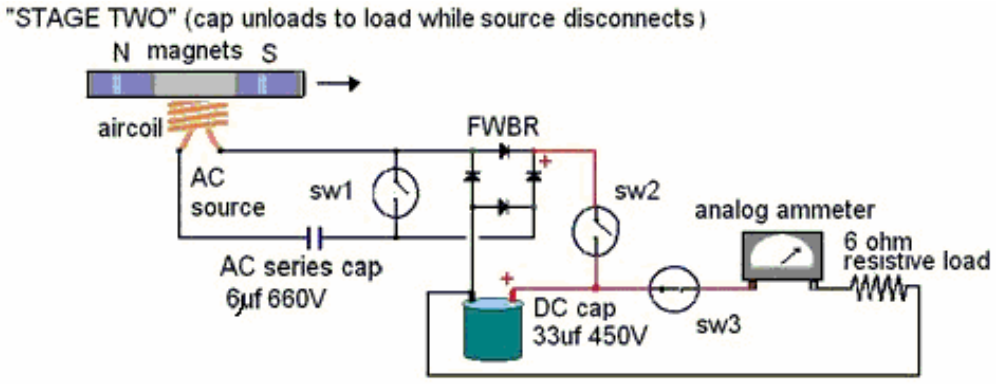
This screen shot shows exactly the same effect with the oscillating pulses plunging down to exactly where the negative trace would be at that time during each of the short-circuited periods. The display is showing a twenty-volt peak-to-peak waveform with each complete sine wave cycle taking 2 milliseconds.

Instead of the original gradual magnetic rise to a single peak, there are now five very sharp magnetic reversals, each of which are substantially larger that the original peak. It is the change of magnetic flux in the pick-up coil which produces the output power, so it can be seen that with this additional switching, a massive increase in flux change has been produced in the output coil. This increase is both a larger magnetic swing and a much greater rate of change of the flux, and as the rotor is spinning at some 1,800 rpm and has many magnets in it, the overall magnetic power increases by a major factor. Please note that in the following diagrams produced by Kone, the rotor magnet has a South pole which reaches the pick-up coil first, followed by a North pole passing the coil. This produces an excellent sine wave output in the coil.

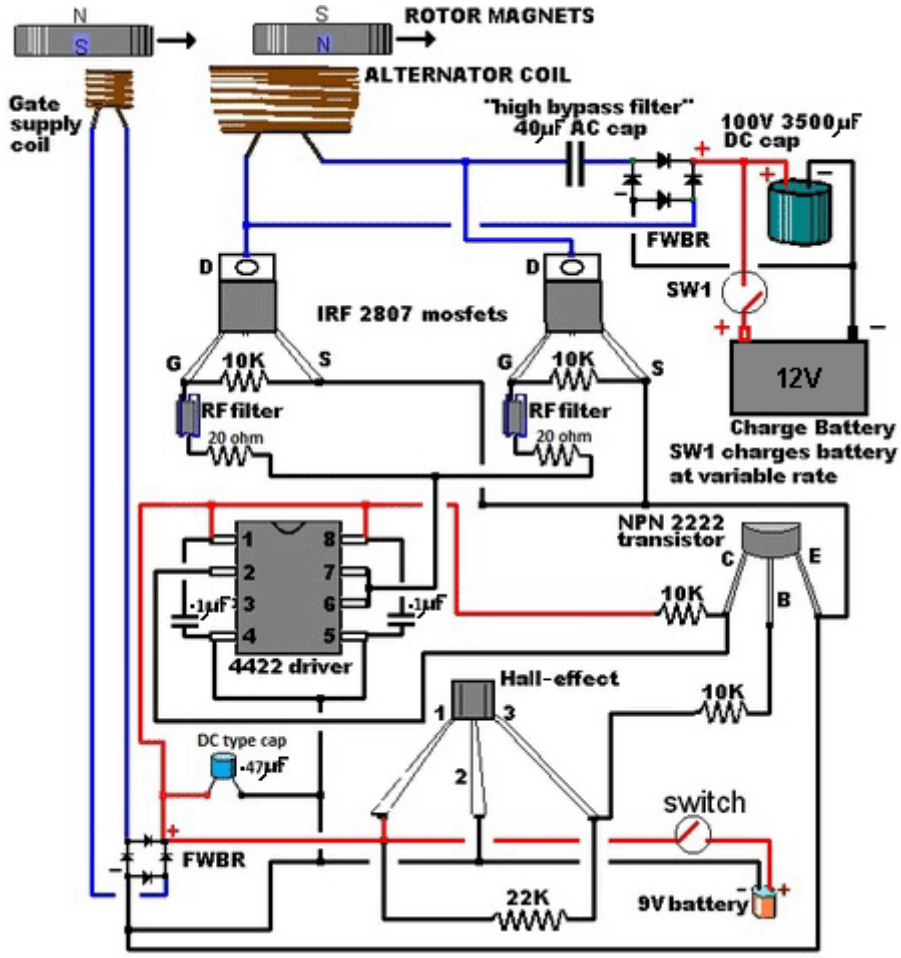
The additional switching is performed by a mechanical brush and contact system and the power collection circuit used for the short-circuited coil is:



and when the coil is not short-circuited, the circuit is:



Doug Konzen has been developing this circuitry and generously sharing his results freely. His web site is at http://sites.google.com/site/alternativeworldenergy/shorting-coils-circuits and his most recent practical circuit is:



There is a video on the web where coil-shorting is used on the output from a replication of John Bedini's Window Motor. John's Window Motor is a cylinder with magnets mounted in it, spun inside a large coil by a pulsed motor:

The motor can be a self-runner, but for the coil-shorting demonstration, it was just spun briefly by hand, producing voltage pulses of about 16 volts. When the coil-shorting is switched on, those pulses rise to about 440 volts even

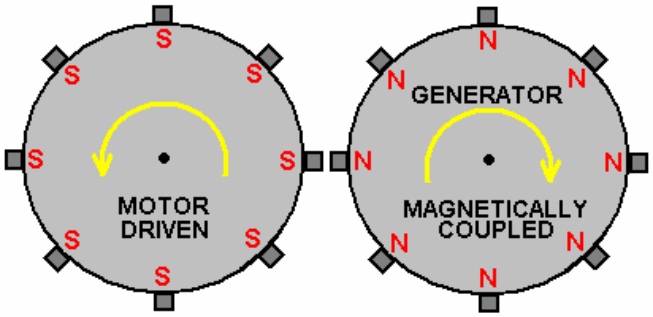
though the coil shorting was not the optimum five times at peak (which would probably have raised the voltage pulses to about 1,600 volts). The oscilloscope displays of the test shown on video are:

I'm told that this coil-shorting technique is used in industry but is consider to be a 'trade secret'. Details of John Bedini's Window Motor can be found at http://www.fight-4-truth.com/Schematics.html.

Raoul Hatem's Magnetic Coupling System.

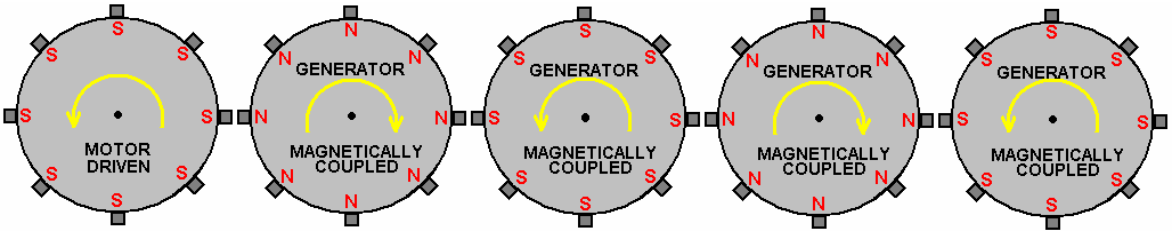
Generally, the RotoVerter has very low input power when not loaded and about a 90% energy reduction when under load. The ideal situation is where there is a constant load as the tuning of the RotoVerter does depend to some degree on the load. However, the RotoVerter performance can be increased very substantially by using the techniques introduced by Raoul Hatem in 1955, which conventional science will not accept because according to current theory, any such energy gain has to be "impossible" and so, cannot happen no matter what evidence there is:

Raoul Hatem's heretical statement is that using spinning magnets draws in energy from the environment, allowing a system to have COP>1 (ever heard of John Searle's spinning magnet systems?). His method is to use a motor (whether RotoVerter or not) to spin a heavy rotor disc with 36 powerful rare-earth magnets mounted on it. Then, using an identical heavy disc with magnets mounted on a generator to give a magnetic coupling between the motor and the generator can give not just coupling, but an energy gain as well:

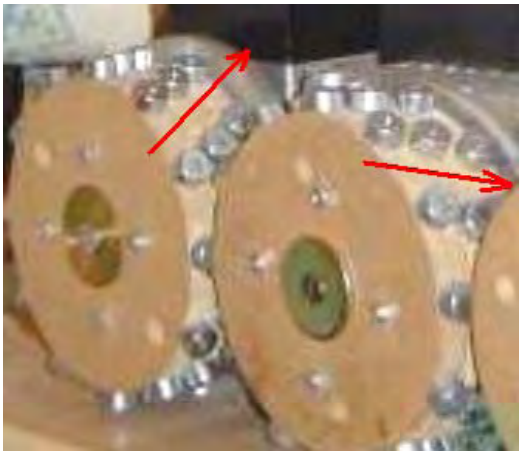


The heavy rotor provides some flywheel effect which helps with the operation of the system. Even with one motor as shown above, there is an energy gain as demonstrated in a recent video demonstration of the effect at http://www.dailymotion.com/video/xi9s9b_moteur-magnetique-de-leon-raoul-hatem_webcam#.UaGyVTcr6Bo where a simple system produces 144 watts of excess power. However, the really big gains are got when several generators are driven by just the one motor. In passing, it may be remarked that there are two separate energy gain systems operating here. Firstly, the rotating magnetic field acts directly on the excess electrons in the local environment, drawing them into the system just as the fluctuating magnetic field of the secondary winding of any transformer does. Secondly, the rotors are receiving a rapid stream of drive pulses, and as Chas Campbell has demonstrated, that draws in excess energy from the gravitational field.

Anyway, you will notice that the powerful magnets used have their North poles outwards on one rotor while the adjacent rotor has the South poles outwards. The very strong attraction between these opposite poles cause the generator disc to rotate in step with the motor disc. This process allows many generators to be driven by just the one motor as shown here and in the photograph above:



For ease of drawing, the diagram above shows only eight magnets per rotor disc, but you will notice in the photograph (and in the video) that there are three stepped rows of magnets on each rotor:

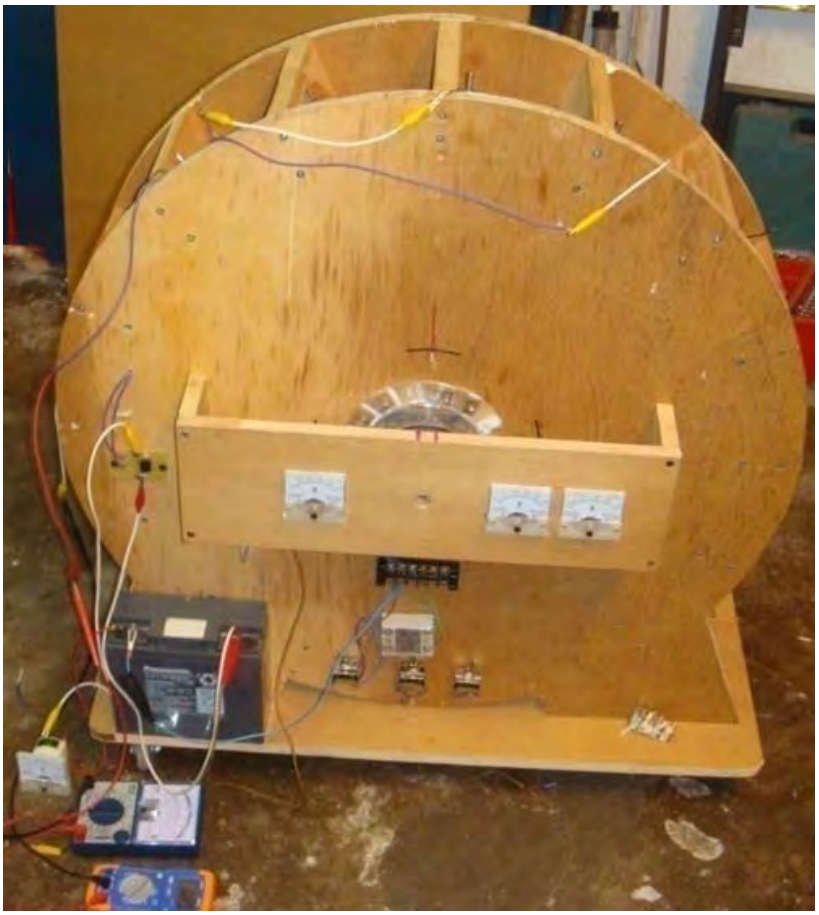


You will also notice that direction of the stepping is reversed on every second rotor disc in order for the magnets to match each other in position as they rotate in opposite directions.

While this type of arrangement gives a major increase in the output power compared to the input power, the situation can be further enhanced by retrieving some of the input power by means of electronic circuitry, and both Phil Wood and David Kousoulides have kindly shared their methods for doing this.

Lawrence Tseung's COP=3.3 Pulsed-Flywheel.

Lawrence has been presenting his theory of lead-out energy which indicates that excess energy is drawn from the environment when there is an impact. The method of producing this effect which he has followed is to create an unbalanced wheel and demonstrate that excess energy is produced. It should be stressed that energy is never created or destroyed and so, when he measures more energy in his device than the energy which he uses to power it, energy is not being created but is instead, being drawn in from the local environment. Lawrence has recently demonstrated a prototype to members of the public:



This simple device was demonstrated to have 3.3 times as much output power as the input power needed to make it operate. This is an early prototype which was demonstrated in October 2009 and Lawrence and his helpers are working on to produce more advanced models which have kilowatts of excess electrical power.

Mr Tseung remarks: "The **Lee-Tseung Lead-Out Energy Theory** was first disclosed to the world on 20th December 2004 at Tai Po, in Hong Kong. The Lead-Out Energy Theory basically says that one can lead-out (or bring-in) Energy from the surrounding environment into a Lead-Out Energy Machine. The total Input energy is equal to the sum of the Supplied Energy plus the Lead-Out Energy. For example, if the supplied energy is 100 units and the lead-out energy is 50 units, the device's total Input Energy will be 150 units. This means that the Output Energy can be more than the Supplied Energy of 100 units provided by the person using the device.

If we ignore the small loss of energy caused by less than 100% efficiency of the device itself, then the Output Energy will be the whole of the 150 units. If we use 50 of the output energy units and feed back 100 of the output units as the Supplied Energy, then that Supplied Energy can again lead-out another 50 units of excess output Energy for us to use. Thus a Lead-Out Energy Machine can continuously lead-out pollution-free, virtually inexhaustible and readily available energy for us to use. We do not need to burn any fossil fuel or pollute our

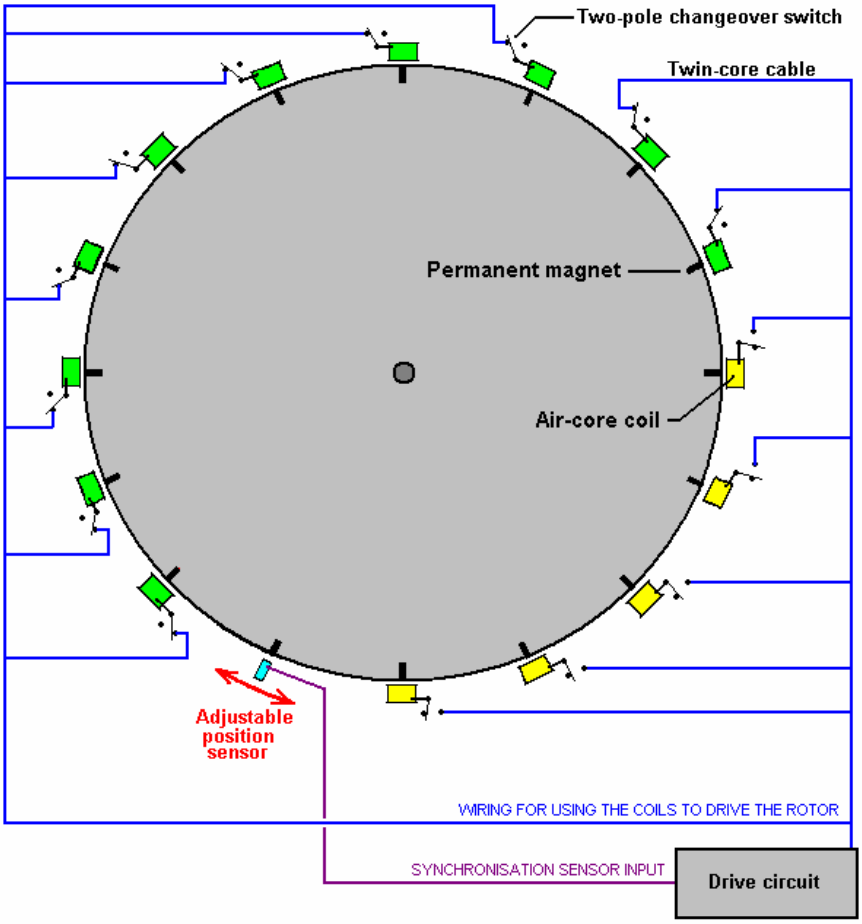
environment. The two examples of Lead-Out energy which we access are Gravitational and Electron-Motion energy.

The Lead-Out Energy theory does not violate the Law of Conservation of Energy. The Law of Conservation of Energy has been used as a roadblock for the so called “Overunity” devices. The patent offices and the scientific establishment routinely dismiss an invention as belonging to the impossible “perpetual-motion machine” category if the inventor cannot identify the energy source of his invention.

We got the help of Mr. Tong Po Chi to produce a 60 cm diameter Lead-Out Energy machine in October 2009. The Output Energy of that device is greater than the Input Energy by a factor of 3 times. These results are confirmed by voltmeters and ammeters measuring the Input and Output energies.

The Tong wheel has been shown at two Open Shows in Hong Kong (Inno Carnival 2009 and Inno Design Tech Expo) in November and December 2009. Over 25,000 people have seen it. The Better Hong Kong Radio Show has video recorded it, the discussions being conducted in Chinese. At this time, the Tong wheel is at the Radio Studio available for experts to view and examine with their own instruments."

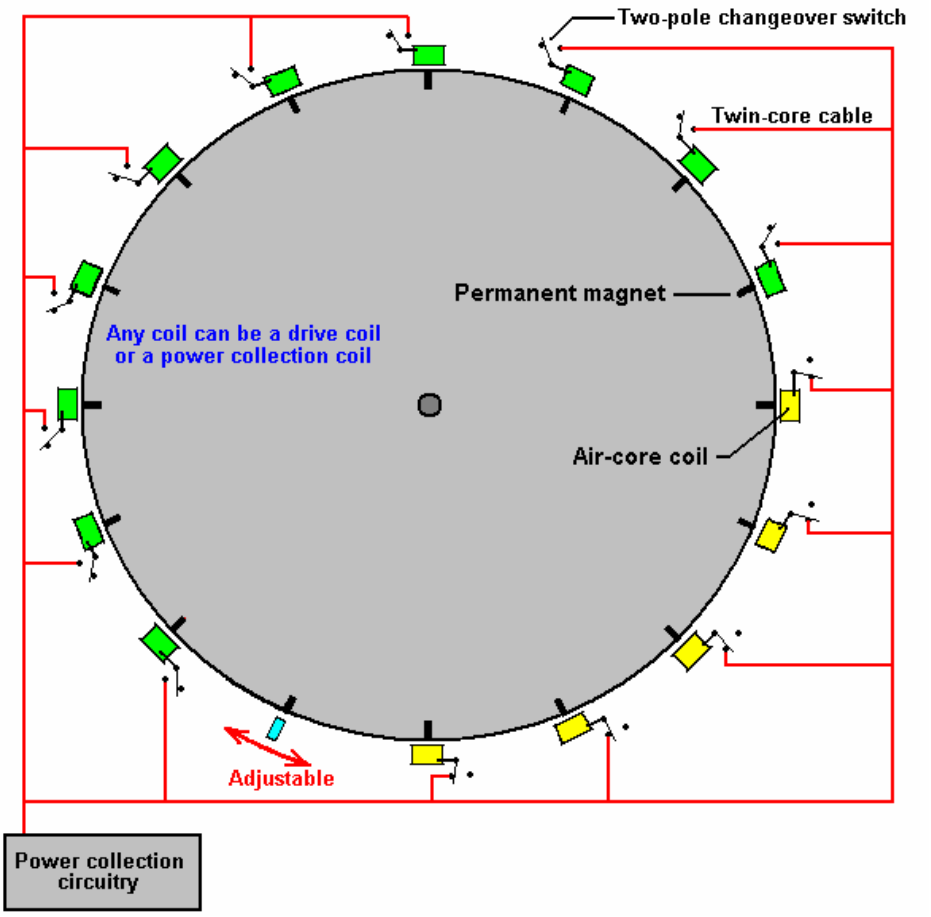
The Tong wheel has a diameter of 600 mm and this large size is considered to be important. It has 16 permanent magnets mounted on its rim and 15 air-core coils mounted around it on the stator. There is one position sensor. The coils can be switched to act as drive coils or as energy collection coils:



With this arrangement, if the positions the switches as shown for ten of the fifteen coils shown here, then they act as drive coils. The sensor is adjusted so that the drive circuit delivers a brief energising pulse to those coils just after the magnets have passed their exact alignment position with the coils. This causes them to generate a magnetic field which repels the magnets, thrusting the rotor around.

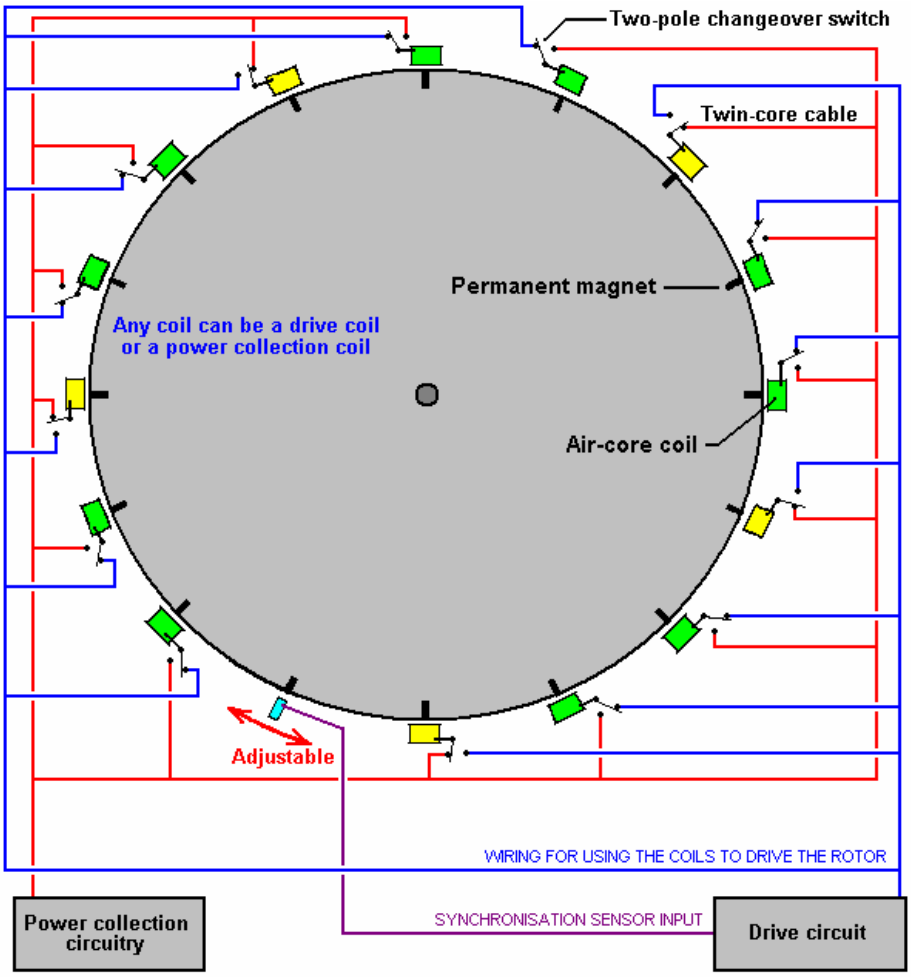
The pulse is very brief, so very little power is needed to accomplish this pulsing. As mentioned before, any number of coils can be switched to provide this driving force. With this particular wheel construction by Mr Tong, the best number has been found to be ten drive coils.

The power pick-up is achieved by gathering the electricity generated in some of the coils as the magnets move past them:



In this particular arrangement, five of the coils gather energy while ten provide the drive. For the sake of simplicity, the diagram shows the five collection coils adjacent to each other and while that would work, the wheel is better balanced if the drive coils are evenly spaced out around the rim. For that reason, this switching would actually be selected to give five sets of two drive coils followed by one pick-up coil as that gives a perfectly balanced thrust on the wheel.

The two diagrams above are shown separately in order to make it clear how the drive switching and the power pick-up switching are arranged. The full design arrangement and the balanced switching are shown in the following diagram which indicates how the full design is implemented on this particular implementation of the wheel design. The sensor can be a coil feeding a semiconductor switching circuit, or it can be a magnetic semiconductor called a Hall-effect device which can also feed a semiconductor circuit. An alternative would be a reed switch which is a simple mechanical switch encased in an inert gas inside a tiny glass envelope. Suitable switching circuits are described and explained in chapter 12 of this eBook.

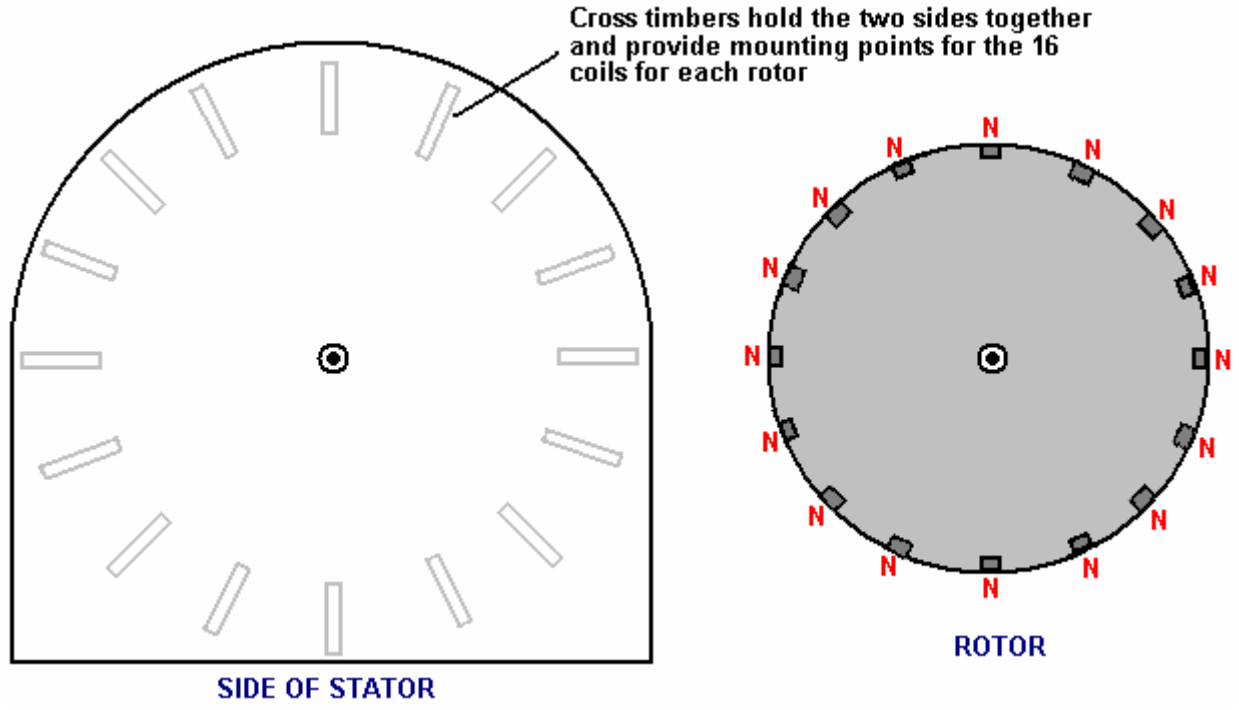


Mr Tseung remarks that the large wheel size is due to the fact that the Pulse Force takes time to impart the impulse to the wheel and lead-out energy from the environment into the system. If you want to see this actual wheel, you can email Dr. Alexandra Yuan at ayuan@hkstar.com to make an appointment. The Tong wheel is located at the Better Hong Kong Radio Studio in Causeway Bay, Hong Kong. Just say that you want to see the Lead-Out Energy Machine. The demonstration can be in English or in Chinese. Ideally, there should be a group of at least six visitors with one or more being a qualified engineer or scientist, and you are welcome to bring your own cameras and/or test equipment. It is planned to produce a version which has a 300 watt output, and another with a 5 kilowatt output. Educational kits are also planned.

If you decide to replicate this particular design, then to raise the output power level you might consider putting another set of coils around the wheel and either using them as fifteen additional energy pick-up coils or alternatively, pulsing the wheel twice as often. Adding one or more additional rotor discs to the same rotating shaft is also an option and that has the advantage of increasing the rotor weight and improving the effect of the impulses on the rotor.

The diameter of the wire used to wind the coils is a design choice which has a wide scope. The thicker the wire, the greater the current and the larger the impulse given to the wheel. The coils are normally connected in parallel as shown in the diagrams.

Because of the way magnetic field strength drops off with the square of the distance, it is generally considered good design practice to make the coils one and a half times as wide as they are deep, as indicated in the diagrams above, but this is not a critical factor. This design is, of course, a version of the Adams motor described at the start of this chapter. Although motors of this kind can be built in many different ways, the construction used by Mr Tong has some distinct advantages, so here is a little more detail on how I understand the construction to be carried out.

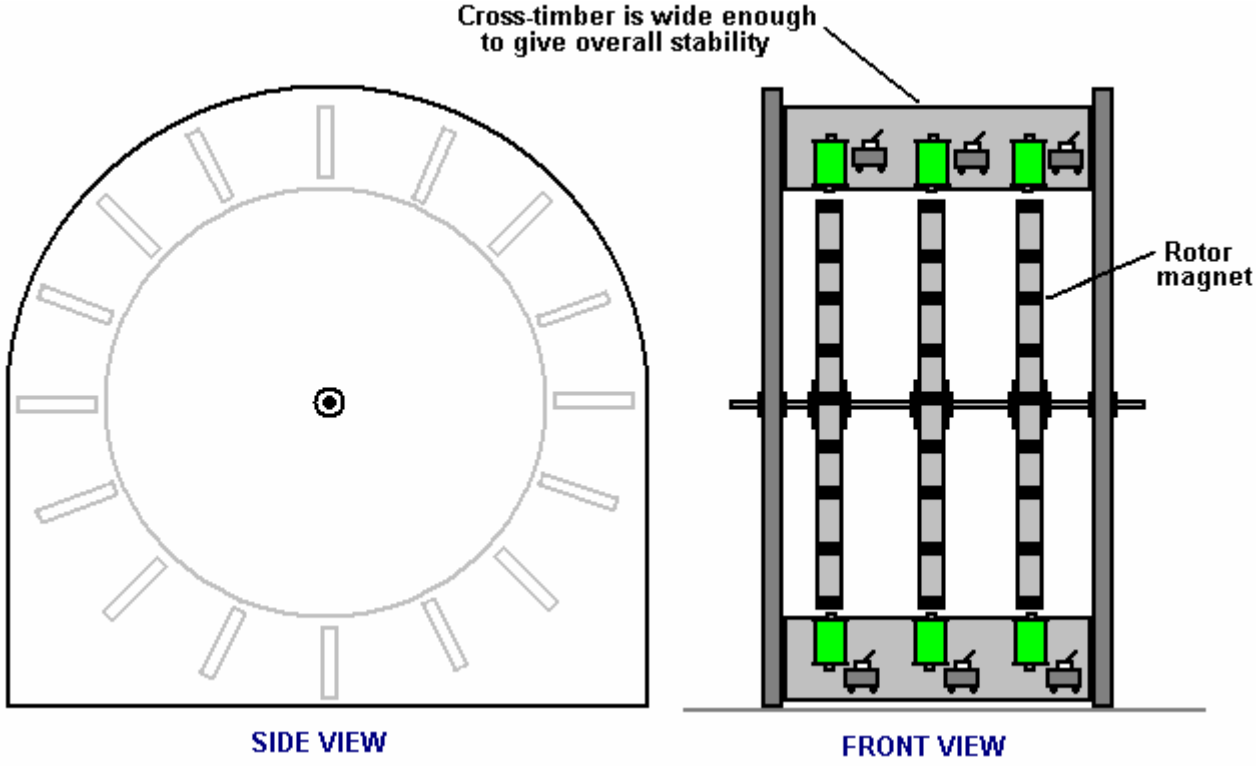


There are two side pieces which are attached together by sixteen cross timbers, each of which are held in place by two screws at each end. This produces a rigid structure while the construction method is as simple as is possible, using readily available materials which are worked with the most basic of hand tools. The construction also allows the motor to be taken apart completely without any difficulty, transported as a “flat-pack” package and then assembled at a new location. It also facilitates people who want to see the motor taken apart after a demonstration in order to assure themselves that there is no hidden power source.

Each of the cross timbers provide a secure mounting platform for an electromagnet and it’s associated switch. In the implementation by Mr Tong, there appears to be just the one rotor, configured as shown above with sixteen permanent magnets mounted in it’s rim. The magnetic poles of these magnets are all orientated in the same direction. That is to say, the magnetic poles facing outwards are all either South or all North poles. It is not critical whether the outward facing poles are North or South as Robert Adams used both arrangements with great success, but having said that, most people prefer to have the North poles facing outwards.

Robert has always said that one rotor was enough, but his techniques were so sophisticated that he was able to extract kilowatts of excess power from a single small rotor. For us, just starting to experiment and test a motor of this type, it seems sensible to stick with what Mr Tong has experienced success. However, this build by Mr Tong is not his final motor but just one in a series of continuously improved motors.

The following diagram shows an arrangement which has three rotors attached to a single shaft and while you may choose to construct this with just one rotor, if the cross timbers are long enough, then one or two extra rotors can be added in very easily at a later date.



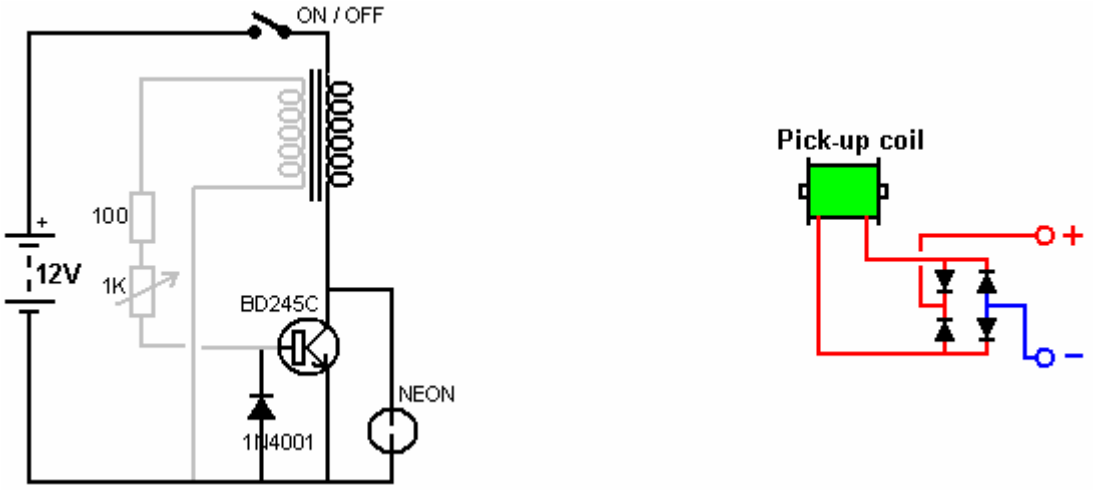
Here, just two of the cross timbers are shown. The electromagnet coils used by Mr Tong are air-core as that type have the least effect on the passing magnets. However, electromagnets with cores tend to be much more power for any given current flowing through them. In theory, the core should be made of lengths of insulated iron wire as that would reduce power loss through eddy currents flowing in the core, but Robert actually recommends solid metal cores, and as he was the most experienced person in this field, paying attention to what he said seems sensible.

The core material needs to be a metal which magnetises easily and powerfully, but which does not retain any of its magnetism when the current stops flowing. Not many metals have those characteristics and soft iron is usually recommended. Nowadays, soft iron is not always readily available and so a convenient alternative is the central bolt of a masonry anchor which has excellent properties:

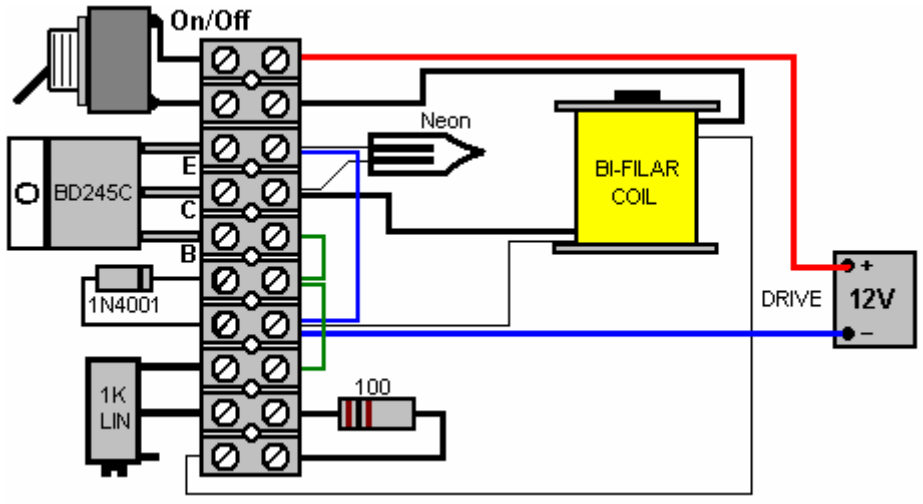
The shaft of the bolt can be cut quite easily with a hacksaw, but be sure to remove (or file down) the head of the bolt as the increase in diameter has a marked effect on the magnetic properties of the electromagnet core if it is left in place. The bolt shown above is a M16 x 147 mm masonry anchor bolt with a bolt diameter of 10 mm. Some makes of dry-ink felt white-board markers have a rigid body which fits the 10 mm bolt exactly and provide an excellent tube for constructing an electromagnet bobbin.

With a core in the electromagnets, the rotor gets additional rotating power. Initially, the magnets on the rotor are attracted to the electromagnet cores, giving the rotor a turning force which does not require any current to be supplied. When the rotor magnets are at their closest point to the electromagnet cores, the windings are powered up briefly and that gives the rotor magnets a strong push away, causing the rotor to spin.

There are many different designs of simple drive circuits and it is probably worth trying out different types to see which works best with your particular build of motor. In the same way, there are many kinds of collection circuits for taking off some of the excess power generated. The most simple of these is just a diode bridge, perhaps feeding a battery and charging it up for use at a later time. If you get sophisticated with the collection circuit and just take power off for a very short period of time at the correct moment, the cutting off of the current draw, causes a back-EMF magnetic pulse in the collection electromagnet which causes it to give the rotor an extra drive push – both current collection and rotor drive in one combined package.



Here are two of the most simple circuits possible, one for drive and one for power collection. The drive circuit transistor is switched on by a voltage generated in the grey coil by a rotor magnet passing by. The transistor then feeds a large current pulse to the black coil, driving the rotor on its way. The neon and the diode are there to protect the transistor and a physical layout for this circuit might be:

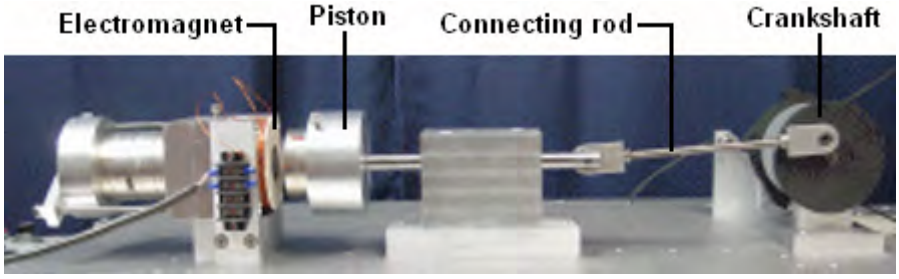


The 1K variable resistor is adjusted to give the best performance and the On/Off switch is optional. More advanced circuits, such as the one on page 2 - 9 can also be tried and the performance compared. Generally speaking, I would expect a three-rotor version to give a better performance than a single rotor implementation, but experimentation is needed.

Art Porter's Magnetic System.

Art uses an electromagnet with a ring magnet mounted on the core. When the coil is pulsed so as to augment the field of the permanent magnet, Art says that his prototype produces 2.9 times the field strength of the permanent magnet on it's own. When the coil is pulsed in the direction which opposes the field of the permanent magnet, the resulting magnetic field is zero.

This is a very serious change of magnetic field which can be used in different applications. One which Art has implemented is using the arrangement to power a crankshaft motor. Art shows several different motor builds including this one:



With this arrangement, Art states that 95% of the motor power comes from the permanent magnet. Art's website is at http://www.gap-power.com/index.html and he has a very interesting, lengthy video showing all of the details at http://www.gap-power.com/videos/Full%20Length%20Video.wmv.

In the video, Art attempts to apply Ohm's Law in an attempt to analyse the operation and is puzzled when the oscilloscope readings do not match his Ohm's Law calculations. He thinks that there is a contradiction between the oscilloscope and Ohm's Law, which he repeatedly stresses is a law of Nature, and he concludes that one of them has to be wrong. In actual fact, neither are wrong because Ohm's Law only applies to DC current flow in resistive circuits, and Art is not using steady DC current or a resistive load.

Applying short DC pulses to a substantial coil of wire is the equivalent of applying AC to that inductor. Ohm's Law does not apply due to the inductance of the coil. There is a Power Factor involved and Back EMF voltage pulses, so the oscilloscope readings are what is needed to calculate the input and output powers.

This arrangement is almost identical to that used in the Charles Flynn magnet motor described in chapter 1, and very close to the techniques used by Robert Adams in a properly tuned Adams Motor as shown at the start of this chapter. In my opinion, the effect which Art is exploiting would best be used if a large pick-up coil is placed against the end of the electromagnet core and the drive coil pulsed at the coil's (high) resonant frequency as that will minimise the input power and maximise the output power. Stacking those units in a bank could well produce a very sizeable excess electrical output. Our thanks are due to Art and his colleagues for sharing their research work freely for others to replicate and progress further.

DC Motor Efficiency

Commercially available DC motors are deliberately designed and manufactured to have extremely poor performance. In my opinion, the reason for this is that a properly designed electric motor could easily do away with the need for using internal combustion engines in vehicles and that would not suit the oil companies or their owners, the New World Order cartels. Worse still, electric motors with COP>1 open the way to self-powered free-energy systems and that would never do !!

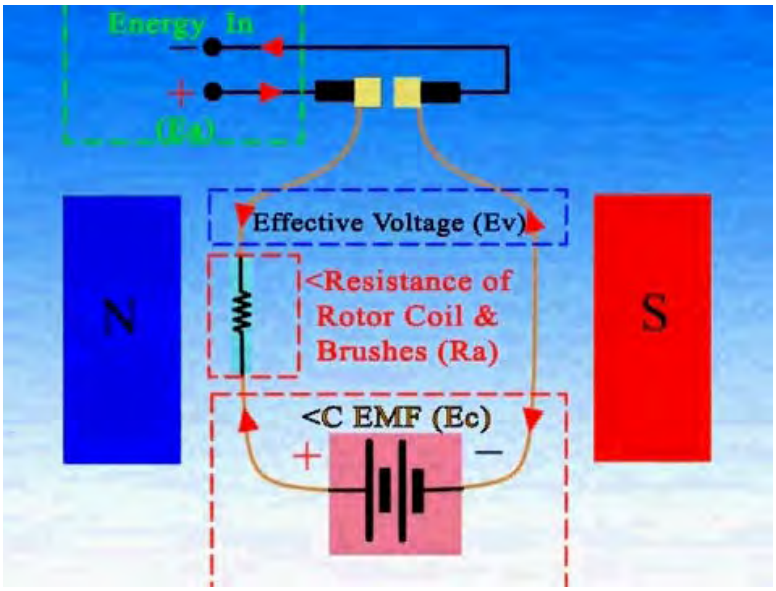
The video: http://torrentdb.in/95d95cff2bbC8039ed9/Peter-Lindemann-Electric-Motor-Secrets.torrent is available on the web and I strongly recommend that you watch all of it. It presents the basic facts very nicely. In brief outline, present day motors act both as a motor and as a generator of electrical power, but they are deliberately wound so that the power generation is used to oppose the input power and so produce a completely crippled output. During World War II, a German Engineer re-wired a standard electric motor and made it self-powered, that is, it ran and produced mechanical output power without the need for any input power once it had been started. That shows the potential of a properly constructed electric motor with the same size and general structure of any commercial electric motor.

Presumably, he did that by adding extra brushes and using some of the windings in generator mode with their output powering the drive windings which were arranged asymmetrically. There was also one other man who achieved self-powered re-wiring of a motor, but neither of those men made their information public knowledge.

The con job which has been run on us for many decades now is to wind the motor in such as way that the magnetic fields inside the motor oppose each other. When a current is passed through a coil of wire, it stores energy in that coil, and when the current flow is cut off, that energy needs to flow back out of the coil and it will do so in the reverse direction. This is sometimes called back-EMF ("Electro-Motive Force") although many people are not happy with that description. However, no matter what you call it, there is energy stored in the coil and that energy can be used to do useful work. But, the motor manufacturers choose to wind the motor so that instead of extracting that useful power, they use it to oppose a major part of the input power, creating a weak motor which heats up due to the wasted energy.

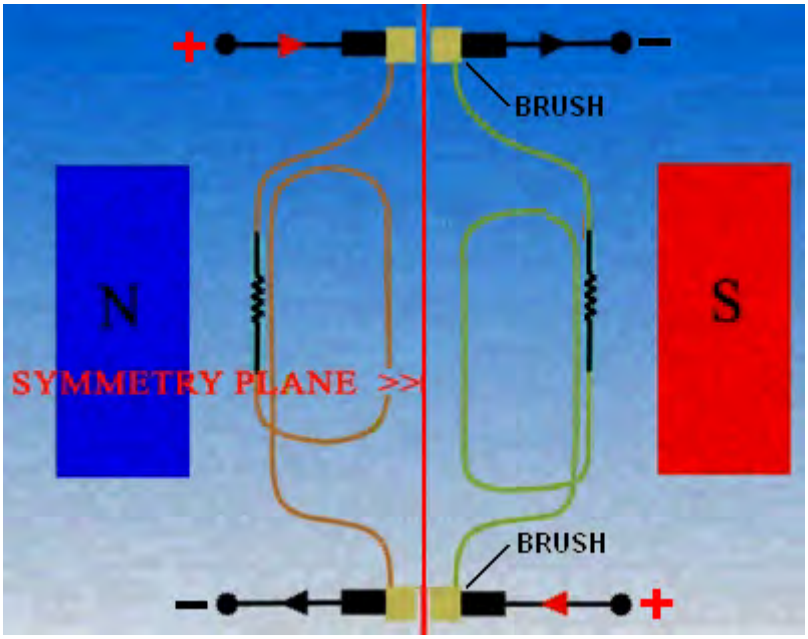
Contributor “UFOpolitics” points out that a deliberate mis-design of electric motors has, for the last 130 years, been presented to us as the only way to make and operate such motors. He states that because the windings are arranged in a symmetrical way, that a braking effect is produced which reduces the output power of the motor by anything from 50% to 90%. That is, a properly wound motor would have anything from twice to ten times the output power for the same input power. This mis-design guarantees that present day motors are always less than 100% efficient and always heat up when run. This mis-design is caused by using symmetrical windings in the motor.

Standard motor wiring is quite different and the killer effect is caused by having two windings which face each other, powered simultaneously with currents flowing in opposite directions. This causes a complete conflict between the magnetic fields and that destroys the efficiency of the motor: A very experienced experimenter has started a forum thread on the energetic-forum, both to explain this and to show new and more advanced construction methods and to answer questions and encourage replications and further developments. The forum is at: http://www.energeticforum.com/renewable-energy/11885-my-asymmetric-electrodynamic-machines.html and is definitely worth visiting, especially if you are good with mechanical devices. The experimenter uses the forum ID of “UFOpolitics” and he has produced an animated video in an attempt to explain the basic problems with present day DC electric motors: http://www.youtube.com/watch?v=Mj4rV0AoI-Q&feature=channel&list=UL. He points out that a problem winding in the standard DC motor looks like this:



The input current for any winding is fed in through a single pair of brush contacts. The generated electrical power “Ec” is not extracted and is forced to oppose the input energy “Ea”, leaving only a fraction of the input power to actually run the motor. It is likely that a motor of this type will only operate at 25% of it’s potential efficiency.

“UFOpolitics” has produced and demonstrated a simple way of overcoming this problem while using the existing motor housing, magnets and brush contacts. He does this by extracting the generated electrical power as a useful output and so preventing that useful power being used against the motor’s operation. To implement this, he adds one additional pair of brushes and re-winds the motor coils like this:



Here, one pair of brushes is at the top and one pair at the bottom of the ‘armature’ (the bit that rotates inside the motor housing and provides the mechanical power output). The coils are rewound to form a series of separate vertical coils, connecting to one brush terminal at the top and one brush terminal at the bottom as shown above.

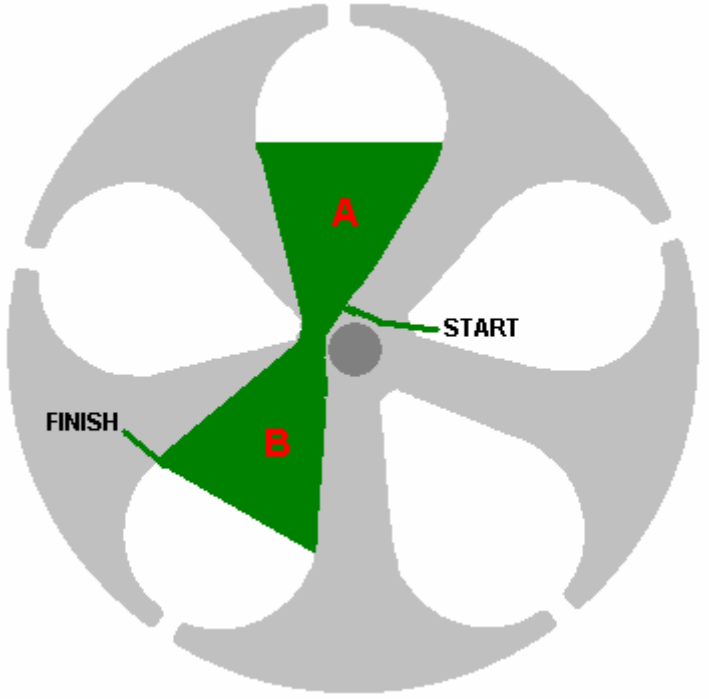
The input power is between the terminals on the left and flows through the coil shown in brown. The current flow generates a magnetic field, causing rotation because of the Permanent magnets marked “N” (for a magnet which has it’s North pole facing the coils) and “S” (for a magnet which has it’s South pole facing the coils). The black zig-zag line represents the resistance to current flow of the wire and brush contacts.

The coil shown in green on the right represents that same coil at a later moment when it has been disconnected from the power supply and rotated until it reaches that position, at which point, the energy stored in it is taken off as a useful output via the right hand pair of brushes. However, this is just an explanatory diagram and it does not show the very important fact that the discharging coil **must not** directly face a driving coil, because if it does, then the energy discharge would create a magnetic field which would interfere with the magnetic field of the driving coil and create a major problem.

Right, to say that again, any one coil is powered on the left hand side to drive the armature around and provide the output shaft with turning power (“torque”). Then that rotation disconnects that coil from the input power, leaving the coil charged with energy which has nowhere to go. That charged coil continues round until it hits the second set of brushes, which allow it to discharge through a load and do useful work.

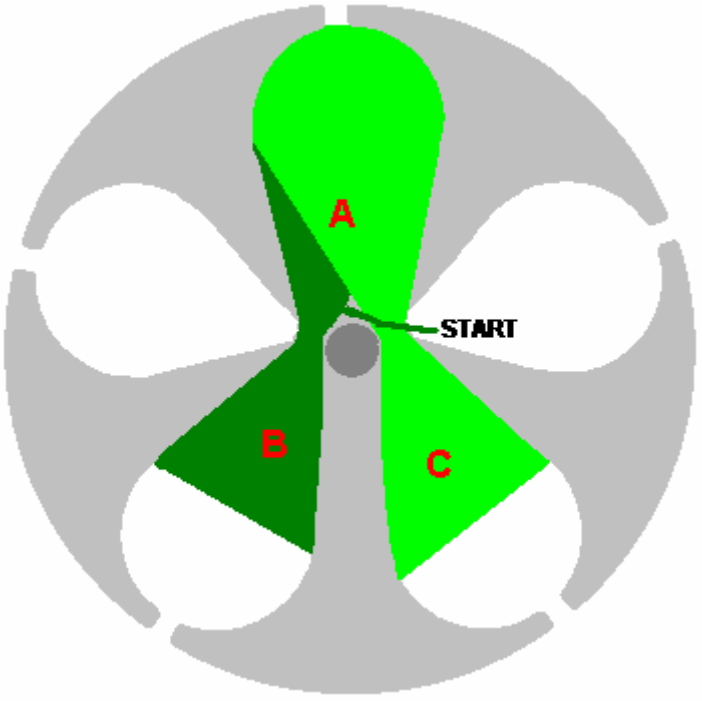
The really clever part of the adaption of the motor is best seen from above the vertical rotor. If, for example, you were to take a five-pole DC motor apart and remove the windings, the shaft and armature body might look like this:

When making an asymmetrical wound rotor, the windings go like this.

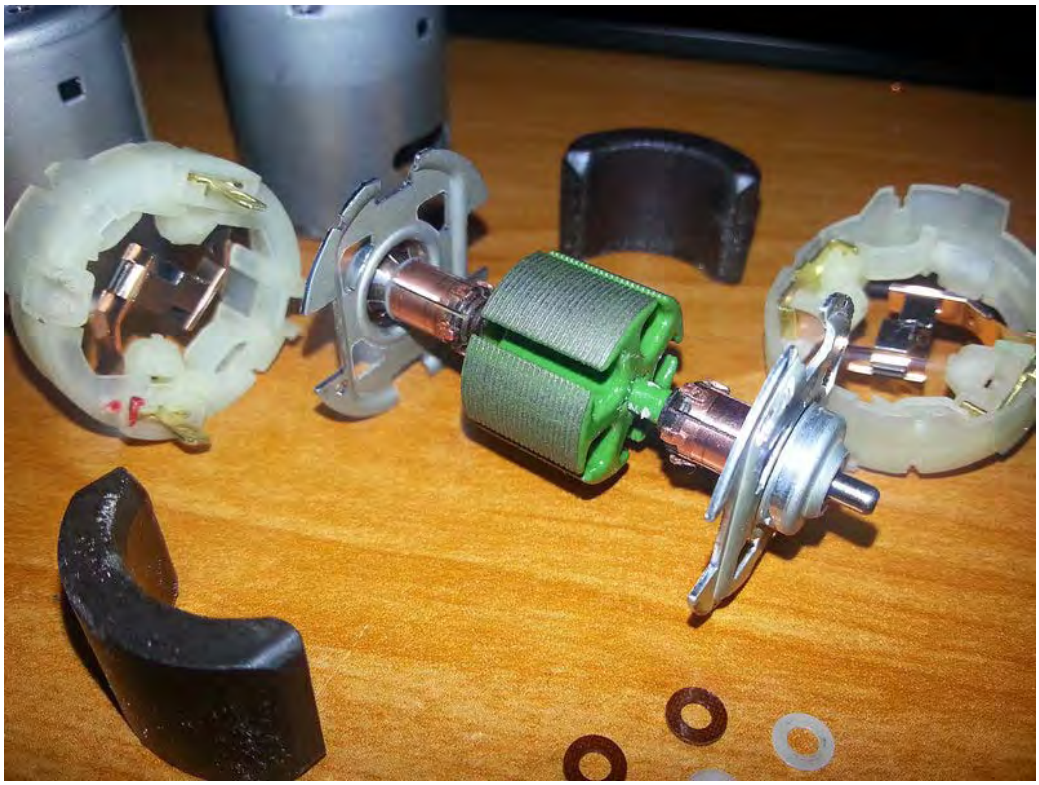


The start of the wire is secured at the top and then fed downwards through the opening “A” and back up through the opening “B”. For the small Radio Shack motor, this winding would be 25 turns of # 30 AWG wire (described as radio Shack ‘red’ wire, with a copper wire diameter of 0.255 mm). If you are re-winding a motor armature, please understand that each wire turn needs to be pulled tight in order to make a tight, solid and robust coil which will not vibrate unduly when the armature is spinning.

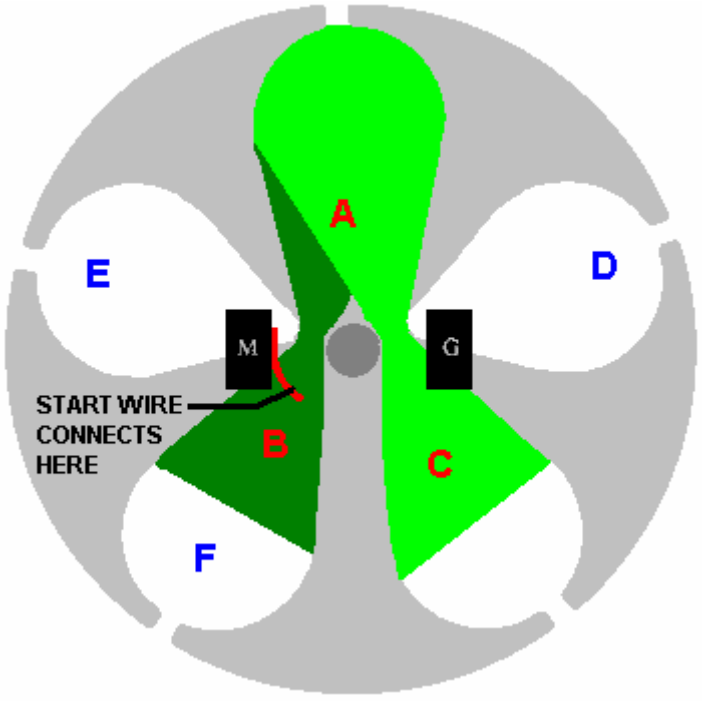
The end of the wire marked “FINISH” is **not** cut, but is taken down through opening “A” and this time, up through opening “C”. For clarity, these continuing turns are shown in a different colour, but please realise that it is the same single strand of wire being used throughout:



The final wire turn goes down through opening “A” and finishes at the other end of the body of the armature. In these views, the wire runs down into the paper, each turn forming a cylinder. This view may give you a better visual picture of what the coils are wound on:



The next step is to connect the START and FINISH wire ends of this V-shaped double coil to the “commutator” slip rings which allow current to be passed through the coil at just the right moment. Seen again from one end of the armature, the connections are like this:



The commutator slip rings are connected further up on the drive shaft and the start of the winding wire (shown previously in dark green) is connected to the top commutator sector in the position shown here. The finishing end of the wire is connected to the corresponding commutator sector at the far end of the shaft – that is, the sector directly in line with the upper sector just connected to the start of the wire.

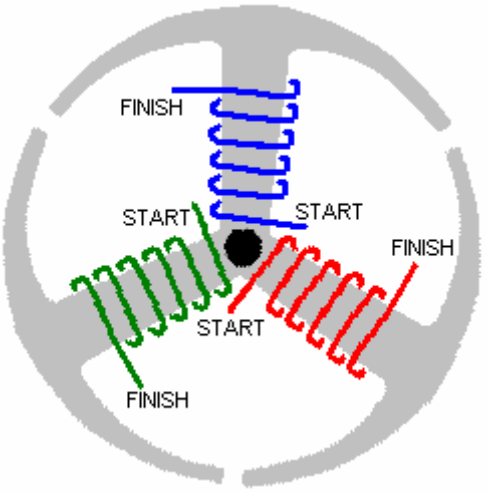
This completes the first of five identical V-shaped coils. The next coil is wound in the same way. The armature is rotated one sector counter-clockwise so that sector “D” replaces “A” at the top and the next coil is wound with the wire starting at the top and going down through opening “D” and up through opening “E”, repeating the same number of turns, and then, without cutting the wire the next set of wires are wound going down through opening “D” and back up through opening “F”. The start of the wire is then connected to the commutator sector which spans between openings “A” and “E” and the end connected to the corresponding commutator sector at the other end of the shaft..

For each of the remaining three windings, the shaft is rotated one position counter-clockwise and the same winding and connecting procedure carried out. When completed, no matter which opening is placed at the top of the view along the shaft, the windings and commutator sector for the wire connections will be identical.

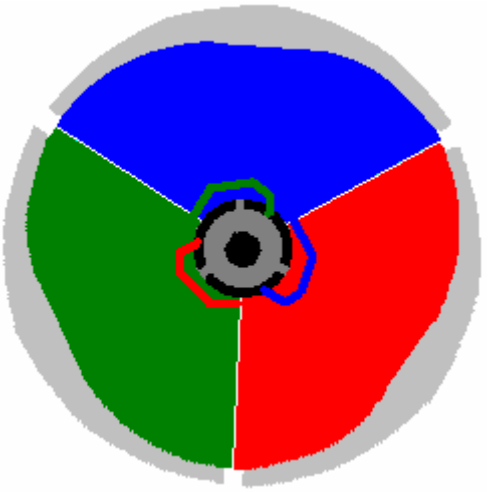
3-Pole Motors

The winding arrangement is slightly different for motors which have three poles (or multiples of three poles such as 6, 9, 12, etc poles). For the very simple 3-pole motors, the armature looks like this:

and with this style of armature, the winds are around the three arms, like this:



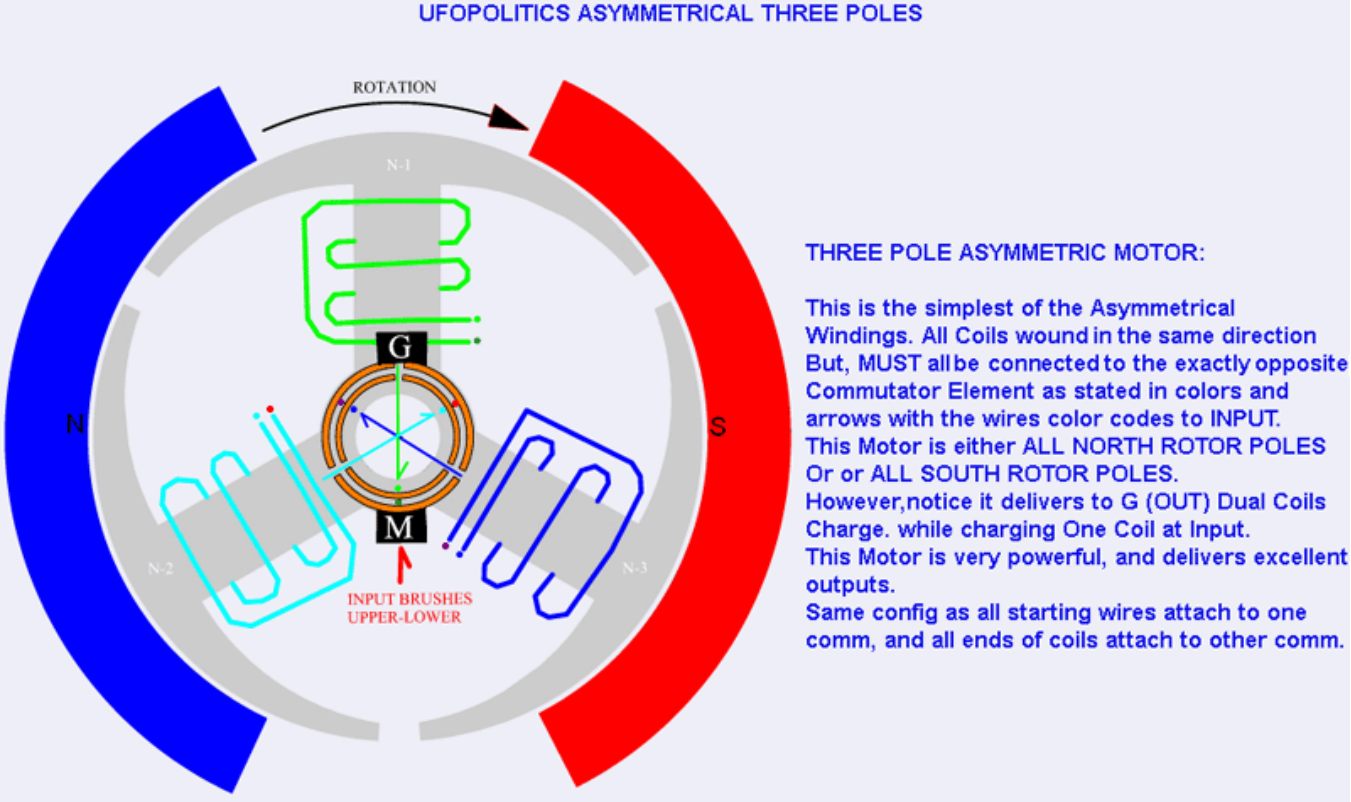
And as before, the commutator sectors at the top are duplicated at the bottom, allowing separate input and output circuits for each of the three coils. The windings have many turns, filling the available space and each winding is connected to the slip ring sector directly opposite it, like this:



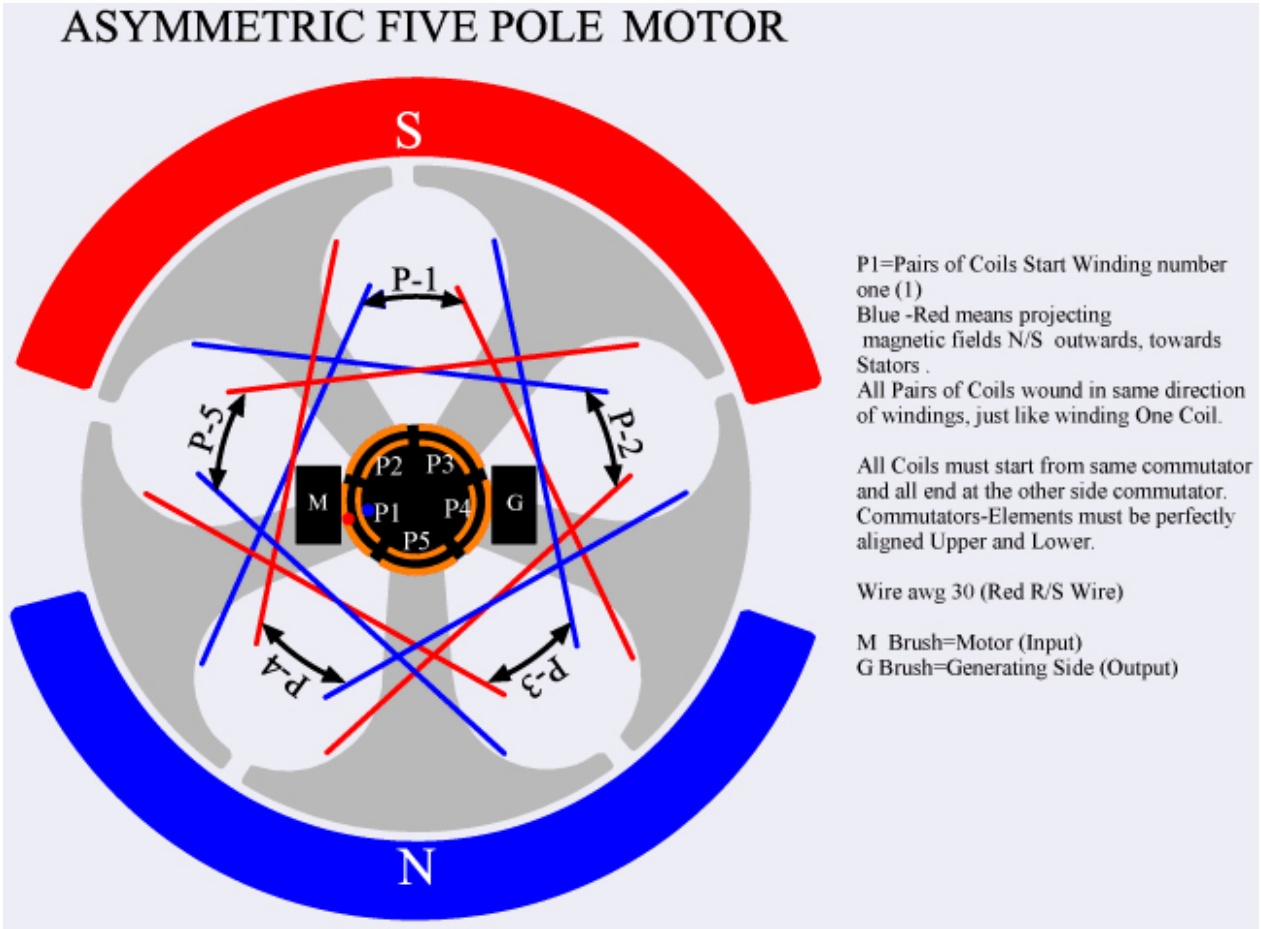
The Start of each winding is connected to the commutator slip ring sector at the top of the armature and the Finish is connected to the slip ring sector directly below it, that is, the sector which is at the same angle as the top one where the Start of the wire is connected. This allows the brushes which press against the slip ring sectors to connect to both ends of each coil in turn as the armature rotates. Three pole motors are particularly powerful and motors with six poles can be re-wound with pairs of adjacent sectors amalgamated to give three larger sectors. Nine pole motors can have three adjacent sectors wound as a single coil to provide the same effect as a three pole motor, and twelve pole motors can have four adjacent sectors wound as a single coil.

The positioning of the brushes is important. With the three-pole and five-pole arrangements, the brushes are aligned with the gaps between the magnets which surround the armature. However, the re-wound motor can be 'tuned' for improved torque and reduced drive current by adapting the motor housing to allow some adjustment of the position of the brush and commutator slip rings relative to the coils. This adjustment need only be slight as the angular movement of the brushes will be small. It is, of course, essential that the upper and lower adjusted positions move by exactly the same angular amount so that every upper commutator slip ring sector remains exactly above it's corresponding lower slip ring sector. In other words, the commutator slip ring sector at the top and bottom of each coil, must be exactly aligned vertically so that the electrical connections are made and broken at exactly the same instant

The commutator and brush arrangement are shown here in UFOpolitics' diagrams:



The Commutator brush marked “G” (for “Generator”) takes away the energy stored in each coil and passes it to an electrical load. The Commutator brush marked “M” (for “Motor”) feeds energy into the coil from the battery which is driving the motor. The red and blue stripes surrounding the armature are two permanent magnets. The magnet shown in red has it’s South pole facing the armature and the magnet shown in blue has it’s North pole facing the armature. This creates a magnetic field flowing horizontally across the armature. The five-pole arrangement is like this:



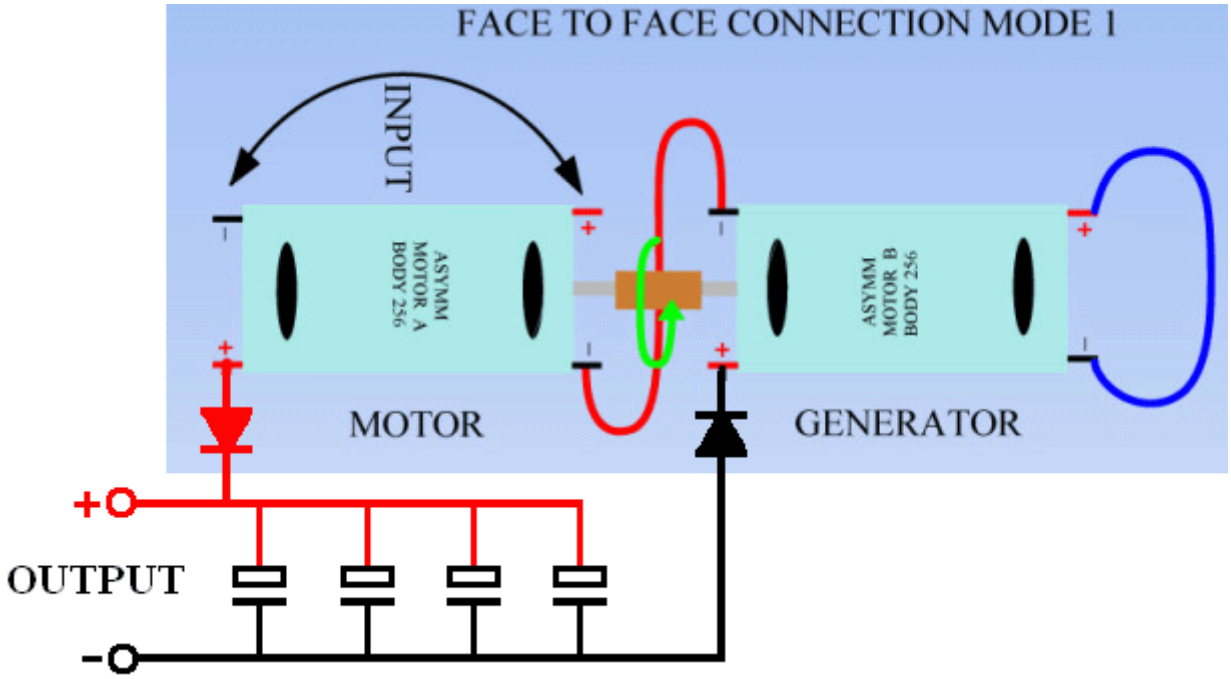
Here, the designation “R/S” stands for “Radio Shack” which is a chain of stores in America. In the forum, that is sometimes changed to “RS” and should not be confused with the large electronics outlet “Radio Spares” whose trademark is “RS”. UFOpolitics has suggested that the cheap 5-pole DC motor available from Radio Shack should be used by experimenters to become familiar with re-winding DC motor coils. Being a cheap product, those motors do not have a particularly high build quality, but they are suitable motors for experiments. Forum members share the details of how they dealt with adapting these and other motors.

I have to admit that motor windings and operation tend to confuse me and I sometimes find it difficult to understand what ‘UFOpolitics’ means when he talks about different winding strategies. However, it seems reasonably clear at this early stage of forum development, that his objective is to produce two things:

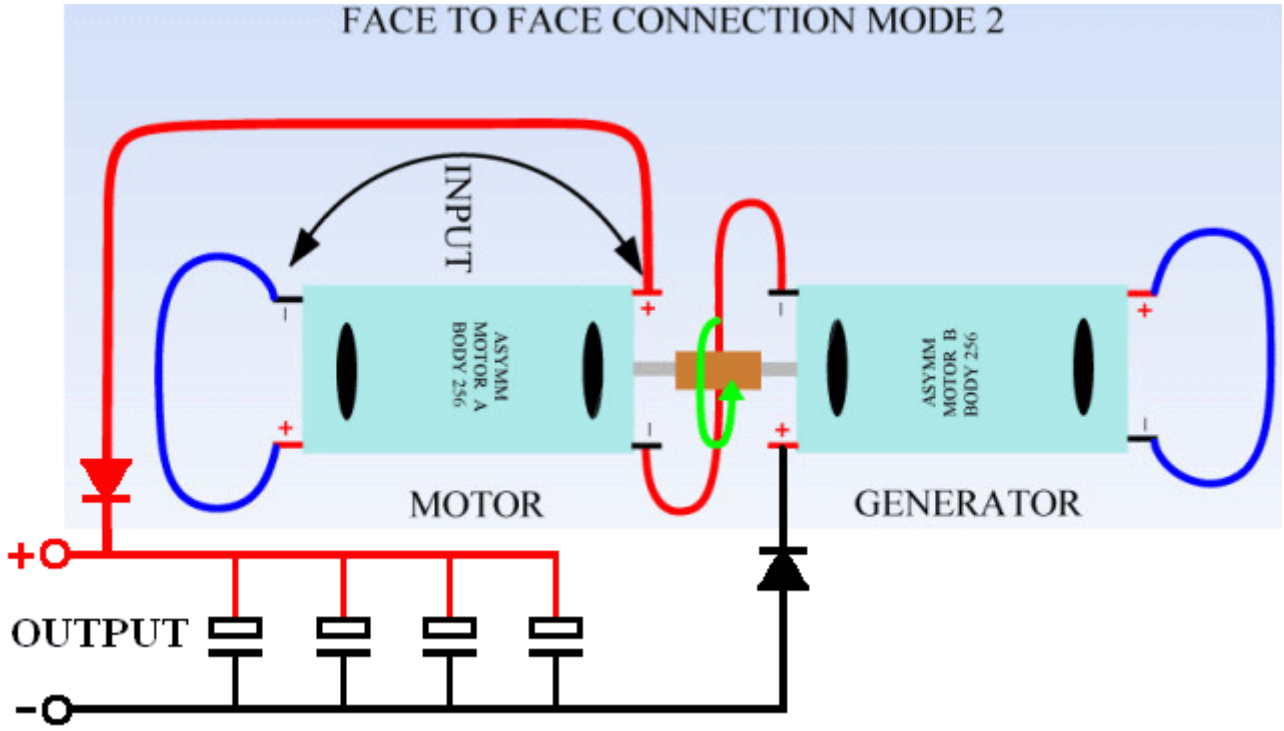
1. A very powerful electric motor which can be used in serious forms of road transport as well as for other practical applications, and

2. A powerful motor/generator combination which can produce useful generated electrical power.

While ‘UFOpolitics’ is very patiently going through many of the possible variations on how a DC motor can be wound and connected, and showing various forum members where they have failed to get some of their windings positioned correctly, he has also shown some of the best ways of connecting a re-wound motor used as a driver or “Prime Mover” as some people like to call it, and a re-wound motor which is to be used as an electrical generator. He shows two important ways for making a very effective Motor/Generator combination, as shown here:



It needs to be realised that these arrangements are not conventional arrangements and that the re-wound motors operate in a different way to motors bought ‘off the shelf’. For this reason, it is necessary to isolate the electrical output to prevent current flowing through the load from affecting the operation of the Motor/Generator combination. This can be done by placing a diode in each of the output lines and charging a capacitor bank which is then used to feed whatever load is to powered. If my understanding is correct, then feeding any cold electricity produced into a capacitor causes the current to become conventional hot electricity. It is not clear if that action is part of this arrangement although the circuitry shown should be used. This is the second version:



'UFOpolitics' comments on these arrangements as follows: As we excite the input of the Motor, the Generator will start producing energy and that additional energy will flow through the Motor Output side because they are connected in series here. Two rectifiers must be connected at both output terminals, Positive and Negative, to avoid back flow from closing the circuit through the load.

As the Motor accelerates, the Generator boosts the energy flow which then runs through the Motor augmenting the Output Fields and when the output is loaded then an 'Engagement' of both Machines occurs as they start to compensate each other through their output flows. It should be understood that the Output should be Capacitor Banked in a dedicated Reservoir.

When designing a Generator for a specific, existing Asymmetric Motor machine, it must be understood that Generator Interactions should be considered to run as "Counter Rotation" to the Motor Machine's originally conceived rotation (which is easily done by just moving brush-lines passing stator bisector angles to the opposite of those needed for a Motor, or alternatively, setting the timing backwards). This will definitively enhance the assisted rotation of both Machines when connected together in this Face-to-Face mode.

As I do not find the forum comments easy to understand, I recommend that you visit the forum and read the posts as you may well understand the conversations easier to follow than I do.

On the forum, 'Sanskara316' states "I have re-wound a small 3-volt 3-pole motor. I used an almost dead, 6-volt sealed lead-acid battery to power the motor. This battery just sits at around 4 volts and if given a load, even a small LED, it's voltage drops to 1 volt. The re-wound motor started very slowly - barely spinning, then after a minute or two it started to spin faster, and I noticed that the voltage on the battery was slowly climbing. I connected a small LED flashlight to the generating side and it lit up. Now the battery voltage under load is around 2+ volts. It's been running for an hour now and the machine squeals a lot. It is conditioning the battery and the meter cannot be showing what really is happening. The motor draws 300 ma?? – That's not possible as the battery just doesn't have that power". To which 'UFOpolitics' remarks: "Well I am glad you have witnessed some of the 'Effects'... these re-wound motors do recondition batteries...remember, Radiant Energy is taking over the Machine...so Radiant Energy comes out through the Input also… which is the reason why we get high Volts-Amps reading on a meter ...these motors use very small amounts of current and volts. Inside the motor, every coil is being 'Self-Electromagnetically-Pulsed' because they auto-disconnect from the power source, then the next coil in the sequence is assisted by the first coil when it has rotated to it's next position, and so on. The commutator switching has become a 'Self-Oscillator' for every independently-energised coil."

Another forum member 'prochiro' says: "I have also replicated the battery-charging events that 'Sanskara316' indicated. I started with a 12-volt 4 Amp-Hour battery which I had been using with another circuit two weeks ago and had not recharged it after using it for hours. It was sitting at 12.40 volts. I took my best-running re-wound motor, plugged it in direct and ran it. The battery voltage dropped to 12.24 volts and stayed at that level for 30 seconds. The battery voltage then started to rise 1/100 of a volt per minute. When it was at 12.27 volts, I disconnected the motor (the total run time was less than 5 minutes). I then let it rest for five minutes. At the end

of the five minutes, the battery voltage had risen to 12.43 volts and is still at that voltage now. Just think what a larger motor would do on a big battery bank. Everybody needs to document this test as it proves what 'UFOpolitics' said."

New DC motors, and particularly cheap motors, will have brushes which do not mate cleanly with the commutator slip ring sectors and so, when the modification has been made, running the motor for some time allows the brushes to wear in and that raises the efficiency of the electrical connections which in turn, improves the performance of the motor. If you wish to build and test one of these motors, then you can find help and support in the forum with your questions answered and numerous videos and photographs from different experimenters to help you.

Direct Coupled Motors

At http://www.youtube.com/watch?v=sj0ovfLvFTQ&feature=share Raoul Melendres shows a very interesting arrangement of two motors:

Probably intended to make you think more than anything else, this circuit appears to have the right hand motor, which is less than 100% efficient, being driven by the left hand motor which is also less than 100% efficient. The output appears to be arranged to provide DC to a transistor astable multivibrator which drives the secondary of a mains transformer, which is also less than 100% efficient. The much higher output voltage from the primary of the transformer is full-wave rectified and then smoothed using a capacitor and fed to the input of the driving motor, which presumably, drags the low-power output down to around six volts. This voltage supposedly drives the motor and has some current left over to charge a cell-phone battery. From a theoretical point of view, this looks impossible but the interesting question is "is it impossible?". Personally, I would have expected the pulley wheel on the drive motor to be larger than the pulley wheel on the generator.

Chapter 3: Motionless Pulsed Systems

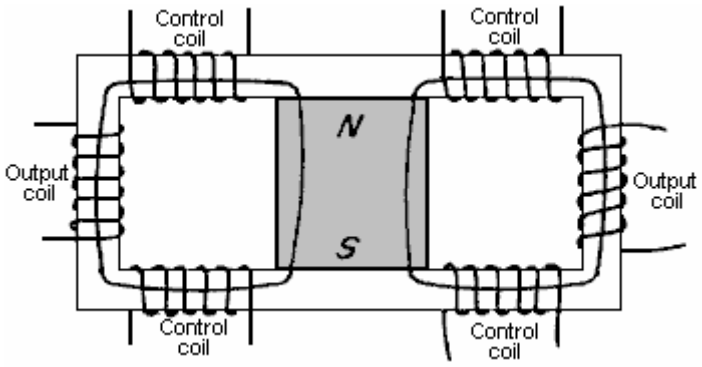
Note: If you are not at all familiar with basic electronics, you might find it easier to understand this chapter if you read chapter 12 first.

The pulsed devices mentioned so far have had moving parts but rotating or fluctuating magnetic fields can be created without moving parts. An example of this is Graham Gunderson's solid-state electric generator shown in US Patent Application 2006/0163971 A1 of 27th July 2006 which is shown on page A-1038 of the appendix. Another example is:

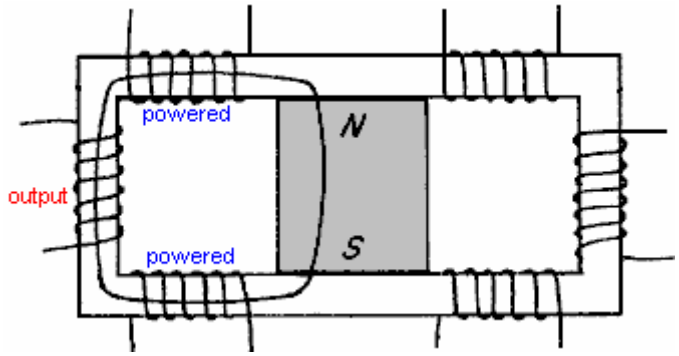
Charles Flynn's Magnetic Frame.

Another device of this type comes from Charles Flynn. The technique of applying magnetic variations to the magnetic flux produced by a permanent magnet is covered in detail in the patents of Charles Flynn which are included in the Appendix. In his patent he shows techniques for producing linear motion, reciprocal motion, circular motion and power conversion, and he gives a considerable amount of description and explanation on each, his main patent containing a hundred illustrations. Taking one application at random:

He states that a substantial enhancement of magnetic flux can be obtained from the use of an arrangement like this:



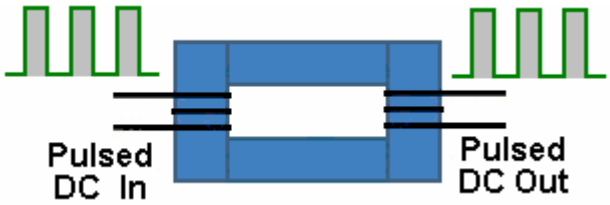
Here, a laminated soft iron frame has a powerful permanent magnet positioned in it's centre and six coils are wound in the positions shown. The magnetic flux from the permanent magnet flows around both sides of the frame.



The full patent details of this system from Charles Flynn are in the Appendix, starting at page A - 338.

Lawrence Tseung's Magnetic Frame.
Lawrence Tseung has recently produced a subtle design using very similar principles. He takes a magnetic frame of similar style and inserts a permanent magnet in one of the arms of the frame. He then applies sharp DC pulses to a coils wound on one side of the frame and draws off energy from a coil wound on the other side of the frame.

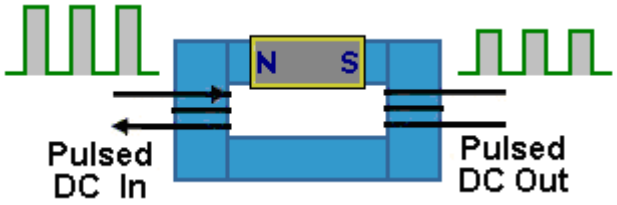
He shows three separate operating modes for the devices as follows:



(1) No Permanent Magnet, No Lead-Out Energy, Maximum COP = 1

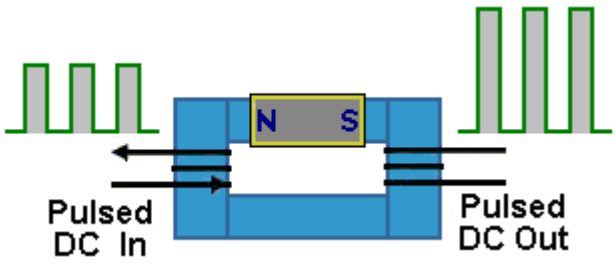
Lawrence comments on three possible arrangements. The first on shown above is the standard commercial transformer arrangement where there is a frame made from insulated iron shims in order to cut down the "eddy" currents which otherwise would circulate around inside the frame at right angles to the useful magnetic pulsing which links the two coils on the opposite sides of the frame. As is very widely known, this type of arrangement never has an output power greater than the input power.

However, that arrangement can be varied in several different ways. Lawrence has chosen to remove a section of the frame and replace it with a permanent magnet as shown in the diagram below. This alters the situation very considerably as the permanent magnet causes a continuous circulation of magnetic flux around the frame before any alternating voltage is applied to the input coil. If the pulsing input power is applied in the wrong direction as shown here, where the input pulses generate magnetic flux which opposes the magnetic flux already flowing in the frame from the permanent magnet, then the output is actually **lower** than it would have been without the permanent magnet.



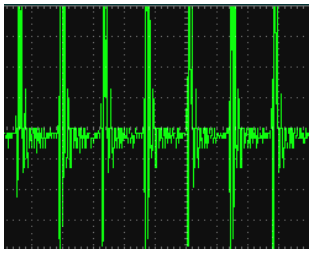
(2) Permanent Magnet Opposes Magnetic Flux: COP < 1

However, if the input coil is pulsed so that the current flowing in the coil produces a magnetic field which reinforces the magnetic field of the permanent magnet then it is possible for the output power to exceed the input power. The "Coefficient of Performance" or "COP" of the device is the amount of output power divided by the amount of input power which the user has to put in to make the device operate. In this instance the COP value can be greater than one:



(3) Permanent Magnet Enhances Magnetic Flux: COP > 1

As it upsets some purists, perhaps it should be mentioned that while a square wave input signal is applied to the input of each of the above illustrations, the output will not be a square wave although it is shown that way for clarity. Instead, the input and output coils convert the square wave to a low-quality sine wave which only becomes a pure sine wave when the pulse frequency exactly matches the resonant frequency of the output winding. The oscilloscope display shown here is a typical output power waveform which has nearly 390,000 of these pulses per second.



There is a limit to this as the amount of magnetic flux which any particular frame can carry is determined by the material from which it is made. Iron is the most common material for frames of this type and it has a very definite saturation point. If the permanent magnet is so strong that it causes saturation of the frame material before the input pulsing is applied, then there can't be any effect at all from positive DC pulsing as shown. This is just

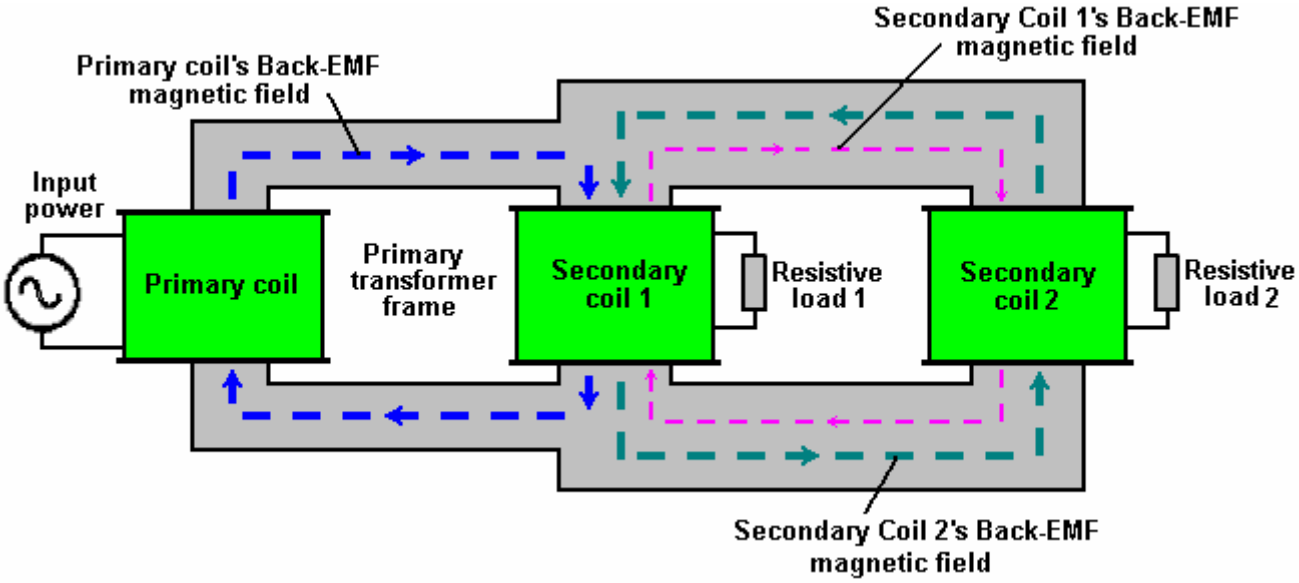
common sense but it makes it clear that the magnet chosen must not be too strong for the size of the frame, and why that should be.

As an example of this, one of the people replicating Lawrence's design found that he did not get any power gain at all and so he asked Lawrence for advice. Lawrence advised him to omit the magnet and see what happened. He did this and immediately got the standard output, showing that both his input arrangement and his output measuring system both worked perfectly well. It then dawned on him that the stack of three magnets which he was using in the frame were just too strong, so he reduced the stack to just two magnets and immediately got a performance of COP = 1.5 (50% more power output than the input power).

The Transformers of Thane Heins.

Thane has developed, tested and patented a transformer arrangement where the output power of his prototype is thirty times greater than the input power. He achieves this by using a figure-of-eight double toroid transformer core. His Canadian patent CA2594905 is titled "Bi-Toroid Transformer" and dated 18th January 2009. The abstract says: The invention provides a means of increasing transformer efficiency above 100%. The transformer consists of a single primary coil and two secondary coils. The two secondary coils are set on a secondary toroidal core which is designed to be maintained at a lower magnetic resistance than the primary toroidal core throughout the entire operating range of the transformer. Thus, when the transformer secondary delivers current to a load, the resulting Back-EMF is not allowed to flow back to the primary due to the higher magnetic resistance of that flux path, instead, the secondary coil's Back-EMF follows the path of least magnetic resistance into the adjacent secondary coil.

You will notice that in the following diagram, the secondary transformer frame on the right is much larger than the primary transformer frame on the left. This larger size produces a lower magnetic resistance or "reluctance" as it is known technically. This seems like a minor point but in fact it is not, as you will see from the test results.



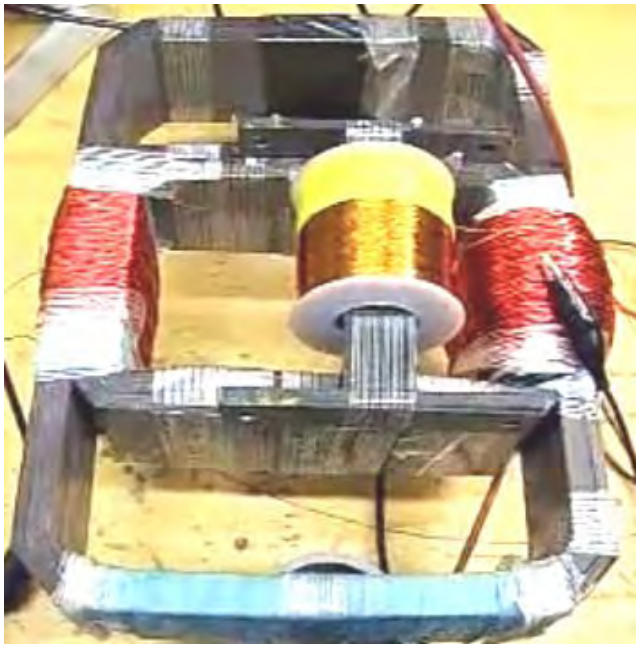
In a conventional transformer, the power flowing in the primary winding induces power in the secondary winding. When the power in the secondary winding is drawn off to do useful work, a Back-EMF magnetic flux results and that opposes the original magnetic flux, requiring additional input power to sustain the operation.

In this transformer, that opposing magnetic flow is diverted through a larger magnetic frame which has a much lower resistance to magnetic flow and which, as a result, bleeds off the problem flux, sending it through secondary coil 2 in the diagram above. This pretty much isolates the input power from any opposition, resulting in a massive improvement in the operation efficiency.

In the patent document, Thane quotes a prototype test which had a primary coil winding with 2.5 ohms resistance, carrying 0.29 watts of power. The secondary coil 1 had a winding with 2.9 ohms resistance, receiving 0.18 watts of power. The Resistive load 1 was 180 ohms, receiving 11.25 watts of power. The secondary coil 2 had a winding with 2.5 ohms resistance, and received 0.06 watts of power. Resistive load 2 was 1 ohm, receiving 0.02 watts of power. Overall, the input power was 0.29 watts and the output power 11.51 watts, which is a COP of

39.6 and while the document does not mention it directly, the primary coil should be driven at it's resonant frequency.

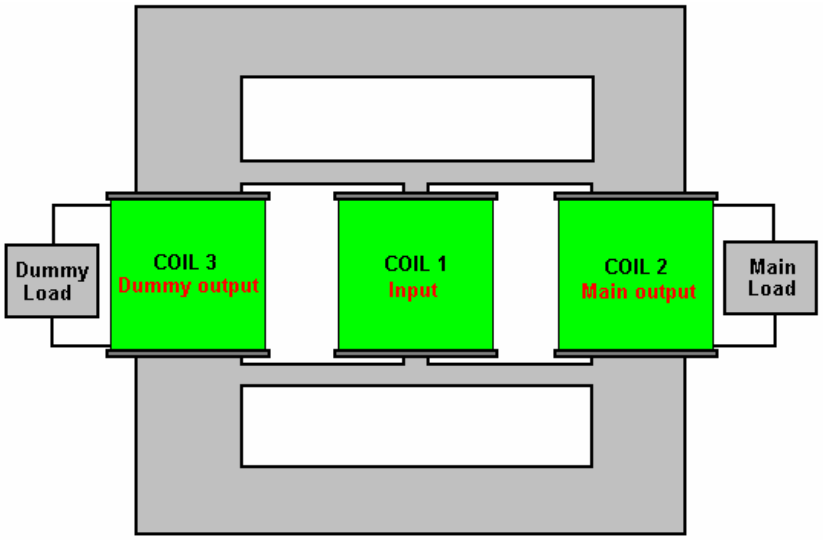
A variation of this arrangement is to attach an outer toroid to the existing bi-toroid arrangement, like this:



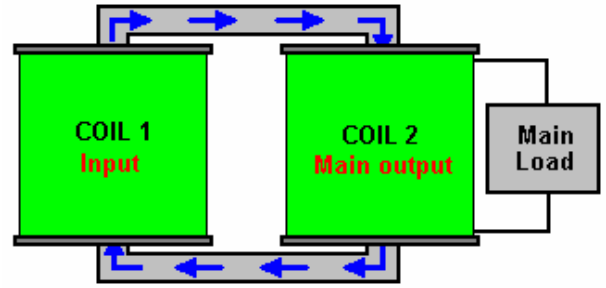
This prototype, as you can see, is fairly simple construction, and yet, given an input power of 106.9 milliwatts, it produces an output power of 403.3 milliwatts, which is 3.77 times greater.

This is something which needs to be considered carefully. Conventional science say that "there is no such thing as a free meal" and with any transformer, you will get less electrical power out of it than you put into it. Well, this simple looking construction demonstrates that this is not the case, which shows that some of the dogmatic statements made by present day scientists are completely wrong.

This version of Thane's transformer is made like this:

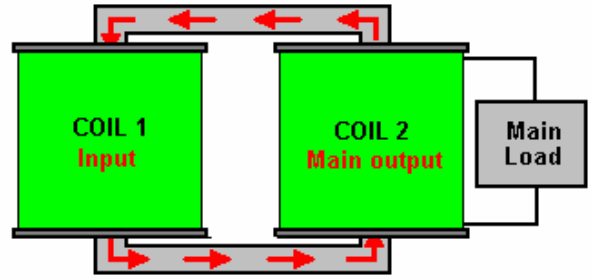


The way that off-the-shelf transformers work at the moment is like this:



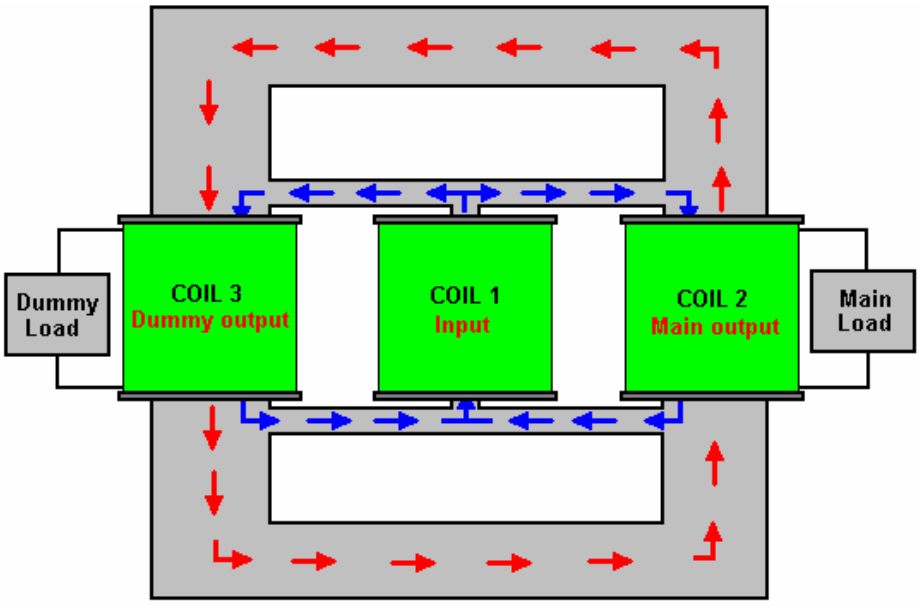
When a pulse of input power is delivered to Coil 1 (called the "Primary winding"), it creates a magnetic wave which passes around the frame or "yoke" of the transformer, passing though Coil 2 (called the "Secondary winding") and back to Coil1 again as shown by the blue arrows. This magnetic pulse generates an electrical output in Coil 2, which flows through the electrical load (lighting, heating, charging, video, or whatever) providing it with the power which it needs to operate.

This is all well and good but the catch is that the pulse in Coil 2 also generates a magnetic pulse, and unfortunately, it runs in the opposite direction, opposing the operation of Coil 1 and causing it to have to boost it's input power in order to overcome this backward magnetic flow:



This is what makes current scientific "experts" say that the electrical efficiency of a transformer will always be less than 100%.

Thane has overcome that limitation by the simple and elegant technique of diverting that backward pulse of magnetism and channelling it through an additional magnetic path of lower resistance to magnetic flow through it. The path is arranged so that Coil 1 has no option but to send it's power through the frame as before, but the return pulse takes a much easier path which does not lead back to Coil 1 at all. This boosts the performance way past the 100% mark, and 2,300% has been achieved quite readily (COP=23). The additional path is like this:



Not shown in this diagram are the reverse pulses from Coil 3. These follow the easier outside path, opposing the unwanted back pulse from coil 2. The overall effect is that from Coil 1's point of view, the tiresome back pulses

from Coil2 have suddenly disappeared, leaving Coil 1 to get on with the job of providing power without any hindrance.

This simple and elegant modification of the humble transformer, converts it into a free-energy device which boosts the power used to drive it and outputs much greater power. Congratulations are due to Thane for this technique.

At the present time there are videos showing how this transformer works:
http://www.youtube.com/watch?v=5KfwiXJ8apk and
http://www.youtube.com/watch?v=GcAYhM0LX9A&playnext=1&feature=sub&list=TLJjwIlLxS9jQ.

The High-power Motionless Generator of Clemente Figuera

Clemente Figuera of the Canary Islands died in 1908. He was a highly respected individual, an Engineer and University Professor. He was awarded several patents and was known to Nikola Tesla. Figuera's design is very simple in outline. He has avoided the performance-killing Lenz Law magnetic feedback by splitting a transformer into three parts. Two parts form the primary winding and are shown on the left and on the right. The third part is the secondary winding which is located in the centre. Because of the splitting of the primary into two parts, Lenz's Law has been abolished for this design, allowing a spectacular performance where the current drawn from the secondary winding has no effect on the current flowing in the two halves of the primary winding. There is also, no back-EMF as current flows continuously in both halves of the primary winding. The very clever method used by Clemente makes the strength of the current in the two halves of the primary to oscillate with one side repeatedly having first much more current and then far less current than the other half. This generates alternating current in the secondary, current which can be drawn off and used for useful work, powering lights, heaters, motors, etc. The following information comes from a man who wishes to remain anonymous. On 30th October 2012, he made the following comments about his repair to a Figuera patent which was missing some of the content. He says:

CLEMENTE FIGUERA AND HIS INFINITE ENERGY MACHINE

I heard of Clemente Figuera for the first time from one of the Tesla articles. In 1902 the Daily Mail announced that Mr. Figueras (with an "s"), a Forestry Engineer in the Canary Islands, and for many years Professor of Physics at St. Augustine's College, Las Palmas, had invented a generator which required no fuel. The newspaper article says that "He claims to have invented a generator which can collect the electric fluid, to be able to store it and apply it to infinite purposes, for instance, in connection with shops, railways and manufacturers. He will not give the key to his invention, but declares that the only extraordinary point about it is that it has taken so long to discover a simple scientific fact. Señor Figueras has constructed a rough apparatus by which, in spite of it's small size and it's defects, he obtains 550 volts, which he utilises in his own house for lighting purposes and for driving a 20 horse-power motor. Señor Figueras is shortly coming to London, not with models or sketches, but with a working apparatus. His inventions comprise a generator, a motor, and a sort of governor or regulator, and the whole apparatus is so simple that a child could work it." [Taken from "Perpetual Motion – A History of an Obsession"].

I was in one of the forums when someone mentioned Clemente Figuera and provided some links to documents referring to his work [1]. In one of the documents, I found what looks to be the only page showing sketches from one of his patents. After restoring the faint lines which show the wire connections, I was very surprised to see the similarities between the embodiment of Mr. Figuera's drawing and one of my own for over-unity transformers.

I was very eager to read any information about Mr Figuera's work and the operation of his 'Infinite Energy Machine'. It looks very suspicious that the pages describing the most important part of the machine have been 'lost'. I then decided to just figure this machine out for myself.

rotating brush O+ Positive connection of the external battery
fixed cylinder "G" (not conductive)

FIG. 14

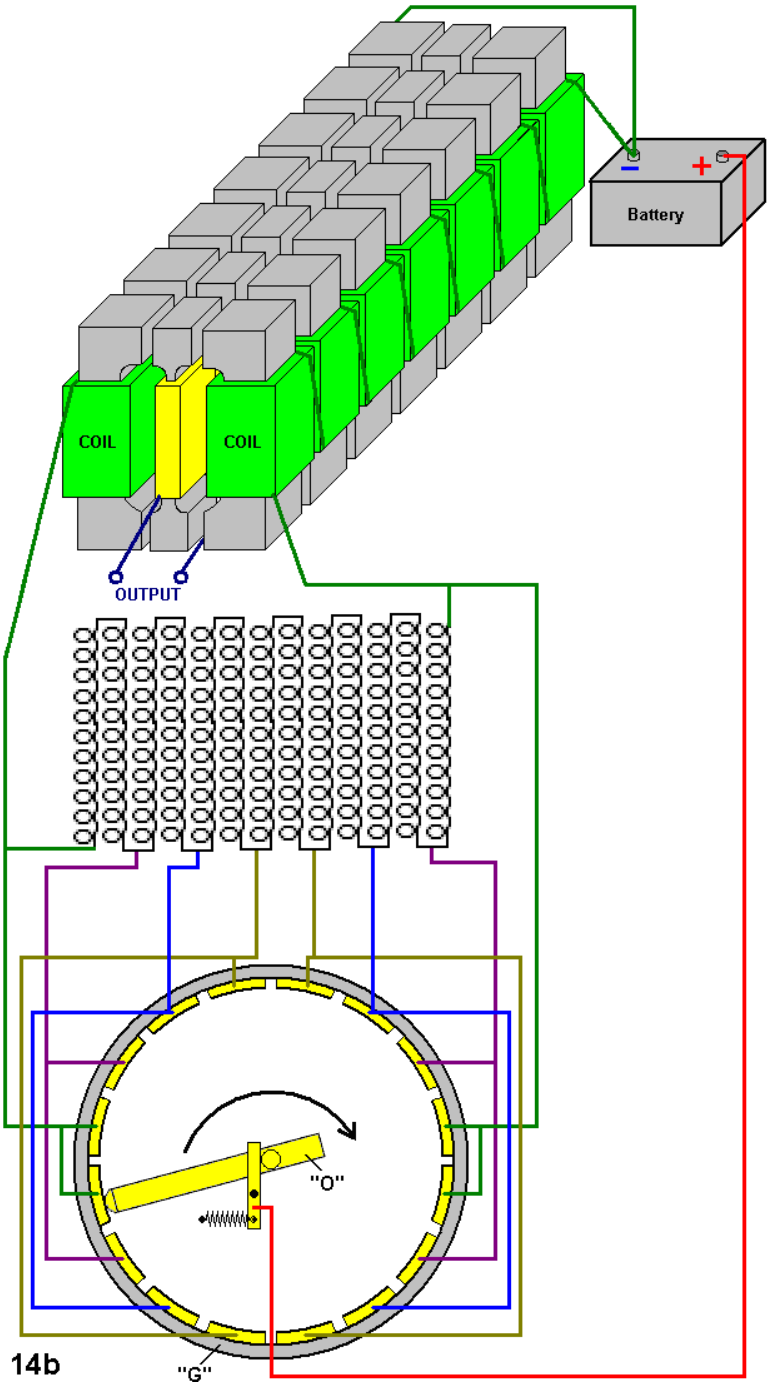

Fig. 14b

Please note that the rotating contact brush needs to be a “Make Before Break” type. That is, it needs to bridge across the gap between adjacent stator contact strips so that there is no sparking due to the current flow being interrupted.

According to Mr. Figuera, an over-unity transformer can be built without using permanent magnets, and based on a very simple concept. Figuera’s generator consists of three rows of electromagnets, where each row is connected in series. The rows of “S” and “N” electromagnets function as the primary of the transformer, while the row of “y” electromagnets, located in the centre, functions as the secondary. The “S” and “N” stand for South and North poles, respectively. The apparatus includes a resistor “R” having multiple taps connected to a type of distributor formed by a cylinder “G” and brush “O”. The brush “O” rotates inside the cylinder “G” changing the connection to the resistor taps. When the brush “O” rotates around the eight taps, it generates two stepped half-cycle sine waves which are 90° out of phase with each other. I suggest that Fig.15 is the wiring diagram as originally disclosed by Mr. Figuera in his patents. The most significant component of the system is the arrangement of the electromagnets shown in section A-A of figure 14. Keep in mind that each electromagnet shown in figure 15 corresponds to a row of seven electromagnets connected in series as shown in figure 14. In addition, I recommend that when building this apparatus, at least for the first implementation, that you try to replicate all of the details of the device shown in the patent. For example, figure 14 shows the top area of the “S” and “N” electromagnets being approximately equal to twice the top area of the “y” electromagnets.

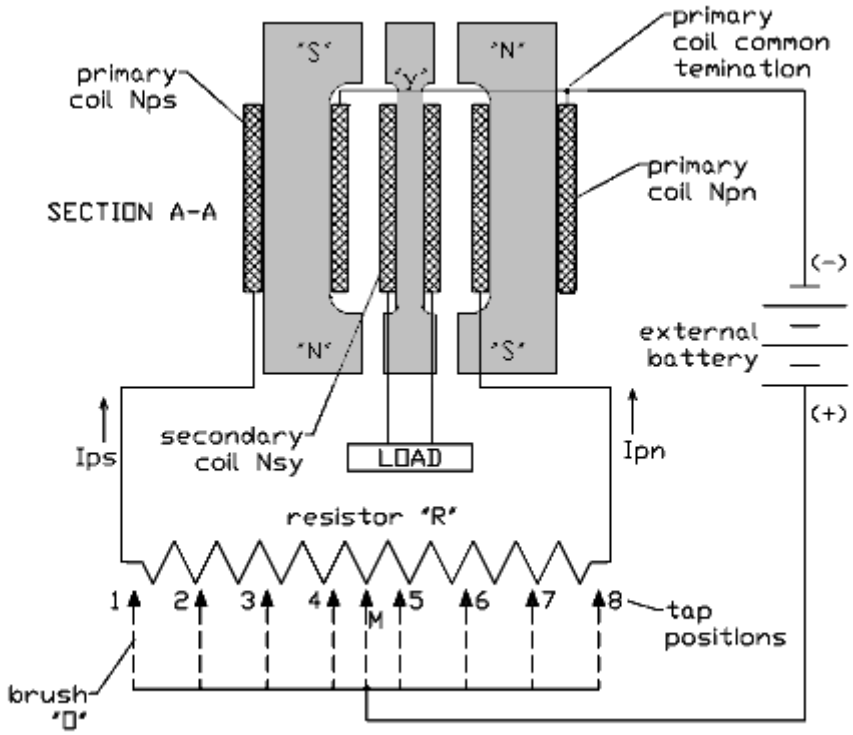

FIG. 15 **SIDE VIEW**

Even though Mr. Figuera used stepped sinusoidal currents **Ips** and **Ipn**, I consider the resistor shown in Fig.15, to be a linear variable resistor having infinite 'taps' and the voltage and current generated to be pure half-cycle sine waves which are 90° out of phase. The coils of the "S" and "N" electromagnets are connected together and attached to the negative terminal of the battery. The other ends of both electromagnets are connected to both ends of the resistor "R". The sliding contact "O" is connected to the positive terminal of the battery and is rotated continuously making electrical connections repeatedly from left to right and then back from right to left across the multi-tap resistor "R". The position of the sliding contact "O", determines the magnitude of the DC currents **Ips** and **Ipn** passing through the primary coils "S" and "N". For instance, when the brush is in position 1, the "S" coils receive the full voltage of the battery, producing the maximum current **Ips** and maximum magnetic field **Bps**, while at the same time, the current **Ipn** and magnetic field **Bpn** of the "N" coils are at their minimum values because they are now connected to the battery through the maximum value of the resistor "R". Figure 21 shows the voltage, current, and magnetic field waveforms flowing through these coils. The voltage induced in the secondary coils "y" is a sinusoidal alternating voltage. The secondary voltage should be zero when the magnitudes of the currents Ips and Ipn are equal. At this point, the magnetic fields **Bps** and **Bpn** induce two voltages of the same magnitude and opposite polarity.

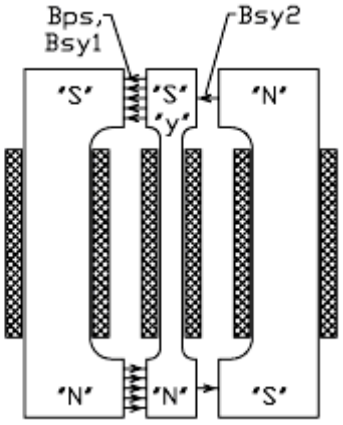

FIG. 16 POSITION 1

The magnetic interaction of the "S", "N", and "y" electromagnets is shown in Fig.16 to Fig.20. Figure 16 illustrates the situation when the brush "O" is at position 1. Here, the current **Ips** and magnetic field **Bps** are at their maximum, while the current **Ipn** and magnetic field **Bpn** are at their minimum values. When the secondary current **Isy** starts flowing, the "y" coils generate a magnetic field **Bsy** which opposes the magnetic field **Bps** in accordance with Lenz's law. As a consequence, a South pole is created at the top of the "y" electromagnet and a

North pole at the bottom. Because magnets of the same polarity repel and opposite polarities attract, it is likely that some of the induced magnetic field **Bsy2** is diverted through the iron core of the "N" electromagnet, which represents a lower reluctance path. And, if the induced magnetic field **Bsy** can be rerouted so as to avoid opposing the magnetic field **Bps** which generates it, then, it might be possible to have an over-unity transformer.

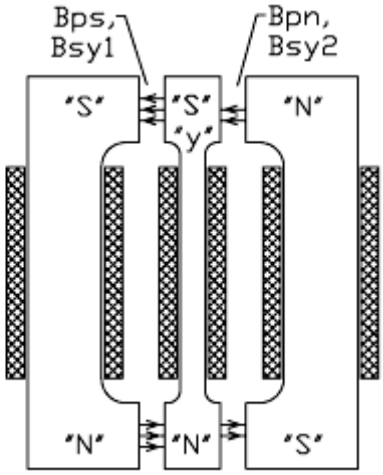

FIG. 17 POSITION 3

Fig.17 illustrates the situation when the sliding contact "O" is at position 3. The primary current **Ips** and the primary magnetic field **Bps** are decreasing in magnitude while the magnitude of the primary current **Ipn** and magnetic field **Bpn** are both increasing. The primary current **Ips** (and **Bps**) is still larger than primary current **Ipn** (and **Bpn**). As shown in the figure, part of the induced magnetic field **Bsy2** is still coupled to the "N" electromagnets.

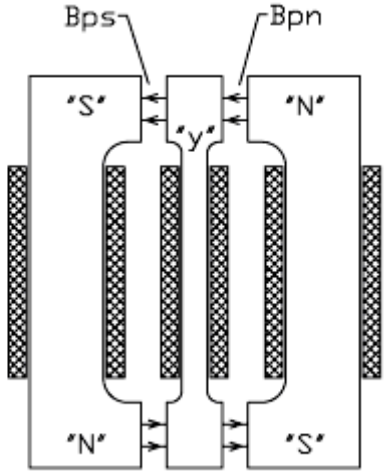

FIG. 18 POSITION M

Fig.18 illustrates the scenario when the brush is at position M. This position is exactly at the centre of the resistor "R" and both currents **Ips** and **Ipn** are of equal magnitudes, and as a result, the magnetic fields **Bps** and **Bpn** are also equal. The net voltage Vsy, current **Isy**, and magnetic field **Bsy** induced in the secondary coils "y" are all zero.

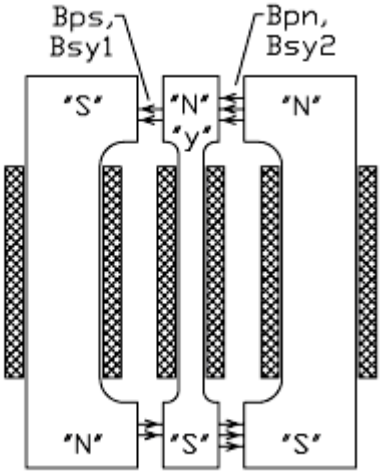

FIG. 19 POSITION 6

Figure 19 shows the situation when sliding contact "O" is at position 6. The primary current **Ips** and the primary magnetic field **Bps** are still decreasing in magnitude while the magnitude of the primary current **Ipn** and the magnetic field **Bpn** are increasing. The primary current **Ips** (and **Bps**) is now of lower magnitude than primary current **Ipn** (and **Bpn**). Because the magnetic field **Bpn** of the "N" electromagnets is stronger than the magnetic field **Bps** of the "S" electromagnets, the polarity of the induced voltage Vsy, current **Isy**, and magnetic field **Bsy** are reversed in accordance with Lenz's law. In this situation, the secondary electromagnets "y" present the north poles at the top and the south poles at the bottom making the "y" and "N" electromagnets to repel and the "y" and "S" to attract. Because of the now higher reluctance of the "N" electromagnets and lower reluctance of the "S" electromagnets, it is expected that part of the induced magnetic field **Bsy** will couple with the "S" electromagnets, and therefore, the effect of Lenz's law is minimised.

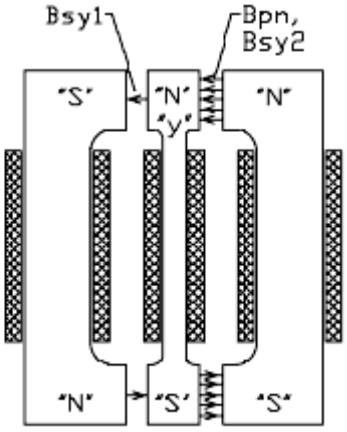

FIG. 20 POSITION 8

Fig.20 illustrates the situation when the brush "O" is at position 8. The primary current **Ipn** and the magnetic field **Bpn** are at their maximum values. The induced secondary voltage Vsy, current **Isy**, and magnetic field **Bsy** are also maximum and of opposite polarities to those which they had at position 1. Again, part of the induced secondary magnetic field **Bsy** is attracted by the "S" electromagnet mitigating the effect of Lenz's law.

Our thanks are due to the anonymous contributor who produced the above information on the work of Clemente Figuera whom I had never heard of before. Recently, the forum member 'hanlon1492' of the overunity.com forum http://www.overunity.com/12794/re-inventing-the-wheel-part1-clemente_figuera-the-infinite-energy-machine/#.UXu9gzcQHqU has shared a translation of Figuera's complete 1908 patent, lodged just days before he died, and it is reproduced here with thanks to 'hanlon1492' for his work and for freely sharing the results:

PATENT by CLEMENTE FIGUERA (year 1908) No. 44267 (Spain)

Ministry of Development General Board of Agriculture, Industry and Commerce. Patents of Invention. Expired. Dossier number 44267. Instruction at the request of D. Clemente Figuera. Representative Mr. Buforn. Presented in the register of the Ministry in the 31st October 1908, at 11:55 received in the negotiated in the 2nd November 1908.

ELECTRICAL GENERATOR "FIGUERA"

BACKGROUND

If we rotate a closed circuit inside a spinning magnetic field, with the closed circuit positioned at right angles to the lines of magnetic force, a current will be induced in the closed circuit for as long as there is movement, and the sign of that induced current will depend on the direction in which the closed circuit moves.

This is the basis of all magnetic machines and electric dynamos from the original, invented by Pixii, in France and later modified and improved by Clarke to reach the design of the current dynamos of today.

The principle on which this theory is based, has the unavoidable need for the movement of either the induction circuit or the magnetic circuit, and so, these machines are considered to be a transformer of mechanical work into electricity.

PRINCIPLE OF THE INVENTION

Considering carefully what happens in a dynamo in motion, we see that the coil turns of the induction circuit approach and move away from the magnetic centres of the magnets or electromagnets, and those turns, while spinning, pass through sections of the magnetic field of different magnetic strengths, because, while the maximum magnetic strength is in the centre of the core of each electromagnet, this action weakens as the induction coil moves away from the centre of the electromagnet, only to increase again when it is approaching the centre of another electromagnet with opposite sign to the first one.

Because we all know that the effects seen when a closed circuit approaches and moves away from a magnetic centre are the same as when the circuit is motionless and the magnetic field increased and decreased in intensity, since any variation of the magnetic flow traversing a circuit produces an induced electrical current. Then, consideration was given to the possibility of building a machine which would work, based, not on the principle of movement as current dynamos do, but based on the principle of increasing and decreasing the strength of the magnetic field, or the strength of the electrical current which produces it.

The voltage from the total current of the current dynamos is the sum of all of the induced currents generated in every turn of the induction coils. Therefore it does not matter if these induced currents were generated by rotating the induction coils, or by varying the magnetic flux which passes through them. In the first case, a greater amount of mechanical work is required than the amount of electricity generated, while in the second case, the force needed to produce the variation of magnetic flux is so insignificant that it can easily be taken from the output generated by the machine.

Up to the present day, no machine based on this principle has been constructed for the production of large electrical currents, and which among other advantages, has overcome the necessity for motion and so, the energy needed to produce it.

In order to attain the production of large industrial electrical currents, using the principle that electrical current can be provided by just changing the flow of magnetic flux through an induction circuit, the above disclosure should be sufficient, however, as this operating principle needs to embodied in a practical machine, there is a need to describe it in order to fully disclose how to carry out a practical application of this principle.

This principle is not new since it is just a consequence of the laws of induction stated by Faraday in the year 1831: what it is new and claimed in this patent, is the application of this principle to a machine which produces large industrial electrical currents and which, up to now, has only been obtained by transforming mechanical work into electricity.

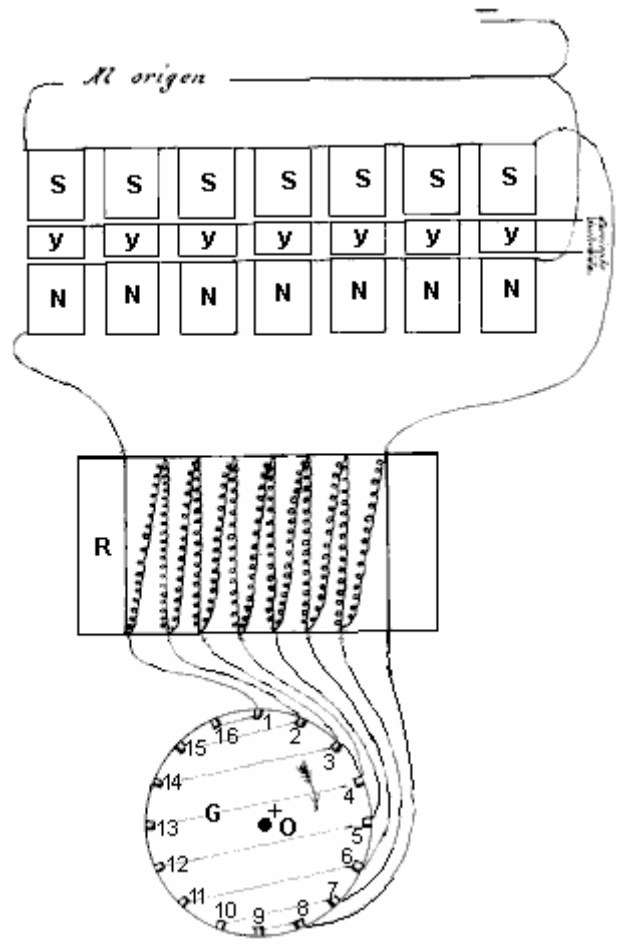
We will therefore, provide a description of a machine based on the above principle disclosed in this patent; but it must be understood, and what is sought is the patent for the application of this principle, that all machines built based on this principle, will be included in the scope of this patent, whatever the form and way that has been used to make the application.

DESCRIPTION OF GENERATOR OF VARIABLE EXCITATION "FIGUERA"

The machine is comprised of a fixed inductor circuit, consisting of several electromagnets with soft iron cores enhancing induction in the induction circuit, which is also fixed in position and motionless, and which is composed of several coils, accurately positioned. As neither of the two circuits spin, there is no need to make them round, nor leave any space between one and the other.

Here what it is constantly changing is the intensity of the excitatory current which drives the electromagnets and this is accomplished using a resistance, through which circulates a operating current, which is taken from one power source and passed through one or more electromagnets, thus magnetising one or more electromagnets. When the current is higher, the magnetisation of the electromagnets is increased, and when it is lower, the magnetisation is decreased. Thus, varying the intensity of the current, varies the magnetic field which crosses through the induction circuit.

To assist in understanding this idea, it is convenient to refer to the attached drawing which is no more than a sketch intended to assist in understanding the operation of the machine built to implement the principle outlined above.



Suppose that electromagnets are represented by rectangles marked '**N**' and '**S**'. Located between their poles is an induction circuit represented by the line of small rectangles marked '**y**'. A resistor 'R', drawn here in a simple form to help understanding of the entire system. Shown as '**+**' and '**-**', is the excitation power, drawn from an external source. As can be seen in the drawing, the different sections of this resistor connect with the commutator bars embedded in a stationary cylinder of insulating material. A sliding-contact brush '**O**', which always connects with more than one contact, rotates, carrying the excitation current. One of the ends of the resistor is connected to the electromagnets **N**, and the other end of the resistor is connected to the electromagnets **S**. Half of the terminals of the resistor go to half of the commutator bars of the cylinder. The other half of these commutator bars are connected directly to the first set of commutator bars.

The operation of the machine is as follows: the brush **O** rotates inside cylinder **G** and is always in contact with two of the commutator bars. When the brush is touching contact **1** the current, flowing from the external source passes through the brush and powers electromagnets **N** to their maximum level of magnetisation, but the current passing through electromagnets **S** is insufficient to magnetise them because the whole of resistance **R** is too great to allow sufficient current to magnetise them. Therefore, the **N** electromagnets are fully powered while the **S**

electromagnets are not sufficiently powered to be magnetised.

When the brush connects with contact **2**, the whole of the current will not flow through electromagnets **N** because it has to pass through part of the resistor. Consequently, some current will pass through the electromagnets **S** because it has to overcome less resistance than in the previous case. This same reasoning applies to the case when brush **O** connects with each of the different contacts around the first semicircle. Then the brush **O** starts to connect with the commutator contacts in the other half, each of which are directly connected to their corresponding commutator contacts in the first half. In short, the resistor has the function of a current-splitter, powering either one set of electromagnets or the other set of electromagnets repeatedly. It can be seen that electromagnet sets **N** and **S** operate in a complementary manner, because while the first set is being progressively powered up, the other set is being progressively powered down. This sequence is repeated continuously causing an orderly a constant variation of the magnetic fields passing through the induction circuit. This action can be maintained by just the simple rotation of a brush or group of brushes which rotate in a circle inside cylinder **G** driven by a small electric motor.

As indicated by the drawing the current, once it has flowed through the electromagnets, returns to the power source where it originated. A small part of the output current from this device can be used to provide the 'external' excitation power mentioned above, thus making the machine self-exciting and to provide the current to operate the small motor which moves the brush causing the switching. Once started with an external power source, that external power source can be removed and the machine will continue to work indefinitely without any external power source.

This invention is really new, very daring, and above all, has huge technical and industrial consequences in all areas. This patent was not applied for until a working machine based on these principles had been built, thus proving the concept to be sound and practical.

ADVANTAGES OF THE ELECTRICAL GENERATOR "FIGUERA"

1. The completely free production of DC or AC electric current of any voltage which can be used for:
   a. Providing a driving force.
   b. Production of light.
   c. Production of heat.
   d. All other existing uses of electricity.

2. There is no need whatsoever for a driving force of any kind or chemical reactions or fuel consumption.

3. Needs little or no lubrication.

4. Is so simple that it can be easily operated by anyone.

5. Does not produce smoke, noise, or vibration when operating.

6. Indefinite operational life.

7. Has a wide range of uses: home management and industrial.

8. Easy construction.

9. Cheap to produce and market

NOTE

A 20-year patent is requested for a "NEW GENERATOR OF ELECTRICITY, so-called "FIGUERA" of variable excitation, designed to produce electrical currents for industrial applications without using either driving force, nor chemical reactions. The machine is essentially characterised by two series of electromagnets which form the inductor circuit, between whose poles induction coils are placed. Both the induction and inductor circuits remain motionless and yet are able to produce a current induced by the constant variation of the intensity of the magnetic field forcing the excitatory current (coming at first from any external source) to pass through a rotating brush which, in its rotation movement, connects with the commutator bars or contacts of a ring distributor or cylinder whose contacts are connected to a resistor whose value varies from a maximum to a minimum and vice versa, according with the commutator bars of the cylinder which operates, and for that reason the resistance is connected to the electromagnets N by one of its side, and the electromagnets S at the other side, in such a way that the excitatory current will be magnetising successively with more or less strength, the first electromagnets, while, simultaneously decreasing or increasing the magnetisation in the second set, determining these variations

in intensity of the magnetic field, the production of the current in the induced, current that we can use for any work for the most part, and of which only one small fraction is derived for the actuation of a small electrical motor which rotates the brush, and another fraction goes to the continuous excitation of the electromagnets, and, therefore, converting the machine to become self-exciting, being able to remove the external power which was used initially to excite the electromagnets. Once the machinery is in motion, no new force is required and the machine will continue in operation indefinitely.

All in accordance with the described and detailed in this report and as represented in the drawings which are attached.

Barcelona, the 30th of October, 1908. Signed: Constantino de Buforn.

*****

There are some practical points which have not been included so far and which need to be mentioned. The Figuera patent shows the electromagnets as just rectangles, and while C-shaped electromagnet cores have been indicated and discussed, there is a distinct possibility that the electromagnet cores are just I-shaped or even a short cylinder which is several times wider than it is tall. These more simple shapes could make it very much easier to construct, although the C-shaped core need only be three straight sections placed together.

It is essential to construct each of the cores of the electromagnets from iron and only iron. While a laminated core does minimise eddy currents, in this application, a laminated core has a major negative magnetic effect (something which is not generally known).

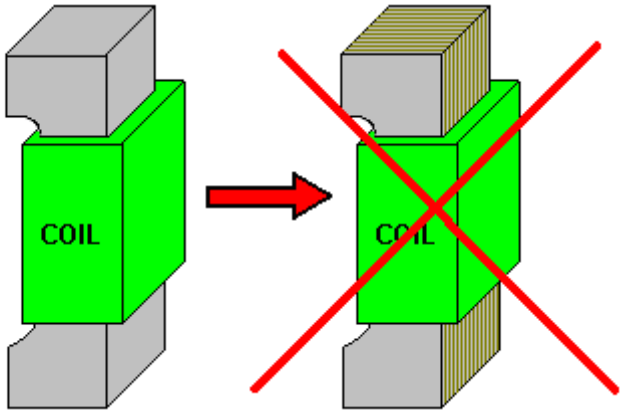


Fig. 22

I have to agree wholeheartedly with the anonymous contributor when he recommends that any attempted replications stay as close to the arrangement shown in the patent drawing, and have seven separate sets of three electromagnets. However, for subsequent experiments, a somewhat easier construction with just one set of electromagnets might be tried, making the electromagnets equal in length to the seven separate units:

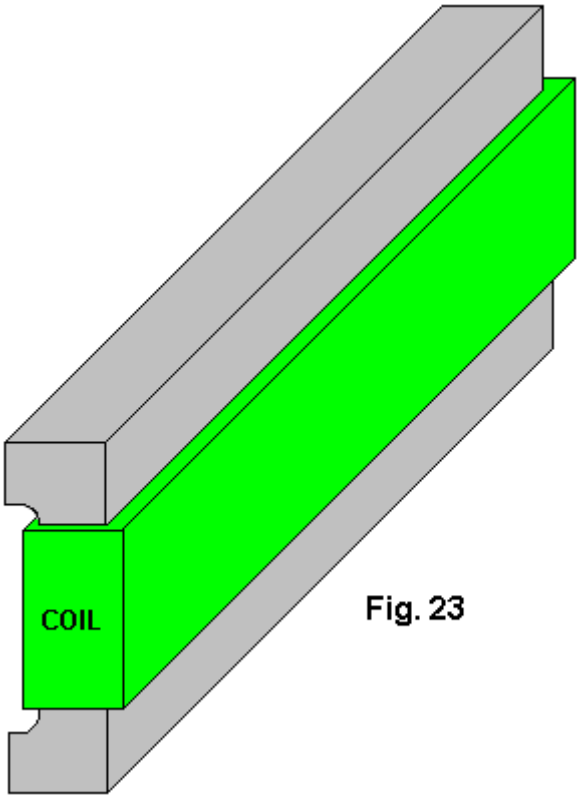

Fig. 23

This arrangement has advantages if the design is taken on into manufacturing as less construction is needed.

Figure 15 shows two electromagnets connected at the top to the battery Minus and at the bottom to the battery Plus. But, one is marked with a North pole at the top and the other with a South pole at the top, so perhaps some explanation would be helpful. If the coils are connected that way, then one will have to be wound in a clockwise ("CW") direction and the other in a counter-clockwise ("CCW") direction:

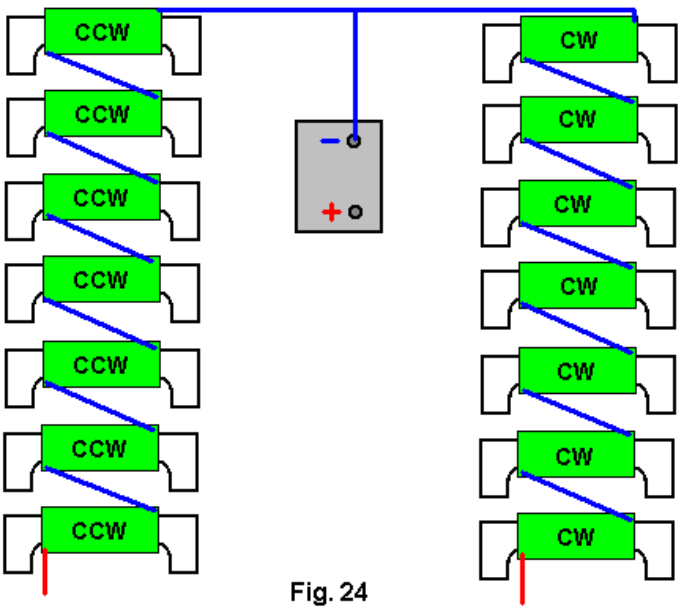

Fig. 24

Or the alternative is to have all of the electromagnets wound in the same way, and adjust the connections:

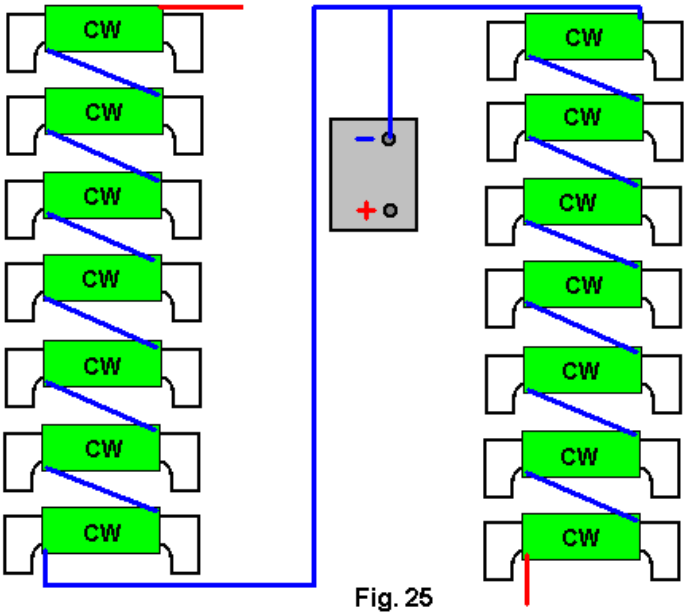

Fig. 25

The Figuera design was implemented more than a hundred years ago, and so Clemente did not have any semiconductors available to him, and so he used a motor-driven commutator arrangement to produce the electrical switching which he needed.

While I am in no way opposed to mechanical switching, especially where prototypes are concerned, there has to be an advantage in using solid-state switching, and while I am by no means an expert in that field, the following suggestions might be useful for experienced circuit builders.

In spite of the wire-wound resistor bank having only eight connection points, the switching has to have sixteen outputs due to the backwards and forwards switching sequence which is used. A solid-state 16-way switching module can be constructed from two CD4017 Divide-by-Ten integrated circuits like this:

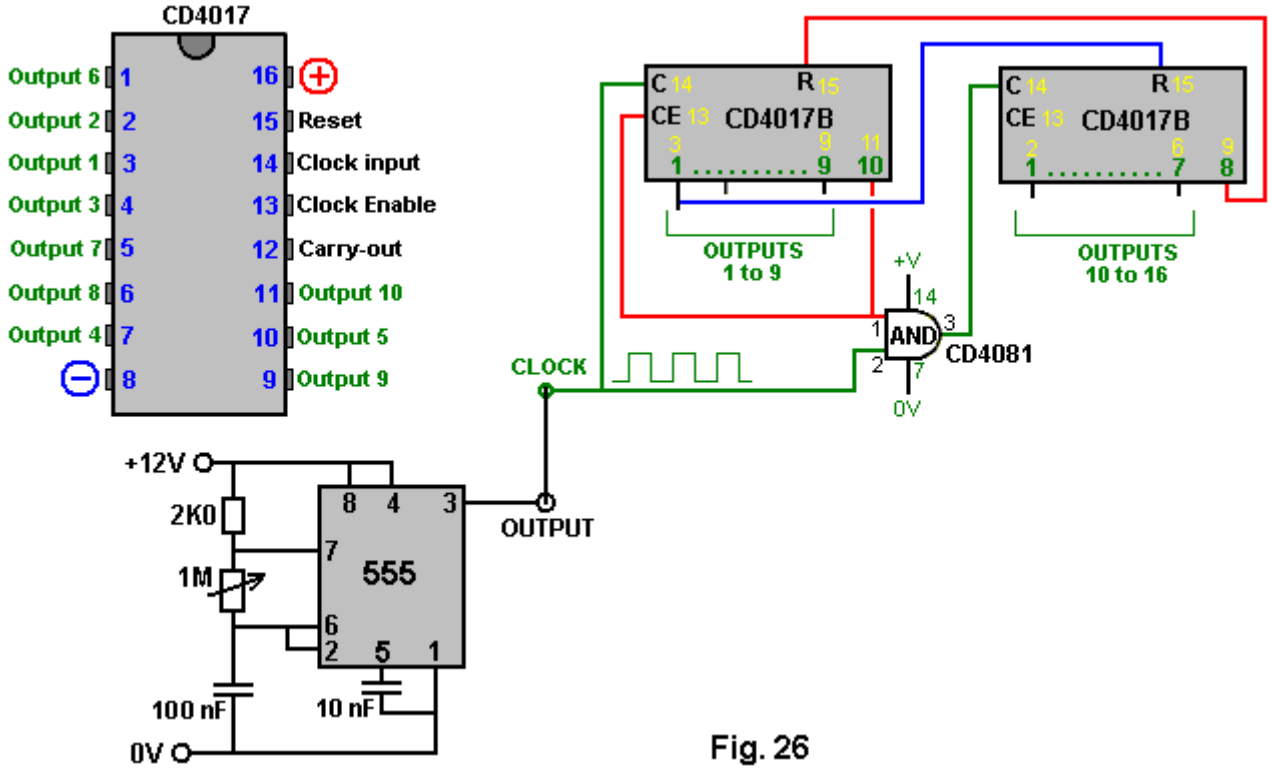

Fig. 26

This arrangement gives sixteen outputs in sequence, so two outputs need to be connected together in order to match the mechanical switching which Clemente used. Presumably, it would not be advisable to connect two outputs directly together, and so an isolation diode (say, a 1N4148 type) would be required on each output.

Please note that the pin connections shown here have been revised as it appears that in this circuit, the output pin 3 of the second 4017 chip does not function as expected:

Output Number	Chip and Pin Nos	Paired with Output	Resistor Connection Point
1	Chip 1 Pin 3	16 (Chip 2 pin 6)	1
2	Chip 1 Pin 2	15 (Chip 2 pin5)	2
3	Chip 1 Pin 4	14 (Chip 2 pin1)	3
4	Chip 1 Pin 7	13 (Chip 2 pin 10)	4
5	Chip 1 Pin 10	12 (Chip 2 pin7)	5
6	Chip 1 Pin 1	11 (Chip 2 pin 4)	6
7	Chip 1 Pin 5	10 (Chip 2 pin 2)	7
8	Chip 1 Pin 6	9 (Chip 1 pin 9)	8
9	Chip 1 Pin 9		
10	Chip 2 Pin 2		
11	Chip 2 Pin 4		
12	Chip 2 Pin 7		
13	Chip 2 Pin 10		
14	Chip 2 Pin 1		
15	Chip 2 Pin 5		
16	Chip 2 Pin 6		

Eight power transistors can be used to energise each resistor connection point in the sequence required. As mechanical switching was used by Clemente, it really did not matter which way round the battery connections were made. We can match his switching exactly by using PNP power transistors (or possibly, P-channel FETs) which would make the arrangement like this (with just two of the eight connections being shown):

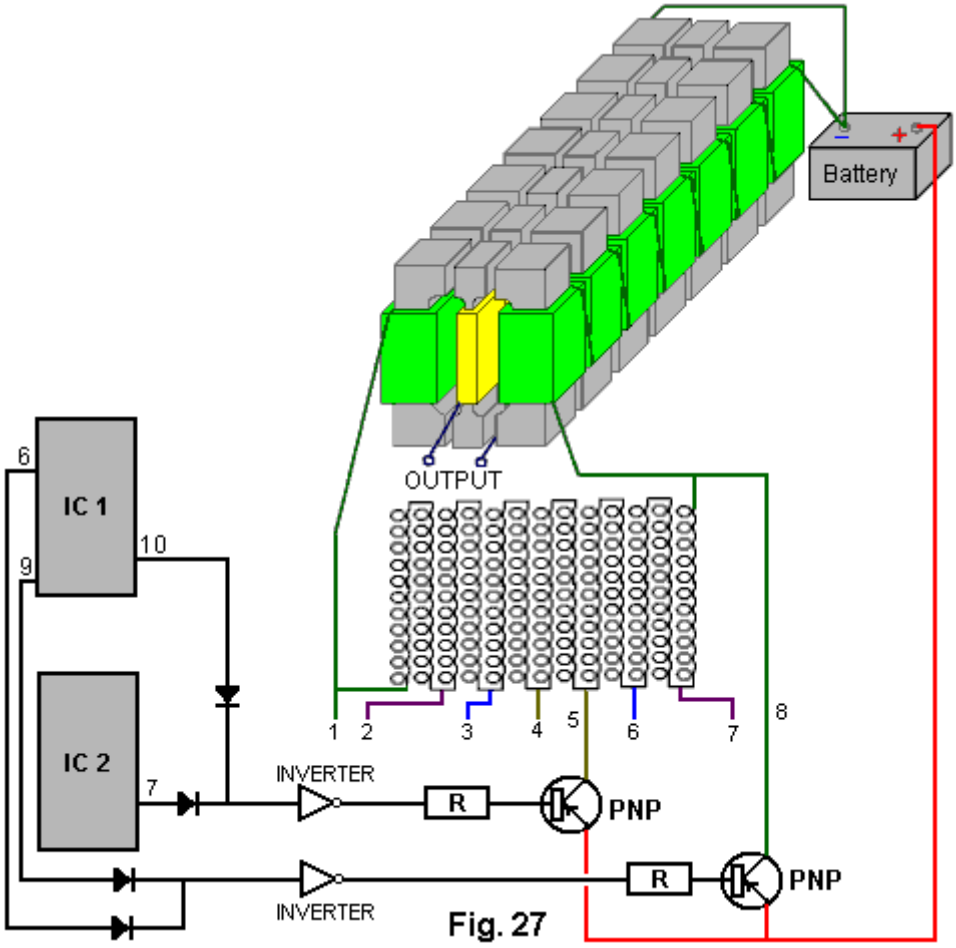

Fig. 27

Or you can reverse the battery for the easier NPN option:

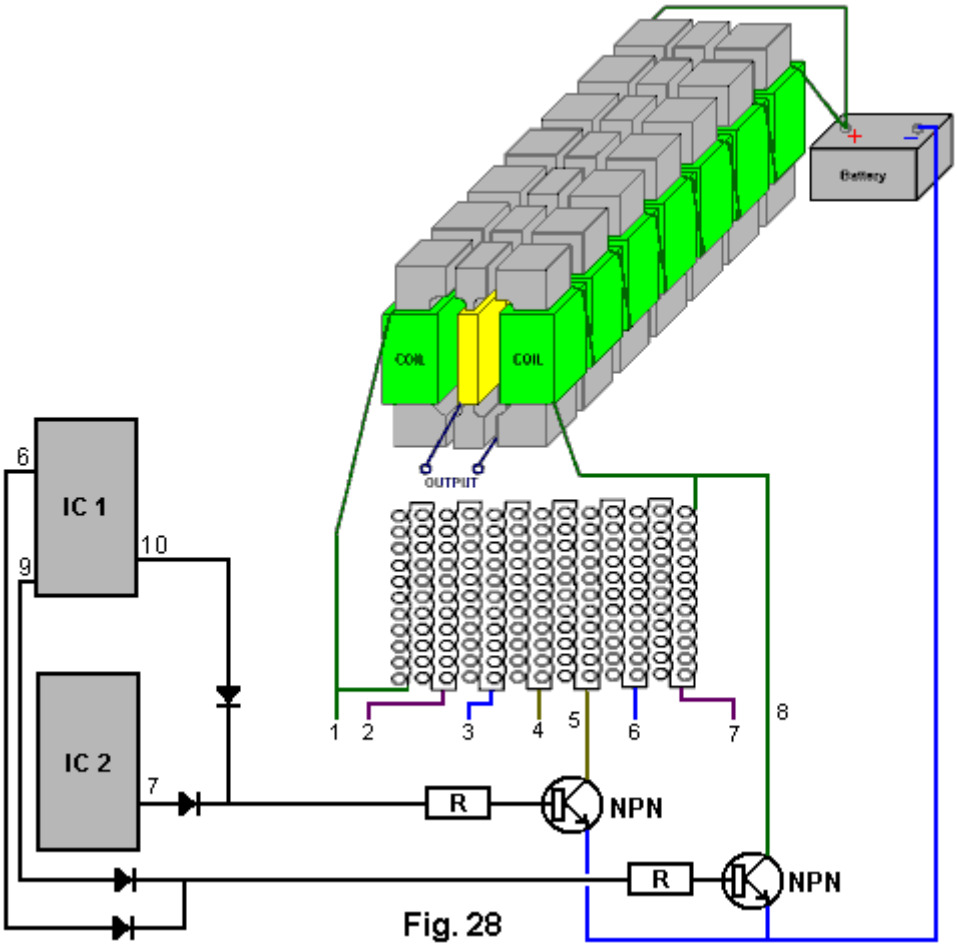

Fig. 28

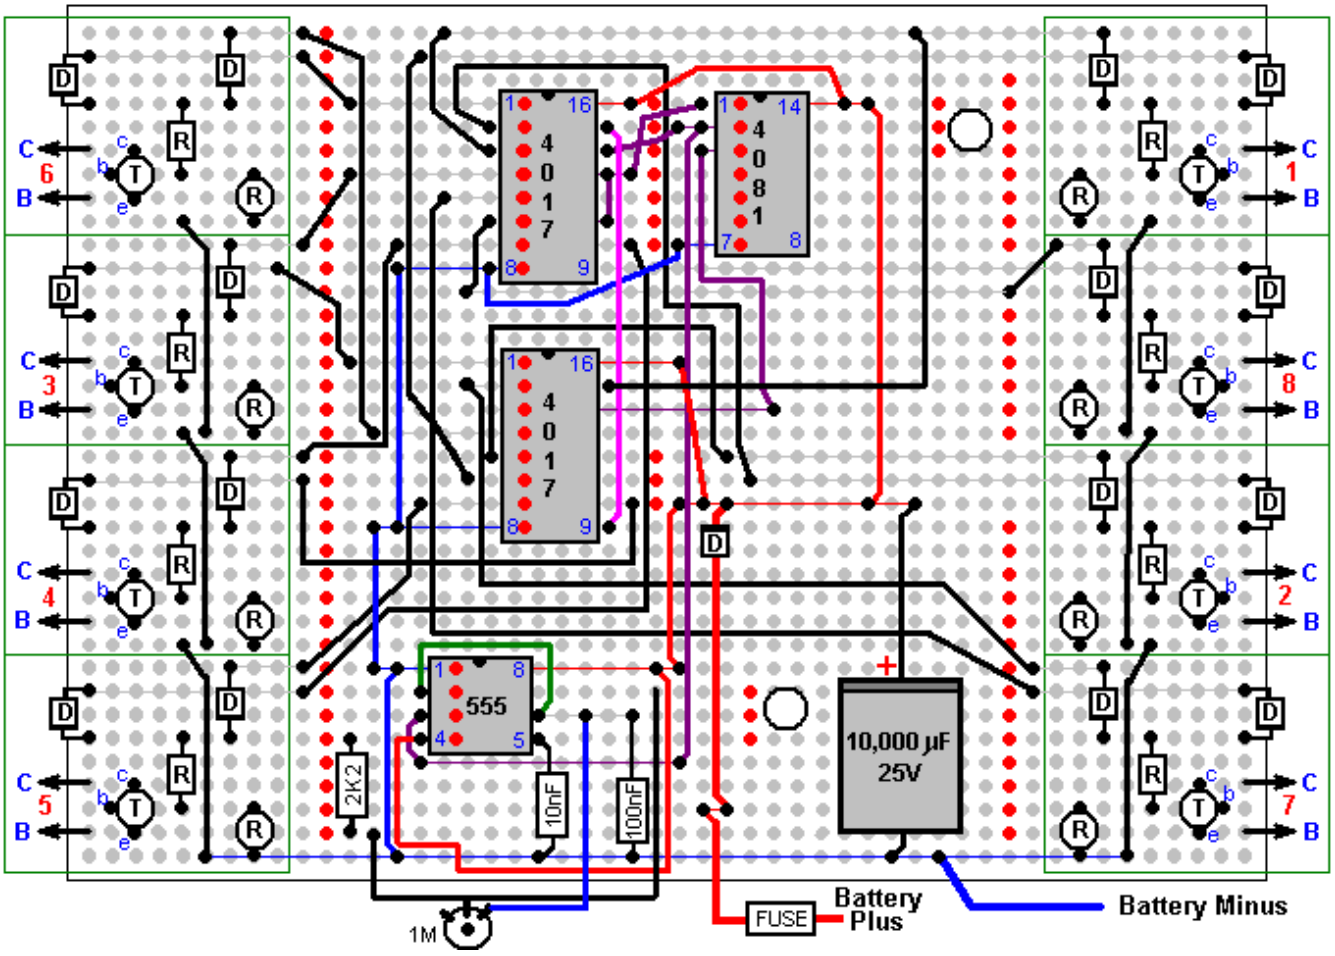
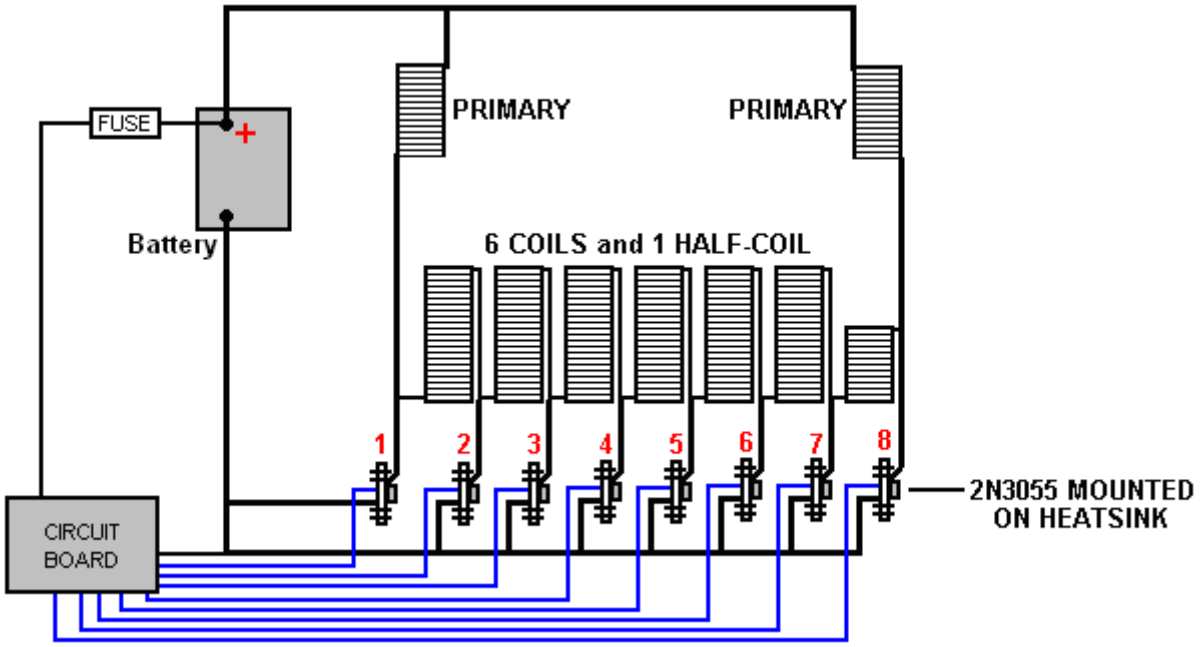
I have been asked by an electronics novice to show a possible construction form for this sort of circuit. I am not particularly good at that sort of thing, but here are a couple of diagrams of a non-optimised layout for a standard size of common stripboard:

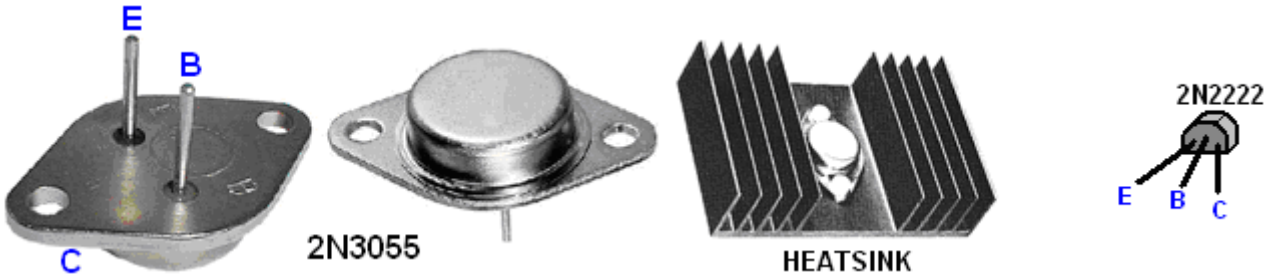
T = 2N2222 Transistor D = 1N4001 Diode R = 4.7K Resistor

C = Connection to 2N3055 Collector B = Connection to 2N3055 Base

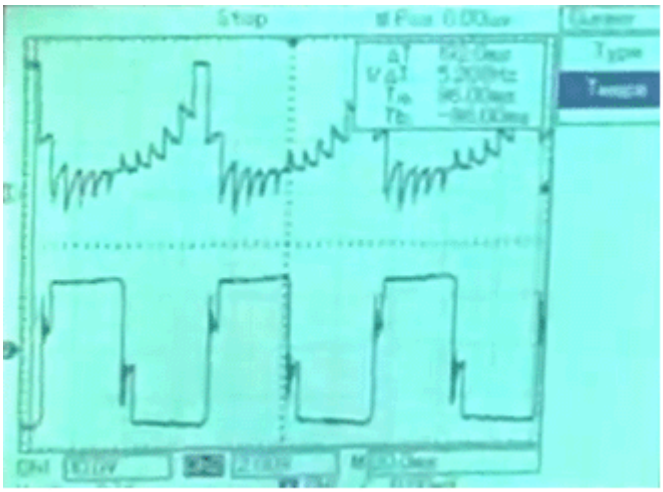
● = Break in the copper strip on the underside of the board



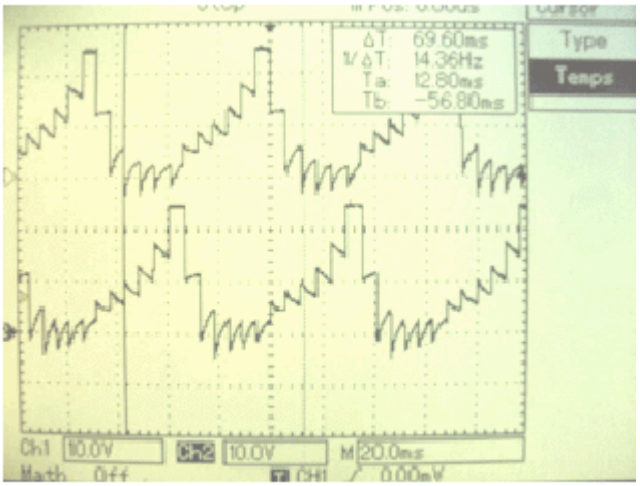




Experienced experimenter 'Woopy' has posted a video of a quick experiment to test the working principle of this Figuera design. It is at http://www.youtube.com/watch?v=HlOGEnKpO-w&feature=g-u-u and in it, he short-circuits the secondary winding, showing that the input power is totally unaffected by the current draw from the secondary.
He shows some very interesting oscilloscope shots:



One primary and the secondary output



Both primaries, showing their phases

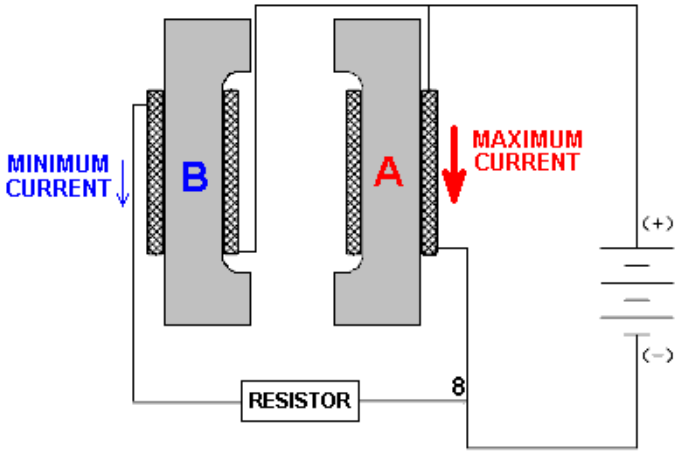
The first screen shot surprises me as it shows clearly that the output is actually an excellent square wave while I would have expected it to be a sine wave as it is coming from a coil which has inductance. The second shot shows very clearly, how the two banks of primary electromagnets operate out of phase with each other thanks to Woopy's mechanical 6-way switching arrangement. It is reported that Mr Figuera ran a 20-horsepower motor with his prototype and if that motor were fully loaded, then that is 15 kilowatts of power, easily enough to power a household.

Please bear in mind that if the electromagnets are made from iron, whether laminated or not, that iron restricts the frequency, probably to 500 Hz or less, and so it is necessary to keep the frequency that low if using a solid-state circuit to drive the transformer. For 60 Hz output with mechanical switching, requires the motor to run at 3,600 rpm which is fairly fast although definitely achievable. Also, the output power will be limited by the current handling capacity of the wire in the secondary winding. The first page of the Appendix shows the current capacities for the standard AWG and swg wire sizes.

Because this Figuera design is so important, being low-voltage, high power and not needing tuning I have recently been asked to explain it in greater detail and suggest some component values for people starting to experiment with it. I am not an electronics expert, and so my suggestions need to be taken as just that, namely, suggestions for a possible starting point for experimentation.

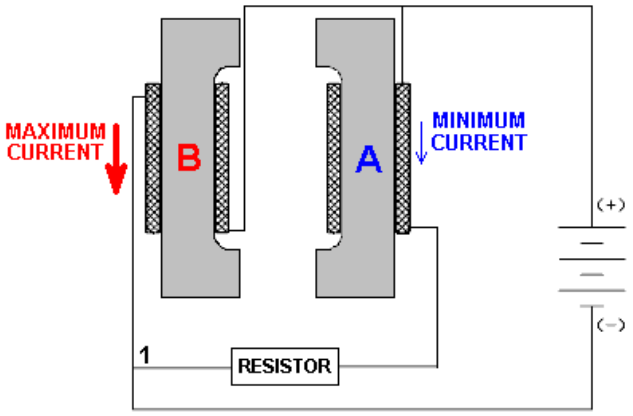
The first point is that the two halves of the primary winding of the transformer become electromagnets when current flows through their windings. The strength of an electromagnet increases as the current flow increases. Large current: strong magnet. Small current: weak magnet.

Clemente Figuera's circuit is arranged so that the current through the windings is made to vary so that when one magnet is strong, the other one is weak. It works like this:



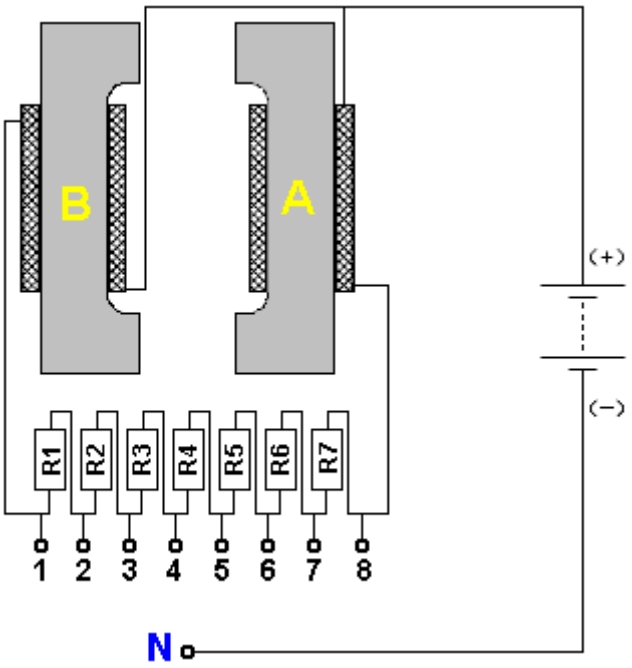
When the mechanical (or transistor) switching connects the battery to point ‘8’ in the previous diagrams, we get the situation shown above. Current from the battery flows directly through the right-hand electromagnet “A”, making it the strongest magnet that it can be at that battery voltage. The electromagnet “B” on the left gets current flow from the battery all right, but that current is reduced because it has to flow through the resistor.

When the switching changes and the battery is connected to point “1” in the previous diagrams, we get this arrangement:



Here, electromagnet “B” is free of the resistor and gets it’s maximum possible current, making it the strongest magnet which it can be at that battery voltage, while electromagnet “A” has it’s current reduced by the resistor getting in the way, making it the weakest magnet it can be when the system is running.

If we switched between these two positions, we would get a square wave style of operation, but Clemente did not do that. Instead, he split the resistor into seven parts (if Fig.14 is drawn correctly, one part having only half the resistance of the other parts). This makes the arrangement like this:



When the battery negative “N” is connected to point “2”, then the current flow through electromagnet “B” is hindered by resistor R1, but the current flow through electromagnet “A” is hindered by resistors R2 and R3 and R4 and R5 and R6 and R7, which together, have a far higher resistance than R1 on its own. This makes the current flow through electromagnet “B” far greater than the current flow through electromagnet “A”.

When the battery negative “N” is connected to point “3”, then the current flow through electromagnet “B” is hindered by resistor R1 and resistor R2, but the current flow through electromagnet “A” is hindered by resistors R3 and R4 and R5 and R6 and R7, which together, have a far higher resistance than resistors R1 and R2. This makes the current flow through electromagnet “B” still greater than the current flow through electromagnet “A”.

When the battery negative “N” is connected to point “4”, then the current flow through electromagnet “B” is hindered by resistors R1, R2 and R3, and the current flow through electromagnet “A” is hindered by resistors R4, R5, R6 and R7, which together, have a higher resistance than resistors R1, R2 and R3. This makes the current flow through electromagnet “B” somewhat greater than the current flow through electromagnet “A” (nearly a balanced flow as resistor R7 is only half the value of each of the other resistors.

When the battery negative “N” is connected to point “5”, then the current flow through electromagnet “B” is hindered by resistors R1, R2, R3 and R4, while the current flow through electromagnet “A” is hindered by resistors R5, R6 and R7, which together, now have a lower resistance than resistors R1, R2, R3 and R4. This makes the current flow through electromagnet “B” somewhat less than the current flow through electromagnet “A”.

When the battery negative “N” is connected to point “6”, then the current flow through electromagnet “B” is hindered by resistors R1, R2, R3, R4 and R5, while the current flow through electromagnet “A” is hindered by resistors R6 and R7, which together, now have a much lower resistance than resistors R1, R2, R3, R4 and R5. This makes the current flow through electromagnet “B” much less than the current flow through electromagnet “A”.

When the battery negative “N” is connected to point “7”, then the current flow through electromagnet “B” is hindered by resistors R1, R2, R3, R4, R5 and R6, while the current flow through electromagnet “A” is hindered by resistor R7, which has a very much lower resistance than resistors R1, R2, R3, R4, R5 and R6 together. This makes the current flow through electromagnet “B” very much less than the current flow through electromagnet “A”.

Clemente has arranged the battery switching sequence to be to points 1, 2, 3, 4, 5, 6, 7, 8, 8, 7, 6, 5, 4, 3, 2, 1, repeating over and over again. This makes the connections to points 1 and 8 to be twice as long compared to the connection times for the intermediate points, giving a sine-wave shape rather than a sawtooth shape.

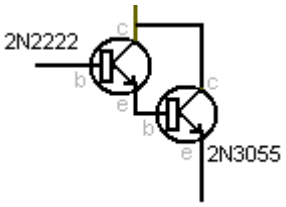
There is current flow through both electromagnets at all times. The current flow is never broken although, as you can see, the intensity of the current flow varies all the time with each electromagnet getting stronger than the other one repeatedly.

The mechanical switching used by Clemente will work perfectly well, although there will be motor noise and wear on the switch contacts. A solid state version will be silent, more reliable and much longer lasting. There are many

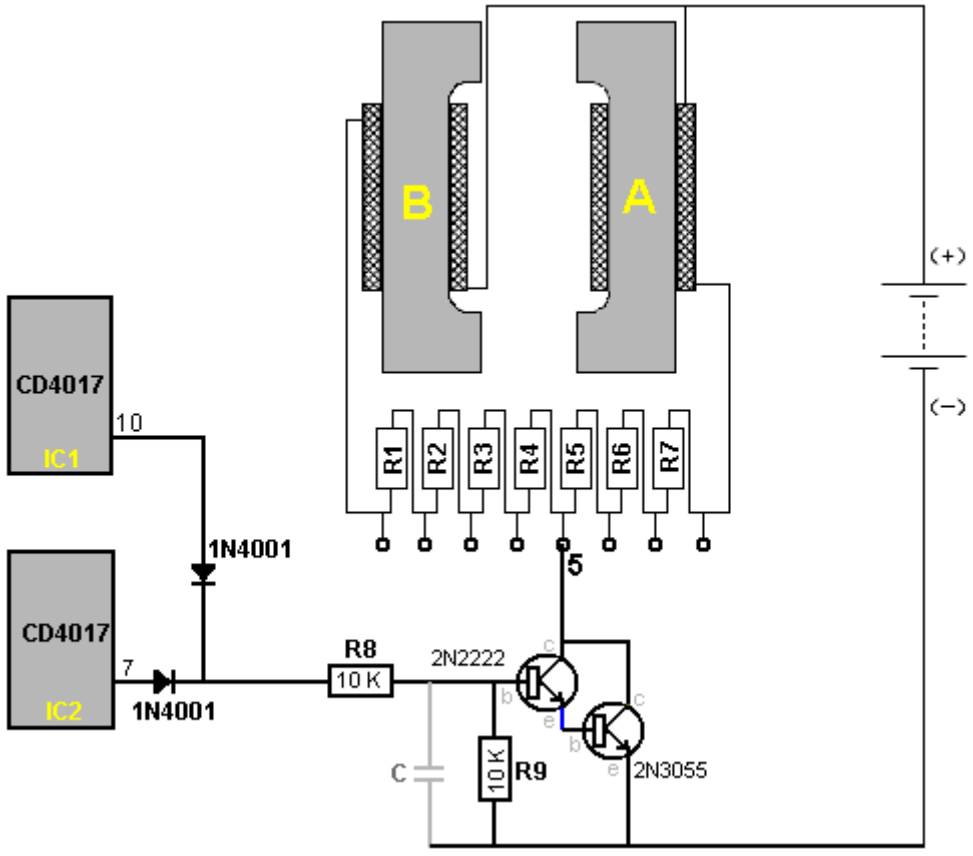
different way to build most electronic circuits and each builder will have his own favourite way of constructing the circuit. This Figuera circuit does not specify the battery voltage and so some people will want to use a twelve volt battery. As many FET transistors need as much as ten volts in order to switch on properly, a twelve volt supply is probably a little low for them, and so I suggest using the older bipolar transistors.

As the transistor has to carry the current which passes through the electromagnets, it needs to be able to handle considerable current flow. The very common 2N3055 transistor can do that (as can many other suitable transistors). The switching rate is very, very slow for a transistor and so speed is not an issue. The voltage is very low, and so that is not an issue either and so the 2N3055 transistor is definitely a possible choice.

In common with most high-power transistors, the current gain is low being between 20 and 30 typically. That means that to switch it on properly, a current of one twentieth of the switched current has to be fed into the base of the transistor. That base current is too high to be convenient, so we can raise the transistor gain to around 6000 by adding in a low-power transistor such as the 2N2222 transistor. The two transistors are connected together in a configuration called a 'Darlington Pair' which looks like this:



In this arrangement, the two Collectors are connected together, while the Emitter of the 2N2222 transistor feeds into the Base of the 2N3055 power transistor. With a high gain of six thousand or so for our transistor pair, we need to limit the current flowing through their combined Base-to-Emitter junction, and so we introduce a current limiting resistor R8 in the following circuit suggestion:



The 10K resistor value shown would limit the transistor current to about nine amps, while a 4.7K resistor would allow around eighteen amps. Each transistor pair is only on for one eighth of the time, but the 2N3055 transistors need to be mounted on a heat-sink. If a single metal plate is used as a heat-sink for all eight 2N3055 transistors, then mica washers (available from the supplier of the transistors) must be used between each transistor and the plate because the Collector of each 2N3055 transistor is it's metal case and in this circuit, the Collectors do not connect to a common point. The mica washers pass heat but not electricity. Separate heat-sinks can, of course, be used.

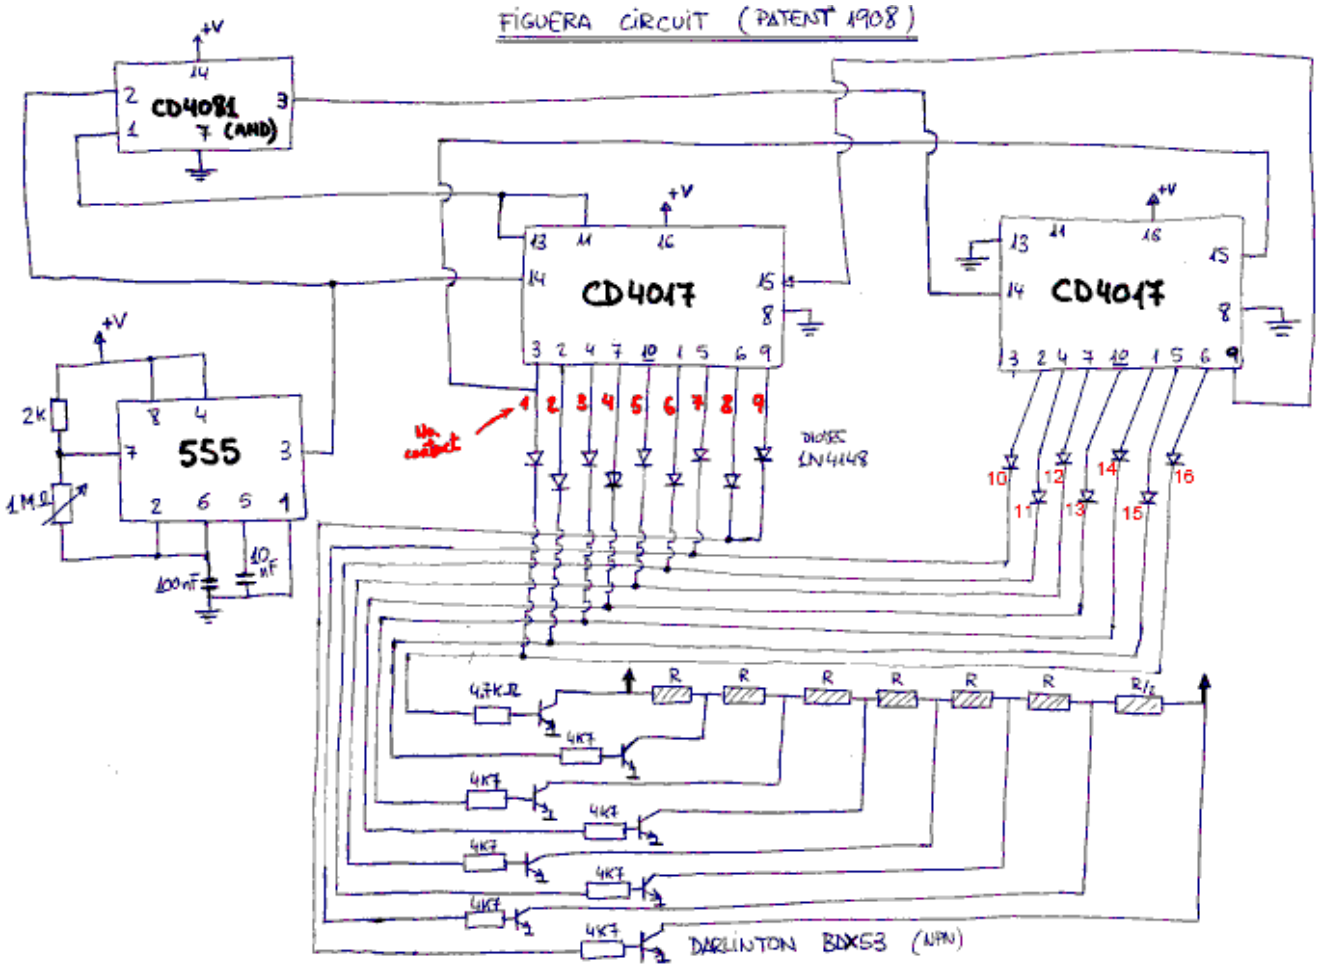
The capacitor “C” in the above circuit diagram will probably not be needed. The switching needs to maintain a constant current flow through both electromagnets. I would expect the 4017 chip switching to be fast enough to allow this to happen. If that proves not to be the case, then a small capacitor (probably 100nF or less) can delay the switch-off of the transistors just long enough to allow the next transistor in the sequence to be switched on to provide the required ‘Make-Before-Break’ switching.

As indicated in the table above, the 4017 pins which feed the transistor pairs through the 1N4148 (or similar) diodes are:

IC1 pin 3 and IC2 pin 6 for resistor connection point 1.
IC1 pin 2 and IC2 pin 5 for resistor connection point 2.
IC1 pin 4 and IC2 pin 1 for resistor connection point 3.
IC1 pin 7 and IC2 pin 10 for resistor connection point 4.
IC1 pin 10 and IC2 pin 7 for resistor connection point 5.
IC1 pin 1 and IC2 pin 4 for resistor connection point 6.
IC1 pin 5 and IC2 pin 2 for resistor connection point 7.
IC1 pin 6 and IC1 pin 9 for resistor connection point 8.

This Figuera design is very attractive as it uses only simple, readily available materials, low voltage and does not require difficult tuning. It also has the potential to be self-powered if part of the output is used to provide a voltage-stabilised power supply for the input power and the remaining output power can be kilowatts if the wire diameters chosen can carry that much current. Chapter 12 explains electronic circuitry in more detail.

A contributor who wishes to remain anonymous does not like the circuit arrangement shown above and prefers this circuit which he has built and tested:

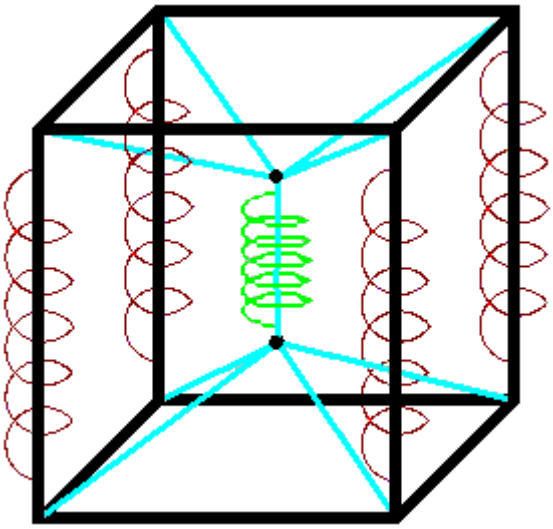


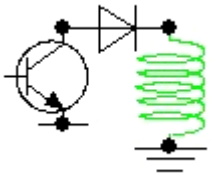
The NPN Darlington transistor BDX53 in this circuit is not available everywhere around the world and if that is the situation in your area, then using a 2N2222 transistor feeding a 2N3055 (or TIP3055) transistor as shown originally will work just the same.

The Alexkor Zero-Back-EMF Coils

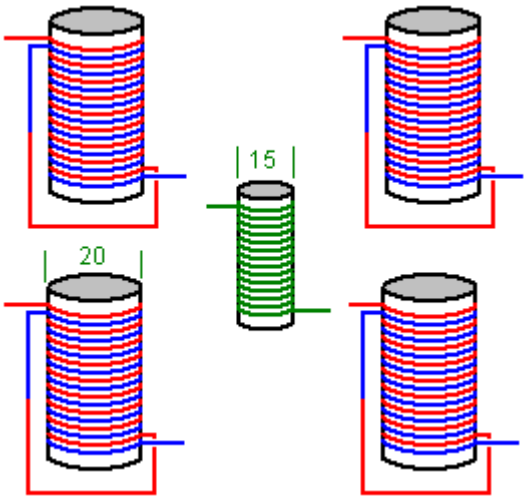
Alex in Russia who has shared several of his motionless pulse-charging systems for batteries, now shares his design which does not appear to have any back-EMF effect on the primary coil. If that is the case, then any increase in output current draw does not have a corresponding increase in the current flowing through the primary coil. That is completely different to the way in which a conventional transformer operates.

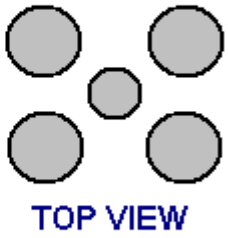
The arrangement is somewhat like the Transmitter / Receiver arrangement of Don Smith and while it looks to be a simple arrangement, is isn't. Alex draws his coil configuration like this:



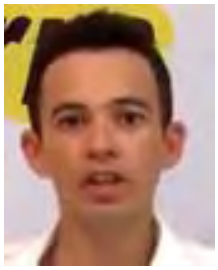


Here, his chosen form of construction is a frame of twelve lengths of 20 mm diameter plastic pipes – four at the top, four at the bottom and four verticals. Each pipe is filled with ferrite powder and there is an output coil wound on each of the four vertical pipes. Suspended in the centre is the primary coil which is 15 mm in diameter. All five coils are wound using 0.5 mm diameter enamelled copper wire (swg 25 or AWG #24). While Alex's drawing shows a single strand of wire, the actual arrangement for the four output coils is that they are wound as a single layer bi-filar coil:





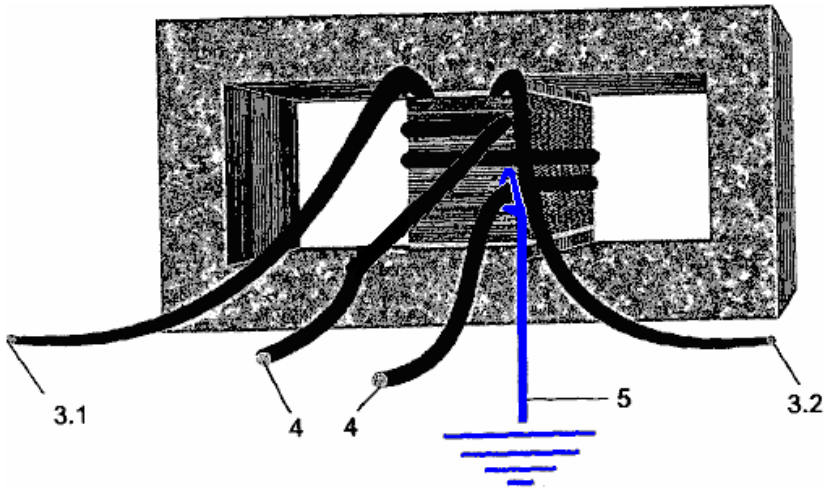
For this, the output coils are wound with two strands of wire side by side, in a single layer along the length of the plastic pipe. Then, the start of one wire is connected to the end of the other wire. As the coils are filled with ferrite, they can operate at high frequency, when the 15 mm primary coil is fed with either DC pulses or an AC sine wave. Each output coil can provide a separate output or the output coils can be connected in series to give a higher voltage or connected in parallel to give a higher output current.



The Self-Powered Generators of Barbosa and Leal

In July 2013, two Brazilian men, Nilson Barbosa and Cleriston Leal, published a series of patents which appear to be very significant. Their patent WO 2013/104042 published on 18th July 2013, is entitled "Electromagnetic device for Capturing Electrons from the Ground to Generate Electricity" and has some very interesting features. It describes a simple device which they describe as an "electron trap". Their patents are written in Portuguese and an attempted translation of three of them is included at the end of the Appendix.

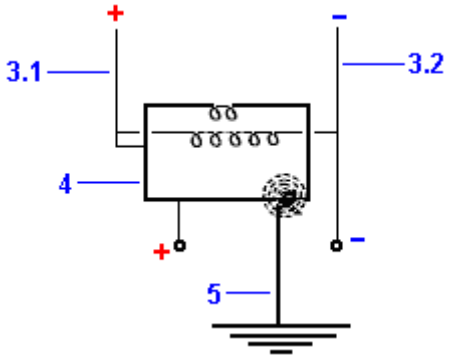
An unusual feature of this design is the fact that it has a continuous conductive loop, in which it is claimed, current flows continuously, even without the need for an applied voltage. Instead, it is the magnetic fields of electromagnets which keep the current flowing. They state that an insignificant amount of input power produces a substantial power output, and they consider a COP of 100 to be about the minimum performance which can be expected from the design. That is a 1 watt input for a 100 watt output. One version of the electron trap looks like this:



The inventors describe their device like this: "this electromagnetic-field-generating device, powered by a power source, produces an electromagnetic field which induces an electric current in a closed conductive circuit, creating an interaction between the magnetic poles of the equipment and the magnetic poles of the earth - through both electromagnetic attraction and repulsion. An endless supply of electrons is drawn from the earth into the conductive closed loop, which is connected to the ground through a conductive interconnected grid. The attracted electrons add to the current already flowing in the conductive closed loop, making power available for driving high-power loads, although the device itself is supplied with only a small amount of power."

One very interesting feature is that the continuous-loop coil formed by wire **4** in the diagram above, is literally, only two turns of wire. The power-gaining mechanism, amazingly, is the earth wire (shown in blue) which is merely wrapped around wire **4** and not directly connected to it as the electron-transfer link is by induction. With this arrangement, the current circulating in the closed loop wire **4**, attracts more electrons from the ground, flowing through the wrapped connection of wire **5,** into wire **4**, augmenting the current flow there by a major amount. Wire **3** can have an alternating voltage applied to it in order to get alternating current in wire **4**, but please understand that the current flowing in wire **4** is **not** the result of the current in wire **3**. If the current in wire **3** is DC, then the current in wire **4** will be DC as this is **not** a conventional transformer, but instead, it is an electron trap, operating in an entirely different way.

The electron trap can be connected in an AC circuit of this type:



Here, the earth wire **5** is wrapped around the continuous loop wire **4**, feeding it additional electrons captured from the ground. The ends of wire **4** are connected together to form the loop, and that connection also forms the positive side of the output (where a DC output is being produced). The magnetic field produced by the current flowing in wire **3**, acts on the electron flow coming from the earth, but as it does not provide any of the electric power flowing in wire loop **4**, the current flowing in wire **3** can be tiny, without affecting the power output.

In their patent WO 2013/104043, also of 18th July 2013, they show several different ways of connecting their electron trap in a useful circuit. For example, like this:

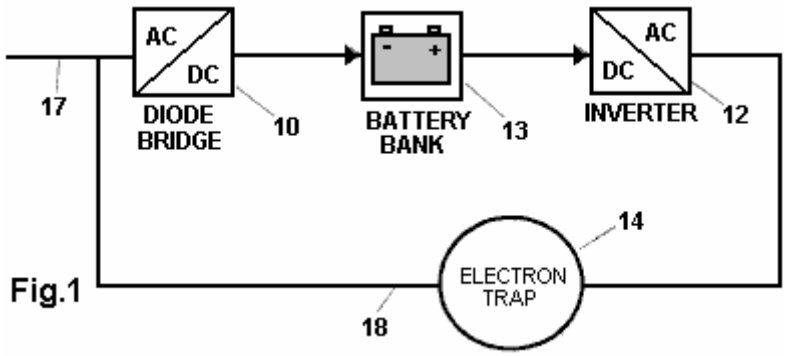


Fig.1

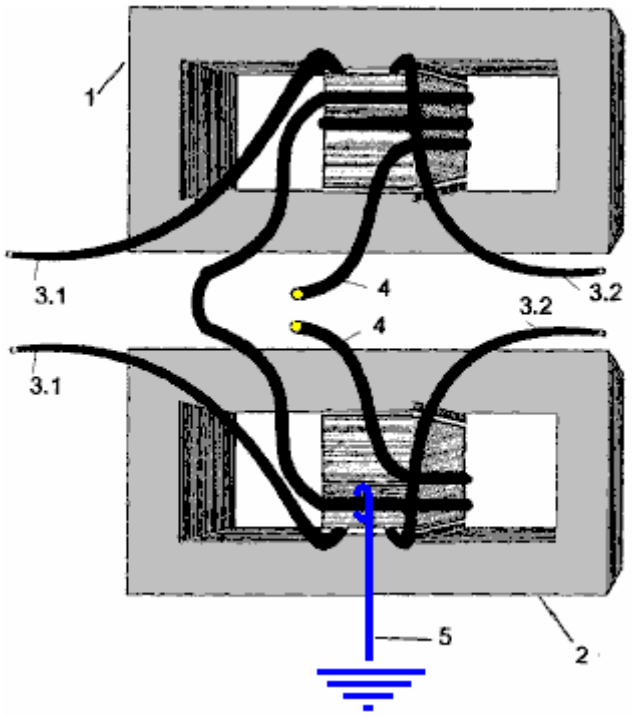
Here, the battery **13**, is used to power an ordinary inverter **12**, which produces a high alternating voltage, in this case, at very low power. That voltage is applied to the wire 3.1 to 3.2 of the electron trap, creating an oscillating magnetic field, which creates an oscillating inflow of electrons into the closed loop wire (4), which creates an amplified electrical output at the same frequency – typically 50 Hz or 60 Hz as those are the common mains frequencies. That amplified power output from the electron trap **14**, is passed along wire **18** to an ordinary diode bridge **10**, and the pulsing DC from the bridge is smoothed and used to replace the battery input to inverter **12**. The battery is now switched out of the circuit and, as well as making the overall circuit self-powered, the power coming from the electron trap is used to recharge the battery if it needs recharging (and/or, perhaps, to charge the batteries of an electric car). Because the electron trap needs almost no input power at all, the input power to the inverter is very small, and so a good deal of additional AC power can be drawn off through cable **17**, and used to drive powerful electrical loads, with no electrical power being needed from the battery. Being self-powered, the COP value for the circuit is infinity.

Just as there are several different ways of using an electron trap in a circuit, there are several ways of constructing and connecting an electron trap. While it is possible to arrange the components so that the power output is 2-phase or 3-phase, here we will just deal with the ordinary, household, single-phase power supply.

The first variation is to use more than one frame. Two frames can be connected like this:



This is the actual drawing from the patent and it presents a slight problem in that it is not physically possible to implement the number **4** wire in the way shown. Each frame will have two complete turns wound on it, although the drawing does not show this. Because of the inaccuracy of the drawing, I am not able to say if the coil turns on frame **2**, are in the same direction as those on frame **1**. There are four possible ways of winding these 2-turn coils when interconnecting them, so perhaps experimentation can be used to determine which method works best.

With this two-frame arrangement, there is just the one earth wire **5**, as before, again, it is wrapped around wire **4** rather than being physically connected to it. The continuous wire loop **4** has two ends as before, but there are now two **3.1** wire ends and two **3.2** wire ends. The Portuguese translation programs produce highly questionable results for this area of the patent, but I gather that the inventors intend the two 3.1 ends to be connected together and the two 3.2 ends to be connected together, and then the joined ends are treated exactly as before, effectively putting the two windings in parallel.

One disadvantage of this design is that it is not portable due to the earth connection. Barbosa and Leal deal with this problem in their patent WO 2013/104041 of the same date where they show a method of constructing an electron trap which collects excess electrons from the air. If you feel that there are no excess electrons in the air, then consider the fact that all of the aerial designs in chapter seven all extract and use those electrons. Also, consider the amount of electricity in a lightning strike, where much of the electrical energy comes from the air, and remember that world wide, there are between 100 and 200 lightning strikes every second.

The free-electrons-in-the-air electron trap is somewhat more complicated than the earth-wire electron trap, with four pairs of coils (**3** and **4**) being mounted inside two aluminium hemispheres (**1**):

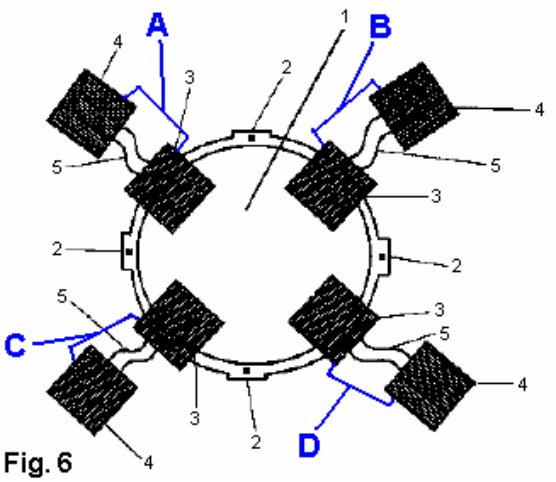


Fig. 6

The methods for using the air-electrons trap are the same as those for the earth-wire electron trap.

An earth-wire video demonstration is here: http://www.youtube.com/watch?v=iRSP7h73u-Q with 22 watts producing 6 kilowatts.

An attempted translation of the three Barbosa/Leal patents is here:

WO Patent 2013/104043 **18th July 2013** **Inventors: Nilson Barbosa and Cleriston Leal**

ELECTRIC ENERGY GENERATION SYSTEM WITH FEEDBACK

Note: These three patents are in Portuguese and what is shown here is a low-quality attempt at translation into English using a translation program. The originals can be downloaded free from: http://worldwide.espacenet.com/singleLineSearch?locale=en_EP.

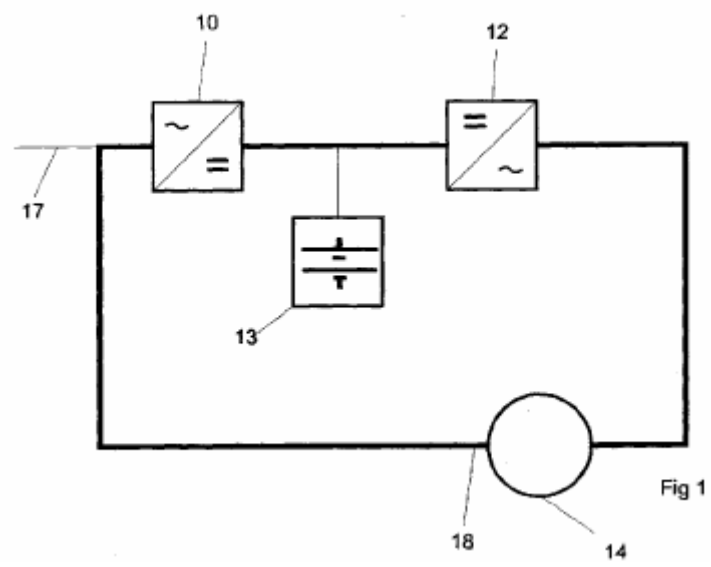

Fig 1

Abstract:
The present invention relates to electric energy generation equipment comprising a basic circuit formed by a rectifier (**10**), for example, an AC/DC converter connected in series to an inverter (**12**), for example, a DC/AC converter, and a bank of batteries (**13**) connected in series between the rectifier (**10**) and the inverter (**12**). An electron-capturing element (**14**), which can be either a free space electron-capturing element or, alternatively, an earth electron-capturing element, is connected in series to the basic circuit formed by the rectifier (**10**), the inverter (**12**) and the battery assembly (**13**). The bank of batteries (**13**) powers the basic circuit because it is connected to the system. Consequently, the inverter (**12**) converts direct current into alternating current and supplies this

current to the electron-capturing element (**14**). After receiving the electric current from the inverter (**12**), the electron-capturing element (**14**) starts capturing electrons from the alternating current and powering the rectifier (**10**), which converts the alternating current into a direct current in order to recharge the bank of batteries (**13**) and power the inverter (**12**) which powers the electron-capturing element, closing the feedback loop, and also providing electric energy for consumption by external loads.

WIPO Patent Application WO/2013/104043 Filing Date: 01/11/2013

SELF-POWERED ELECTRICITY GENERATOR.

Technical field

The present invention relates to a device for generating electricity, in particular self-powered equipment for generating electricity.

Description of the Related Art

There are many methods for generating electricity using electromagnetism, but all of these are electromechanical devices using magnets and have limited generating capacity and an ecological impact which makes them unsuited to large scale projects.

Objectives of the Invention

The aim of this invention is the sustainable generation of electricity, using a generator which is able to produce large amounts of electricity from an extremely low input current, which initially is supplied by a bank of batteries, but subsequently is supplied by the output from the generator which is also able to power external loads.

The above objective, and other objectives, are achieved by the present invention through the use of a typical Uninterruptible Power Supply circuit comprising of an AC/DC rectifier feeding a battery bank which powers a DC/AC inverter, which is connected to a device to trap electrons from space (as described in Brazilian patent application No. BR1020120008378 of 13th January 2012) or alternatively, a device which extracts electrons from the Earth (as described in Brazilian patent application No. BR1020120008386 of 13th January 2012), which then passes the extracted electrons to the AC/DC rectifier, charging the battery bank, thus closing the loop as well as providing electricity to power external loads.

The self-powered system for generating electricity from the present invention can be fixed or mobile. It is fixed when using electron capture from the earth due to the ground connection, or mobile when using electron capture from space.

The self-powered electricity generating system of this invention may be configured in several different ways, each using the same inventive concept but using different arrangements of components. Different versions include single-phase, two-phase or three-phase versions, producing outputs of any power and voltage.

Brief Description of the Drawings

The present invention will now be described with the aid of drawings, but this patent is not limited to the versions and details shown in these drawings, although they show additional details and advantages of the present invention.

The drawings:

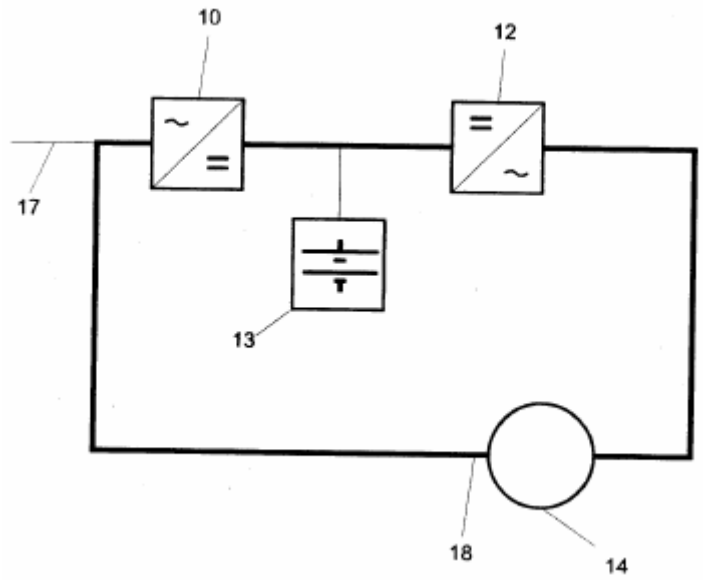

Figure 1 - shows a basic circuit system for self-powered electricity generation of the present invention

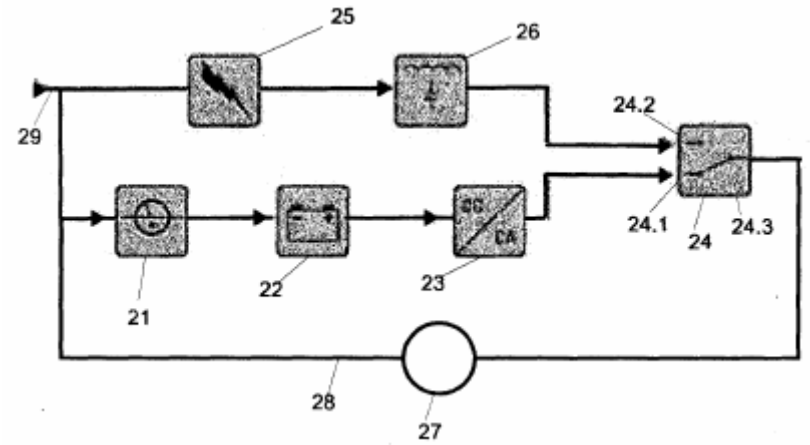

Figure 2 - shows a first embodiment of the constructive system for self-powered electricity generation of the present invention;

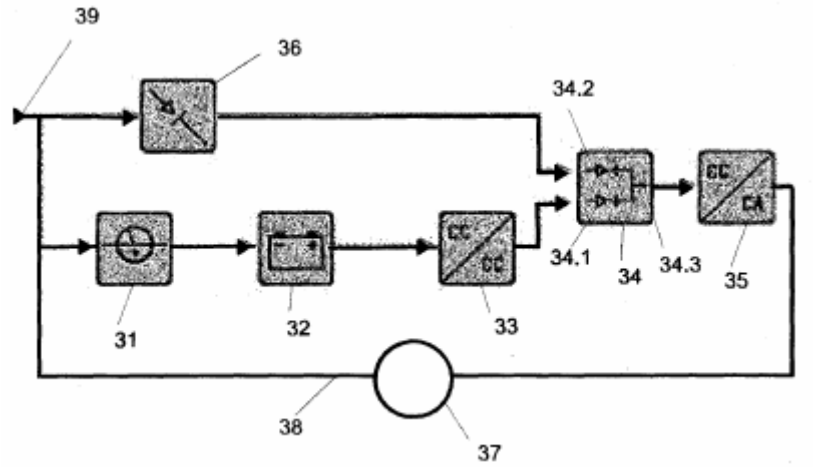

Figure 3 - shows a second embodiment of the self-powered system for generating electricity of the present invention;

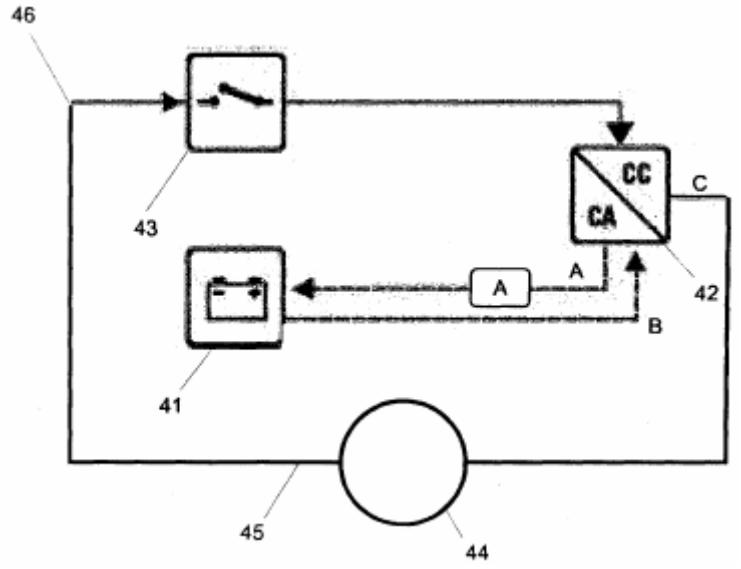

Figure 4 - shows a third embodiment of the self-powered system for generating electricity of the present invention;

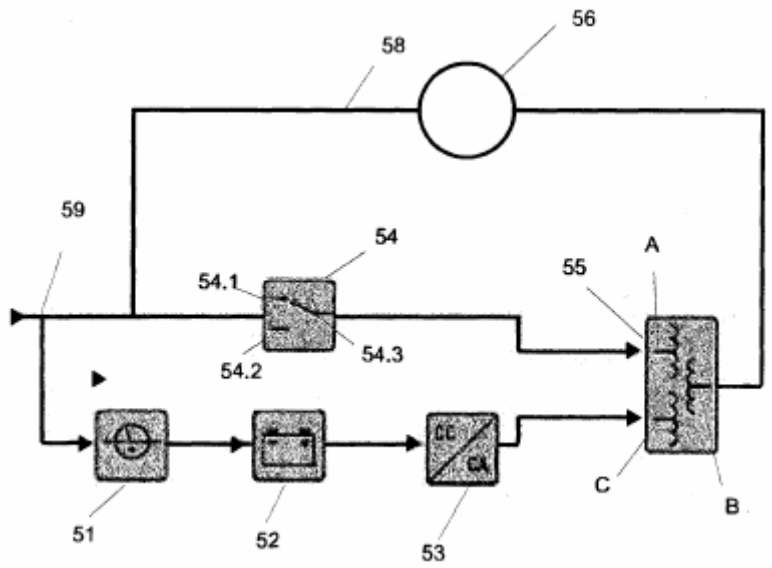

Figure 5 - shows a fourth embodiment of the self-powered system for generating electricity of the present invention;

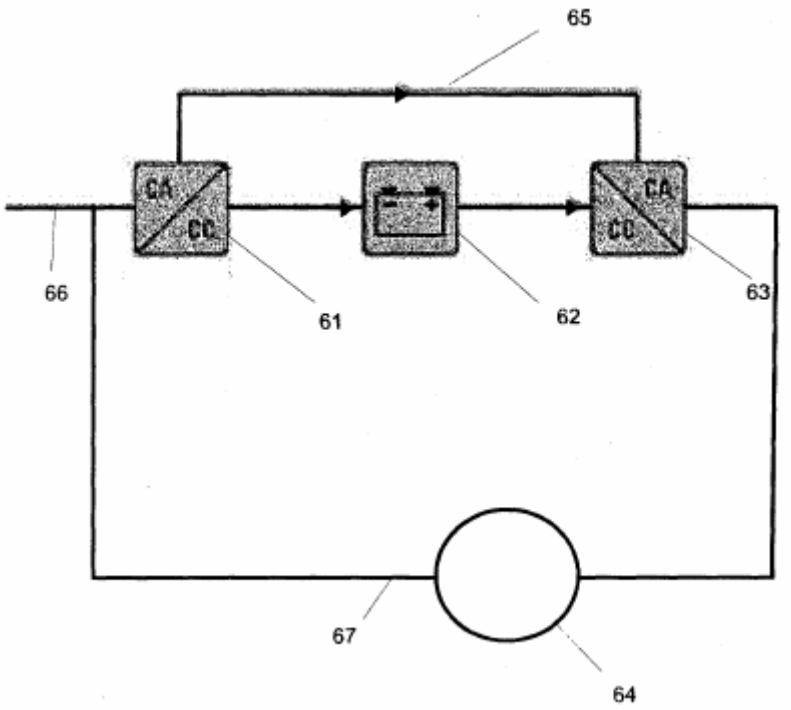

Figure 6 - shows a fifth embodiment of the self-powered system for generating electricity of the present invention;

Detailed description of the Invention:

There are different ways of closing the self-feeding cycle depending on the circuit configuration chosen. Some of these arrangements are shown in **Figures 2** to **6**, wherein the main circuitry continues to oscillate, continuously generating instant electricity.

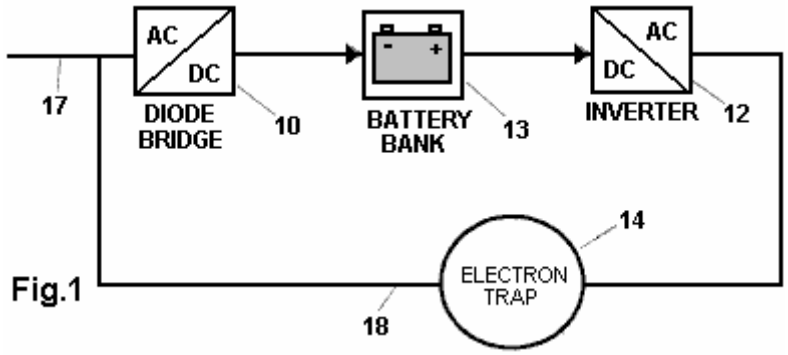

Fig.1

As shown in **Fig.1**, the self-powered system for generating electricity comprises a basic circuit consisting of a rectifier (AC/DC converter) **10** which is connected in series to an inverter (DC/AC) **12**. A bank of batteries **13** is connected between the rectifier **10** and the inverter **12**. The output from the DC/AC inverter **12**, connects to an electron-trap **14** which can extract electrons from space (as described in Brazilian patent application No. BR1020120008378 of 13th January 2012) or alternatively, extracts electrons from the Earth (as described in Brazilian patent application No. BR1020120008386 of 13th January 2012).

When connected, the battery bank **13** provides power to the DC/AC inverter **12** which converts the direct current into alternating current and provides current to the electron-trap **14**. The output of the electron trap **14** is passed through wire **18**, to the AC/DC bridge rectifier **10**, which keeps the battery bank charged as well as powering the DC/AC inverter **12**. Additional power is passed to external equipment through wire **17**.

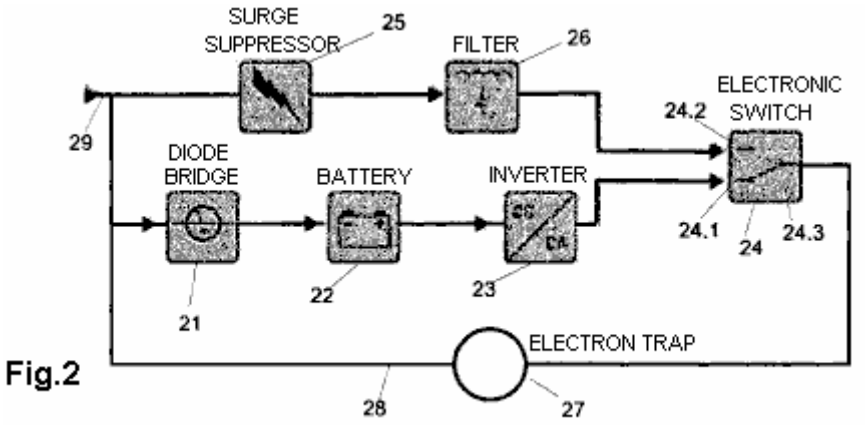

Fig.2

Fig.2, shows another embodiment of the system of this self-powered electric power generation equipment. It comprises a typical Uninterruptible Power Supply circuit of a battery charger (AC/DC converter) **21** connected to a drive device (a DC/AC inverter) **23** and between them, a battery bank **22** forming the basic circuit. Additional devices are an electron-trap **27** which may collect free electrons from space (as defined in Brazilian patent application No. BR1020120008378 of 13th January 2012) or, alternatively, collects electrons from the Earth (as described in Brazilian patent application No. BR1020120008386 of 13th January 2012). The 3-phase electronic switch **24** normally connects **24.1** to **24.3** connecting the electron trap **27** to inverter **23**. Connected in parallel is the surge suppressor **25**, which, when activated, via filter **26**, causes switch **24** to disconnect the **24.3** to **24.1** link and instead, connect **24.3** to **24.2**.

An alternative arrangement for use in emergency situations, is to use the system no longer self-powered. For this, the system is comprised of a power input from an external power source, directly to the interconnection point **29** to provide power to surge suppressor **25**, which provides power to feed the power output point **28** in order to power external loads. When the electron-trap **27** is turned off, the electronic transfer switch **24** reverts to its default position which connects point **24.1** to point **24.3** causing the circuit to function, once again, in its self-feeding mode. As soon as the electron sensor **27** provides sufficient power to the over-voltage sensor **25**, it operates the transfer switch **24** through filter **26**, ending the self-feeding phase and supplying energy directly to the power output point **28**, in order to feed external loads.

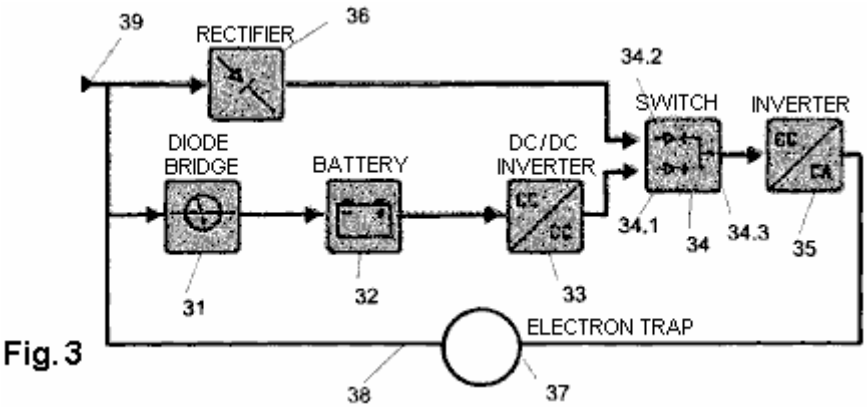

Fig. 3

Fig.3 shows another embodiment of the self-powered system for generating electricity, comprising a device which includes the basic circuit of a typical Uninterruptible Power Supply, consisting of a battery charger (AC/DC converter) **31** connected to a drive device (inverter DC/AC) **35** and attached to them, a battery bank **32**. This basic circuit together with other devices is connected to an electron-trap **37** for collecting free electrons from surrounding space or, alternatively, an Earth-connected electron trap **37**. We have then, a bank of batteries **32** connected to the DC/DC converter **33**, which is connected to the phase transfer switch **34 / 34.1** which is connected to point **34.3**, which connects to the inverter **35**, and so, the electron-trap **37**.

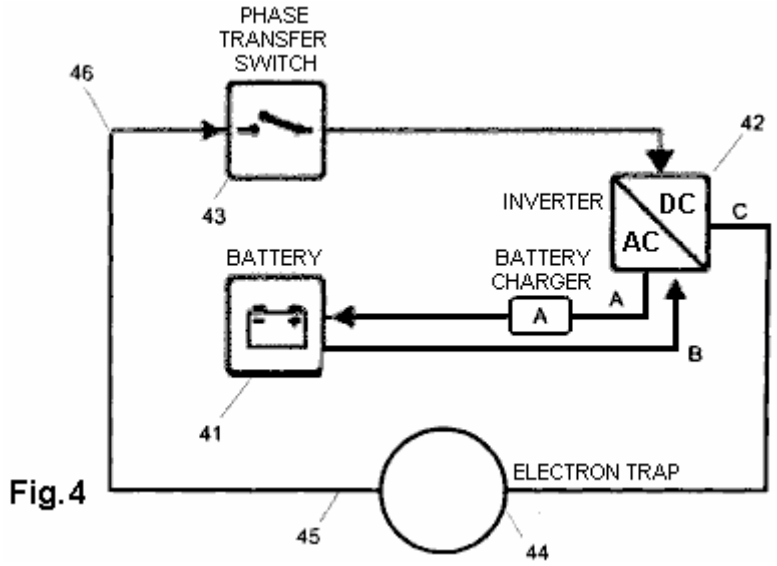

Fig. 4

Fig.4 shows another embodiment of the system for self-powered electricity generation which is comprised of a basic circuit of a typical uninterruptible power supply, consisting of a battery charger (AC/DC converter) **A** connected to an inverter (DC/AC) **42** and attached to them, battery bank **41**, and this basic circuit together with other devices are connected to a free space electron-capture device **44** or an earth-connection electron-trap **44**. Comprising thus, a battery charger **A** connected to a battery bank **41**, which is connected in series with inverter **42** at point **B** which is in series with point **C** of inverter **42** which is in series with the electron sensor **44**, which is in series with the phase transfer switch **43** via the three-phase load output connection point **45**. The phase transfer switch **43** is in series with the inverter **42**, which is connected in series the (AC/DC converter) battery charger **A** feeding the battery bank **41**.

An alternative construction for use in emergency situations, in which the system ceases to be self-powered, the system may include power input from an external power source, via the interconnection point **46**, thus providing electricity output **45**, to power external loads. The battery bank **41** provides power to the inverter **42** which converts the direct current into alternating current and feeds the electron trap **44**. The phase transfer switch closes when the batteries need recharging.

Sensor **44** captures electrons, producing alternating current, which feeds the phase transfer switch **43** with alternating current input power. The phase transfer switch **43** feeds the inverter **42** which charges the batteries, closing the self-powering loop which provides power at the output **45**, feeding both the power input and any external loads.

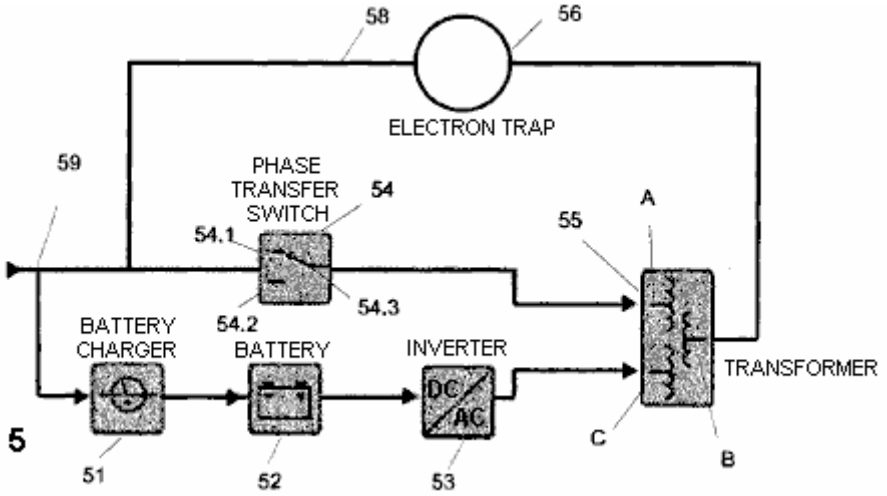

Fig. 5

Fig.5 shows another embodiment of the system for self-powered electric power generation equipment comprising a circuit which includes a typical uninterruptible power supply comprising a battery charger (AC/DC converter) **51** connected to a DC/AC inverter **53** and attached to them, a battery bank **52**. This basic circuit together with other devices are connected to a space free-electron capture device **56** (as defined in Brazilian patent application No. BR1020120008378 of 13/1/12) or, alternatively, an earthed free-electron collector **56** (as defined in Brazilian

patent application No. BR1020120008386 of 13/1/12). This then comprises a battery charger **51** which is connected in series with a battery bank **52**, which is connected in series with the inverter **53**, which is connected in series with the transformer **55** at its point **C**, which is in series with its point **B** which is in series with the electron collector **56**, which is in series with the battery charger **51** which is connected to the load exit point **58**, which is also the circuit entry point **59**, which is in series with the phase transfer switch **54** section **54.1**, which is connected to terminal **54.3**, which is in series with point **A** of the transformer **55** which exits at point **B**. Points **A** and **54.3** as well as the parallel points **54.1** and **54.2**, are all parallel to the battery charger **51**, the battery bank **52**, the inverter **53** and to point **C** of the transformer **55**.

An alternative construction for use in emergency situations, in which the system ceases to be self-powered, the system may include an external power input point **59**, allowing phase transfer switch **54** to provide power output **58**, to feed external loads. Battery bank **52** provides power to the inverter **53**, which converts the direct current into alternating current, feeding point **C** of the transformer, which comes out at points **B** and **A** of the transformer **55**. Point **B** of the transformer feeds the electron-trap **56** producing alternating current which feeds the battery charger **51**, recharging the battery bank **52**.

The battery charger **51** is connected in parallel with the transfer switch **54** via connection points **54.1** and **54.3**, feeding point **A** of the transformer, which comes out at point **B**. Point **A** of the transformer and the switch transfer points **54.3** and **54.1** are in parallel to the battery charger **51**, the battery **52**, the inverter **53** and point **C** of the transformer **55**.

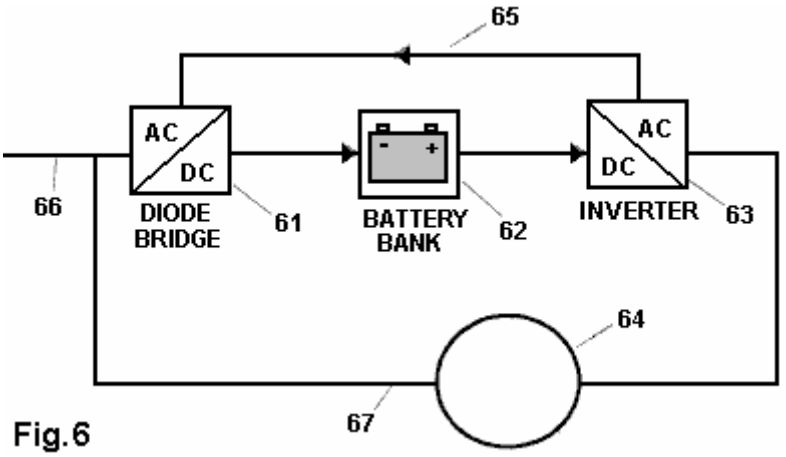

Fig.6

Fig.6 shows another embodiment where a rectifier **61** is connected to an inverter **63** and a battery bank **62**, and to a space free-electron trap **64** or alternatively, an earth electron trap **64** comprising thus, a delta (AC/DC) converter **61**, which is connected in series to a battery bank **62**, which is connected in series with the (DC/AC) inverter **63**, which is in series with the electron collector **64** which is connected in series with the delta converter (AC/DC) **61** whose AC part is in series with the alternating AC current inverter **63** via a connecting wire **65** which is in parallel with the DC part of the delta converter **61** with the battery bank **62** and the DC part of inverter **63**. An alternative construction for use in emergency situations, in which the system ceases to be self-powered, the system may comprise a power input from an external power source, via the interconnection point **66** connected to the delta converter **61**, the output **67** supplying power, to the external loads.

Battery bank **62** provides power to the inverter **63**, which converts the direct current into alternating current, powering the free-electron collector **64**. The captured electrons from collector **64** form an alternating current which feeds the delta converter **61** via an output power load wire **67**.

The alternating part of the three-phase delta converter **61** is fed with alternating current from inverter **63** via connecting wire **65**, which is connected in parallel to the continuous DC delta converter **61**, which feeds the battery bank **62** and with the continuous portion the inverter **63**, closing the cycle of self-feeding and supplying power at the output **67**, which is the output power point.

Having described examples of preferred embodiments, it should be understood that the scope of the present invention encompasses other possible forms of construction, using the electron collectors connected to a basic circuit of a typical uninterruptible power supply of energy, known as a UPS, comprising a rectifier device (an AC/DC converter) **10**, connected to one inverter (DC/AC converter) **12**, and attached between them, an energy storage device (typically, a battery bank).

A very important part of the above patent is the device described as a “collector of free-electrons”, either from the earth or from space. We have to go to the patent applications mentioned above to find the details of these designs:

ELECTROMAGNETIC ELECTRON TRAP FOR ELECTRIC POWER GENERATION

Technical Field

The present invention refers to electromagnetic equipment for electric power generation or alternatively for thermal power generation. More specifically equipment capable of producing abundant electricity and thermal energy from a tiny amount of input electrical energy

Description of the Related Art

According to Lenz's law, any induced current has a direction such that the magnetic field it generates opposes the change in magnetic flux which produced it. Mathematically, Lenz's Law is expressed by the negative sign (-) that appears in the formula of Faraday's Law, as follows.

The magnitude of the induced emf (ε) in a conducting loop is equal to the rate of change of magnetic flux (Φ_B) with time:

$$\varepsilon = -\frac{d\Phi_B}{dt} \qquad \text{Equation 1}$$

As an example of application of Faraday's Law, we can calculate the electromotive force induced in a rectangular loop that moves in or out, with constant speed, a region of uniform magnetic field. The magnetic field flux through the surface limited by the loop is given by:

$$\phi = xLB \qquad \text{Equation 2}$$

and its variation in time:

$$\frac{\Delta\phi}{\Delta t} = \left(\frac{\Delta x}{\Delta t}\right)LB = vLB \qquad \text{Equation 3}$$

So:

$$\varepsilon = vLB \qquad \text{Equation 4}$$

and if the coil has a resistance (R) and the induced current:

$$i = \frac{\varepsilon}{R} = \frac{vLB}{R} \qquad \text{Equation 5}$$

A conductor traversed by an electric current immersed in a magnetic field undergoes the action of a force given by:

$$F = I\vec{L} \times B \qquad \text{Equation 6}$$

Thus, the effect of the current induced in the loop appears as forces Ff, and F - FM. The first two cancel each other out and the third is cancelled by an external force P_{EXT} needed to maintain the constant speed loop.

As the force FM must oppose the force F_{EXT}, current (i) induced in the loop by varying the magnetic flux must have the meaning indicated in **Fig.3**. This fact is a particular example of Lenz's Law.

Considering the experimental activities discussed with Faraday's law, when a magnet approaches a coil, the induced current in the coil has a direction as shown in **Fig.1**. This generates a magnetic field whose north pole is

facing the north pole of the magnet, that is, the field generated by the induced current opposes the motion of the magnet.

When the magnet is moved away from the coil, the current induced in the coil has a direction opposite to that shown in **Fig.1**, thereby generating a magnetic field whose south pole is facing the north pole of the magnet. The two poles attract each other, that is, the field generated by the induced current opposes the movement of the magnet away from the coil. This behaviour is present in all current power generators, and known as 'engine brake' is highly undesirable as it increases the resistance and so, the energy loss.

When two electromagnetic coils are placed facing each other, as shown in **Fig.2**, there is no current in either of them. At the instant of power-up of one of the coils, the current in the coil, generates an induced current in the second coil. When powered up, the current in the coil goes from zero to its maximum value, and then remains constant.

Thus, when the current is changing, the magnetic field generated by it, (whose north pole faces the second coil) is also changing and so the magnetic flux of this field through the second coil is also changing. Then there is a current induced in the second coil whose sense is such that the magnetic field it generates tends to decrease the flow mentioned above, that is, its north pole confronts the north pole of the first field coil.

When the power switch is opened, the current in the first coil drops from its maximum value to zero, and correspondingly its magnetic field decreases. The flux of the magnetic field in the second coil also decreases, and the induced current now flows in the opposite direction. This current flow direction produces an enhancing magnetic field, that is, it has a south pole facing the north pole of the field of the first coil.

Thus, there is a realisation of the principle of conservation of energy, expressed by Lenz's law, wherein any induced current has an effect which opposes the cause that produced it. Assuming that the induced current acts to favour the variation of the magnetic flux that produced the magnetic field of the coil, it would have a south pole facing the north pole of the approaching magnet, causing the magnet to be attracted towards the coil.

If the magnet were then released, it would experience an acceleration toward the coil, increasing the intensity of the induced current and thus create an enhanced magnetic field. This field, in turn, would attract the magnet with increasing force, and so on, with a continuing increase in the kinetic energy of the magnet.

If energy were to be withdrawn from the magnet-coil system at the same rate at which the kinetic energy of the magnet increases, then there would be an endless supply of energy. So it would be a perpetually operating motor, which would violate the principle of conservation of energy. Therefore, it can be concluded that current generators feature a large energy loss during the generation of electricity.

Objectives of the Invention

An objective of the present invention is to contribute to the generation of sustainable energy, proposing an electromagnetic machine capable of producing abundant electricity from an extremely low input of electrical energy.

The above objective and other objectives are achieved by the present invention by a device comprised of at least one electromagnetic field-generating device (without a core or with at least one core) powered by an electrical power source (without a core or with at least one core) having their coils, or sets of coils, wound on at least one common conductive member in a closed circuit which itself has a polarised voltage which is connected to at least one conductive interconnection element which is connected to a grounding grid, these interconnections creating a new technical effect, namely, the appearance of an electric current which keeps circulating in a closed conductive loop, and which can therefore be used to power external loads.

The device which is the object of the present invention operates as follows: the electromagnetic field generating device, powered by a power source, produces an electromagnetic field which induces an electric current in a closed conductive circuit, creating an interaction between the magnetic poles of the equipment and the magnetic poles of the earth - through both electromagnetic attraction and repulsion. An endless supply of electrons is drawn from the earth into the conductive closed loop, which is connected to the ground through a conductive interconnected grid. Attracted electrons add to the current already flowing in the conductive closed loop, making power available for driving high-power loads, although the device itself is only supplied with a small amount of power. Thus, advantageously, the device which is the object of the present invention, acts as a trap for electrons from the earth and this allows the generation of electricity.

Advantageously, the present electromagnetic equipment generates either electricity or thermal energy, providing access to this new source of energy is through an electromagnetic field. The interconnections of the components

of the electron-trap of the present invention, cause an advantageous new technical effect, namely, the appearance of an electric current which keeps circling in the conductive closed circuit, with or without voltage being applied and even without a load being connected to the loop - provided that the electron-trap is connected.

The proposed sensor can also be used to generate thermal power, depending on the form in which you want to use the effect of the flow of electrical current produced in this electromagnetic equipment.

For the generation of thermal energy in amounts proportional to the power of the electron-trap, through the movement of electrons in the conductive closed loop itself, the resistance should be increased by increasing the number of turns around the cores in the conductive element of the closed circuit, and in that instance, the coils of the electromagnetic field generating device, will then be made of heat-insulated electrical circuit components, bearing in mind the required temperature which is to be produced. The thermal energy generated by the electron-trap can be used in any application from domestic to industrial applications.

This technology can also be used for various technical purposes in electric machines. By "electrical machines", it should be understood to include: static electrical machines, transformers, ballasts, rotating electrical machines, synchronous machines, dual power supply machines, current rectifiers in synchronous cascade, external pole machines, synchronous current machines alternating current machines and/or direct current machines, electronic equipment and electrical resistances. The capture of electrons can provide single-phase, two-phase or three-phase supplies, operating at low, medium or high voltage.

The capture of electrons by induction, does not impact on the environment. The fact is that we use as the capturing force, only a negligible amount of electricity relative to the current captured by the sensor. The relationship between power input and the quantity of electricity generated by the electron-trap is at least 1 to 100, that is, for each 1 watt provided to the sensor, there is at least 100 watts of power available for external loads. This relationship, however, is not limited, as it depends on the mounting of the electron-trap and the objectives of the circuit, and so, the generated power can be greater than 100 times the input power.

Another advantage of the earthed electron- trap proposed in the present invention is that the electron-trap can transport electrons from point "A" to point "B" without a voltage drop across the closed-loop conductive element - if it is biased with a voltage - regardless of the distance between the points depending on the strength and quantity of the electromagnetic field generating devices. It is also possible to transport electrons when the conductive element in a closed circuit is itself not polarised. Thus, the electric current is transported without voltage, just by the magnetic field formed between the device and the generator of the electromagnetic field.

Brief description of the Drawings

The present invention will now be described with the aid of drawings, but the design is not limited to the implementations shown in these drawings, although they show other details and advantages of the present invention.

Detailed Description of the Drawings

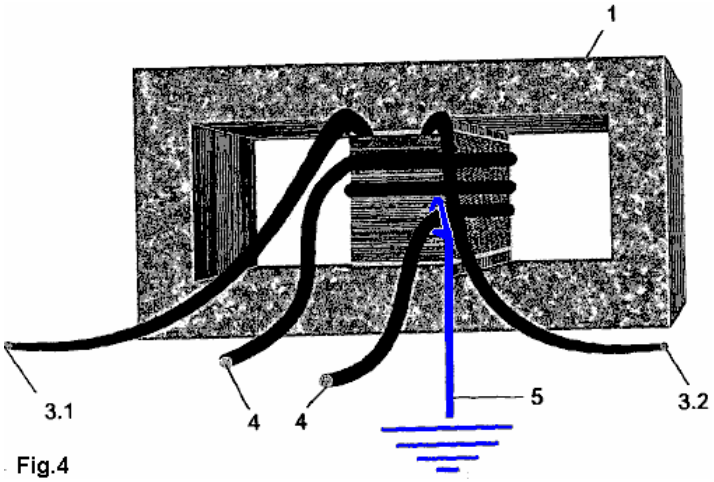

Fig.4

Fig.4 shows one of several types of electron-trap proposed by the present invention, where the electron-trap is single-phase and consists of at least one electromagnetic field-generating device with at least one set of coils, in this case it happens to be an electromagnetic type coil with one common magnetic core, but it could alternatively have any number of windings of any kind and shape. However, the electron-trap proposed by the present invention can be constructed with a different type of electromagnetic field generating device, such as an electromagnetic inductor or magnet of any type or shape, or any combination of them, and in unlimited numbers for each phase of the electron trap.

When winding these coils, for example, coil **4-4**, each coil must have at least one complete turn, preferably two turns if the objective is to generate electricity, and preferably four turns if the objective is provide thermal energy. The number of turns in the coils wound around the common core, is directly related to the amount of current to be generated.

At least one conductive interconnection element, in this case the driving member **5** - which can be copper or any other suitable conductive, material whether insulated or not insulated, connects or loop-links wire **4** to the ground grid. The connection between the conductor **5** and wire **4** is by electromagnetic induction. Winding **4** is also the power supply for the loads which are to be powered by the captured electrons.

Also in **Fig.4**, the power wires **3.1** and **3.2** (live phase and neutral) have an input from an external power coil **1** which can be energised from any external source of electricity such as a power grid. The trapped electrons can be configured to supply DC or AC current. Thus, if the coil **1** power source is alternating electrical current - AC, then the electron-trap provides alternating electrical current. If the power source is continuous electrical current - DC, then the electron-trap provides continuous electrical current - DC. The electrical supply provided by the trapped electrons can be single-phase, two-phase or three-phase, and at low, medium or high voltage.

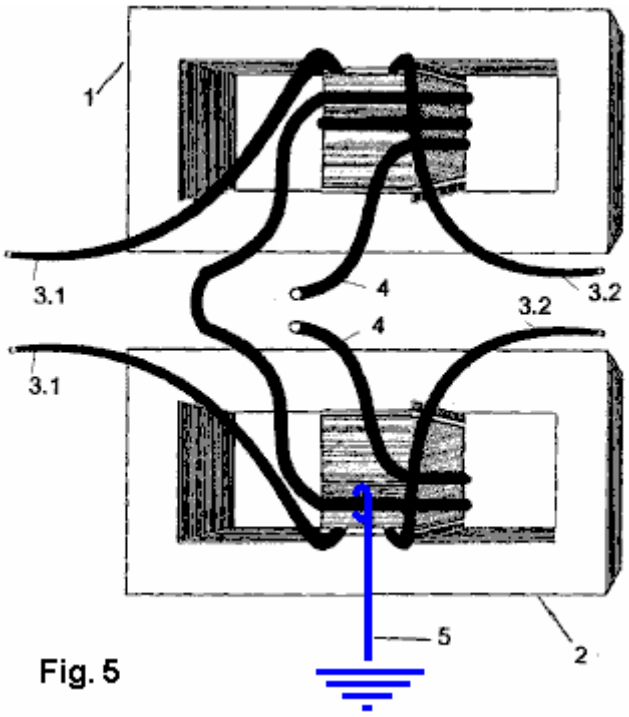

Fig. 5

Fig.5 shows an electron-trap with two single-core phase coils: **1** and **2**, although these coils may be of any type and shape. However, the electron-trap proposed by the present invention can be constructed with other types of electromagnetic field generating device, with at least one electromagnetic inductor or electromagnet which can be of any type and shape, with any combination of them, and in unlimited quantities in each phase of the electron-trap.

The coils on frames **1** and **2** may have other shapes, but they must each have at least one complete turn, particularly in coil **4**. The number of turns in this winding are directly related to the amount of current to be generated. This coil also makes the interconnection between the coils **1** and **2** forming the link between their two cores.

At least one conductive interconnection element, in this case the driving member **5** - which can be copper or any other suitable conductive, material whether insulated or not insulated, connects or loop-links wire **4** to the ground grid. The connection between the conductor **5** and wire **4** is by electromagnetic induction.

In electron-traps which have numerous sets of coils **1** and **2**, the ends of all of the power-supply conductors **3.1** can all be connected to each other, and all of the **3.2** conductor ends may be connected together. Thus, all of the coils **1** and **2** can be fed exactly the same voltage. The power to energise coils **1** and **2** can be provided from any external source of supply of electricity such as a power grid.

In electron-traps which have numerous coils **1** and **2**, a single coil winding **4** connects the cores of all of the coils **1** and **2**.

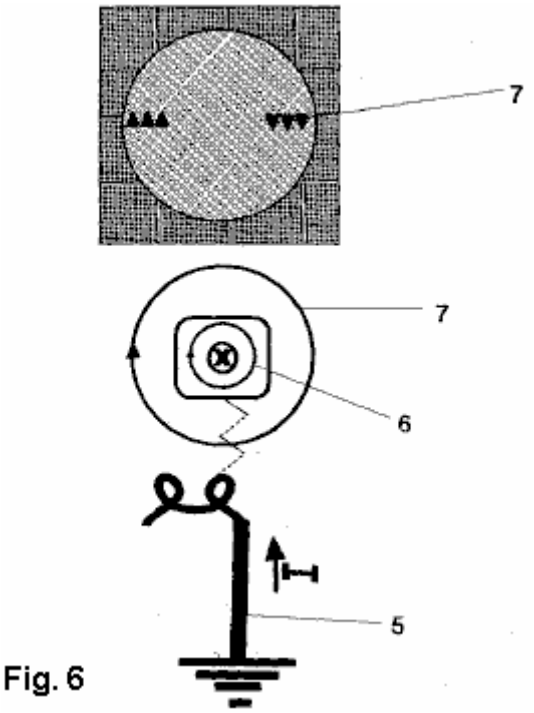

Fig. 6

The diagram shown in **Fig.6**, illustrates the magnetic induction **6** around the core "**X**" of the coil **1**. This induction causes electrical current flow in the conductor coil link **7/4**, attracting electrons from the earth, through the conductive member **5**, to the magnetic field of the electron-trap, where those electrons are added to the current generated by induction in the link coil **4** conductor loop circulating between north and south magnetic poles.

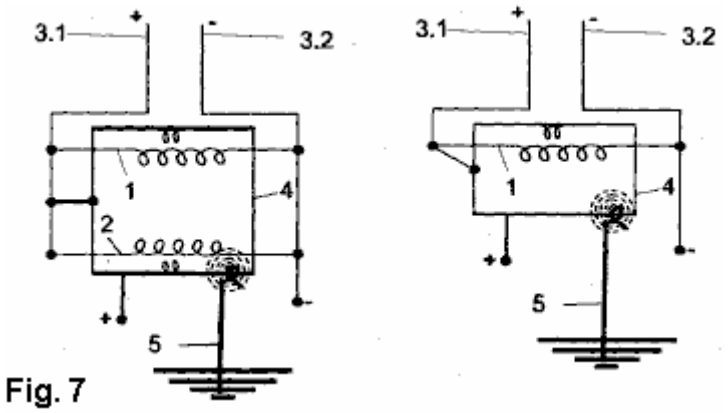

Fig. 7

Fig.7 shows how the connections should be made in one version of the electrical circuit of the electron-trap proposed in this invention. The diagram shows the electrical circuit of an electron-trap where the link/coil driver **4** is polarised with a voltage. This is one form of construction for an electron-trap which has two coils **1** and **2**, where a link/coil loop conductor **4** is biased with a voltage, that is, there is a link connecting the coil conductors **4** of a power supply **3.1** or **3.2**, whatever the stage.

In this way, earth electron-traps, by adopting this circuit, that is, with the link/conductor loop **4** and polarised voltage on coils **1** and **2**, besides being used as a power source for external loads, can also be used for thermal power generation.

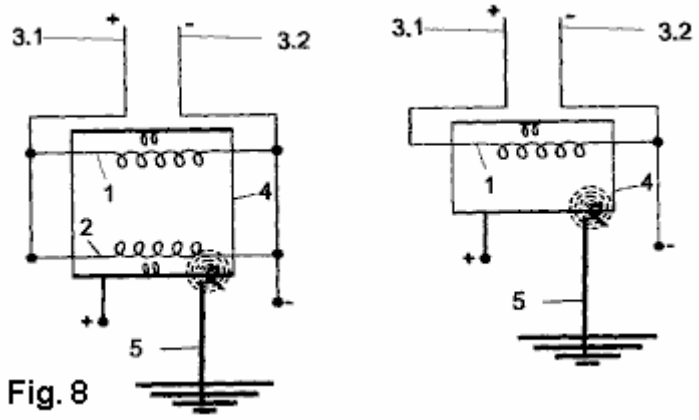

Fig. 8

Fig.8 shows how connections should be made in another electric circuit electron-trap proposed in this invention. the circuit illustrates a circuit of an electron-trap with a non-polarised link / coil driver **4**. This is one form of construction of the electron-trap where a link / coil conductor **4** of the spiral conductor coils **1** and **2** is not polarised, that is, there is no such link connecting conductor / conductor coil conductors **4** of a coil **3.1** or **3.2**.

Thus, earth electron-traps adopting this circuit, that is, with the link coil not polarised, the current flows without there being voltage in the link/coil conductor **4** joining the first and second coils by electromagnetic induction. They can also be used for generating thermal energy.

The structure of the circuit - in the open or closed coils **1** and **2**, and always in the closed link / loop lead **4** - makes it possible to generate current by induction and electron capture by electromagnetism on the link conductor **4** - where current is generated and stays in motion with or without voltage, as the coils **1** and **2** are being fed. Thus, the present invention provides a new concept for electrical energy generation, since it is obtained from an electric current circling without consumption and even without an output load being attached to it.

Additionally, because the induced electrical current flows regardless of the voltage present, it can be used as a current stabiliser for electrical networks whether they be single-phase, two-phase or three-phase, with low, medium or high voltage.

ELECTROMAGNETIC DEVICE FOR CAPTURING FREE SPACE ELECTRONS TO GENERATE ELECTRICITY

Application Number: BR2013/000014

Publication Date: 07/18/2013

Filing Date: 01/11/2013

Abstract:

The invention relates to a device that comprises at least three sets (**A, B, C, D**) of at least one device for generating an electromagnetic field (**3**) and (**4**), powered by an electricity source (without a core or with at least one core) the cores thereof or any extension thereof, preferably the windings or sets of windings thereof, being surrounded by at least a single conductive element forming a polarised and energised closed-circuit (**5**), the sets of electromagnetic-field generating devices (**3**) and (**4**) being linked together by their opposing poles to encourage the interaction of their electromagnetic fields, which ideally, are located between two hollow metal hemispheres (**1**) so as to concentrate and enhance the electromagnetic fields, these interconnections causing, as a novel technical effect, the emergence of an electrical current that circulates, with or without voltage, in the conductive element forming a closed-circuit (**5**) - even if no load is connected.

Description:

"ELECTROMAGNETIC EQUIPMENT FOR FREE ELECTRON-CAPTURE FROM SPACE, FOR ELECTRICITY GENERATION".

Technical Field

The present invention relates to electromagnetic equipment for electrical power generation and/or thermal power generation. More specifically, equipment capable of producing abundant electricity and thermal energy from a tiny input of electrical energy.

Description of the Related Art

According to Lenz's law, any induced current has a direction such that the magnetic field it generates opposes the change in magnetic flux that produced it. Mathematically, Lenz's Law is expressed by the negative sign (-) that appears in the formula of Faraday's Law, as follows.

The magnitude of the induced emf (ε) in a conducting loop is equal to the rate of change of magnetic flux (Φ_B) with time:

$$\varepsilon = -\frac{d\Phi_B}{dt} \qquad \text{Equation 1}$$

As an example of application of Faraday's Law, we can calculate the electromotive force induced in a rectangular loop that moves in or out, with constant speed, a region of uniform magnetic field. The magnetic field flux through the surface limited by the loop is given by:

$$\phi = xLB \qquad \text{Equation 2}$$

and its variation in time:

$$\frac{\Delta\phi}{\Delta t} = \left(\frac{\Delta x}{\Delta t}\right)LB = vLB \qquad \text{Equation 3}$$

So:

$$\varepsilon = vLB \qquad \text{Equation 4}$$

and if the coil has a resistance (R) and the induced current:

$$i = \frac{\varepsilon}{R} = \frac{vLB}{R} \qquad \text{Equation 5}$$

A conductor traversed by an electric current immersed in a magnetic field undergoes the action of a force given by:

$$F = IL \times B \qquad \text{Equation 6}$$

Thus, the effect of the current induced in the loop appears as forces Ff, and F - FM. The first two cancel each other out and the third is cancelled by an external force P_{EXT} needed to maintain the constant speed loop.

As the force FM must oppose the force F_{EXT}, current (i) induced in the loop by varying the magnetic flux must have the meaning indicated in **Fig.1**. This fact is a particular example of Lenz's Law.

Considering the experimental activities discussed with Faraday's law, when a magnet approaches a coil, the induced current in the coil has a direction as shown in **Fig.2**. This generates a magnetic field whose north pole is facing the north pole of the magnet, that is, the field generated by the induced current opposes the motion of the magnet.

When the magnet is moved away from the coil, the current induced in the coil has a direction opposite to that shown in **Fig.2**, thereby generating a magnetic field whose south pole is facing the north pole of the magnet. The two poles attract each other, that is, the field generated by the induced current opposes the movement of the magnet away from the coil. This behaviour is present in all current power generators, and known as 'engine brake' is highly undesirable as it increases the resistance and so, the energy loss.

When two electromagnetic coils are placed facing each other, there is no current in either of them. At the instant of power up one of the coils, the current in the coil, generates an induced current in the second coil. When powered up, the current in the coil goes from zero to its maximum value, and then remains constant.

Thus, when the current is changing, the magnetic field generated by it, (whose north pole faces the second coil) is also changing and so the magnetic flux of this field through the second coil is also changing. Then there is a current induced in the second coil whose sense is such that the magnetic field it generates tends to decrease the flow mentioned above, that is, its north pole confronts the north pole of the first field coil.

When the power switch is opened, the current in the first coil drops from its maximum value to zero, and correspondingly its magnetic field decreases. The flux of the magnetic field in the second coil also decreases,

and the induced current now flows in the opposite direction. This current flow direction produces an enhancing magnetic field, that is, it has a south pole facing the north pole of the field of the first coil.

Thus, there is a realisation of the principle of conservation of energy, expressed by Lenz's law, wherein any induced current has an effect which opposes the cause that produced it. Assuming that the induced current acts to favour the variation of the magnetic flux that produced the magnetic field of the coil, it would have a south pole facing the north pole of the approaching magnet, causing the magnet to be attracted towards the coil.

If the magnet were then released, it would experience an acceleration toward the coil, increasing the intensity of the induced current and thus create an enhanced magnetic field. This field, in turn, would attract the magnet with increasing force, and so on, with a continuing increase in the kinetic energy of the magnet.

If energy were to be withdrawn from the magnet-coil system at the same rate at which the kinetic energy of the magnet increases, then there would be an endless supply of energy. So it would be a perpetually operating motor, which would violate the principle of conservation of energy. Therefore, it can be concluded that current generators feature a large energy loss during the generation of electricity.

Objectives of the Invention

The present invention aims to contribute to the generation of sustainable energy, proposing electromagnetic equipment capable of producing abundant electricity from an extremely low input of electrical energy.

The above objective and other objectives are achieved in the present invention by a device comprising at least three sets of at least one electromagnetic field generating device (without a core or with at least one core) powered by an electrical power source, having their cores or any extension of them, with their coils or sets of coils, wound on at least one common conductive member in a closed circuit which is polarised by a voltage source, and these sets of electromagnetic field generating devices are arranged with their poles in confrontation, to promote the interaction of electromagnetic fields, and, preferably, positioned between two hollow metallic hemispheres, in order to focus and enhance their electromagnetic fields - these interactions cause a new technical effect - the emergence of an electric current which keeps flowing in a closed loop, with or without voltage being applied to that closed loop, current which is capable of powering external loads - even if no load is attached to it.

The device which is the object of the present invention operates as follows: Sets of electromagnetic field generating devices to be powered by an electrical power source, produce an electromagnetic field which induces an electric current in a closed conductive circuit, creating an interaction between the magnetic poles, and through repeated electromagnetic attraction and repulsion, provides an endless supply of electrons to the conductive closed loop itself.

The electrons attracted by this technique, augment the current flowing in the closed conductive loop, which provides the current to power external loads of high power, in spite of the fact that the device itself is supplied with only a small level of power. Thus, advantageously, the device which is disclosed in the present invention forms a trap for electrons from space, resulting in the generation of electricity. The interconnections of the components of the electron-trap cause, a new technical effect, namely, the appearance of an electric current which keeps circling in a closed circuit, even without any voltage being applied to the closed circuit, and even without a load being connected to it. The present electromagnetic equipment generates electricity or thermal energy, providing access to this new source of energy through the use of an electromagnetic field.

The proposed sensor can also be used for the generation of thermal energy depending on the form of circuit which is to be used, resulting from the flow of electric current produced by this electromagnetic equipment.

This field generates a flow of electric current induced by electromagnetic coils, which appears in the linking interconnecting devices generating electromagnetic fields with electromagnets, inductors or magnets. This chain operates in a manner favourable to the variation of the magnetic flux produced by the magnetic field in the electron-trap. Thus, it creates a north pole and a south pole, providing an endless supply of electric current without resistance between the links which interconnect the devices which are generating the electromagnetic fields. So, induced electric current is generated with or without voltage in the interconnection links of electromagnetic field-generating devices, depending on the connection method of the electrical circuit of the electron-trap.

The free-electrons collected by the space electron-trap can form alternating current (AC) or direct current (DC). The ratio of input power to output power is 1 to 100, that is, the generated power can be 100 times greater than the input power when there is at least one link / coil driver between the coils and the inductors or electromagnets. This relationship, however, is not limited to a factor of 100, as it depends on the shape of the electron-trap and its objective.

Another advantage of the free space electron-trap of the present invention is that, with thermal insulation of the components in the electric circuit, it is possible to produce thermal energy at low, medium or high temperature, through the movement of the electrons in the conductors, coils and/or electromagnets. The temperature generated is linked directly to the number of turns in the coils.

Thermal power generation performed by the sensor can be used for boiling and/or evaporation of liquids to be used in other types of energy generation, for example, replacing the use of coal and natural gas.

Another advantage of the proposed electron-trap of the present invention is that the electron-trap can transport electrons from one point "A" to a point "B", without a voltage drop in the link - if it is polarised - regardless of the distance between the points, depending on the strength and quantity of the electromagnetic field-generating devices. It is also possible to transport the electrons when the link devices generating the electromagnetic field are not polarised. In this way, the electric current is conveyed without voltage but only by the magnetic field formed between the coils. This methodology can be used in various fields.

Because of its simple construction, the electron-trap is a simple device which is compact, and performs low-cost power generation which can be used in all types of machinery, equipment and devices of all kinds, and many areas of application which require electricity in order to operate. The electron-trap can have single-phase, two-phase or three-phase output, and can generate electric current at low, medium or high voltage.

Brief description of the Drawings

The present invention will now be described with the aid of drawings, but the design is not limited to the implementations shown in these drawings, although they show other details and advantages of the present invention.

The figures show:

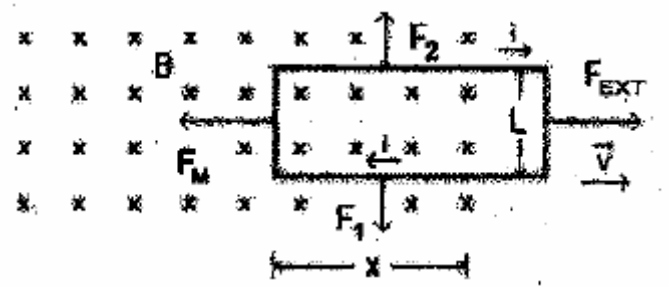

Fig.1 - illustrates Faraday's law.

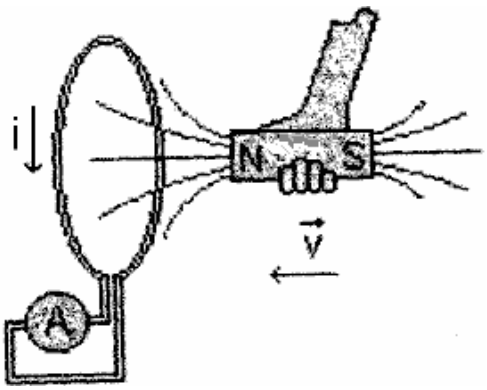

Fig.2 illustrates Faraday's law where a magnet approaches a coil of just one turn..

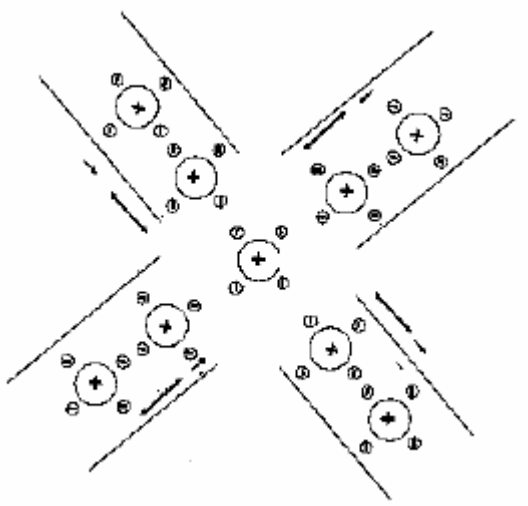

Fig.12 is a representation of the electrons being attracted and repelled by the device.

Detailed Description of the Drawings

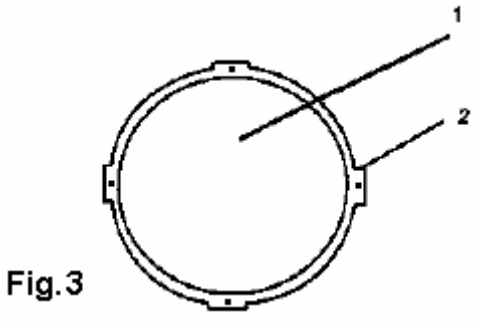

Fig.3 is a top view of one of the two hollow metallic hemispheres **1** which is part of the electron trap of free space proposed in this invention. Hemisphere **1** is preferably made from, but not limited to, aluminium, and it has mounting tabs **2**.

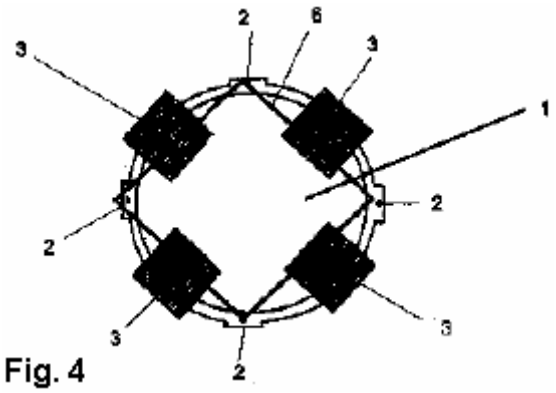

Fig.4 is a bottom view of metallic hemisphere **1**. It has four electromagnetic field generating devices **3**, positioned around the hemisphere and fixed to support **6** which is attached to hemisphere **1** by mounting tabs **2**.

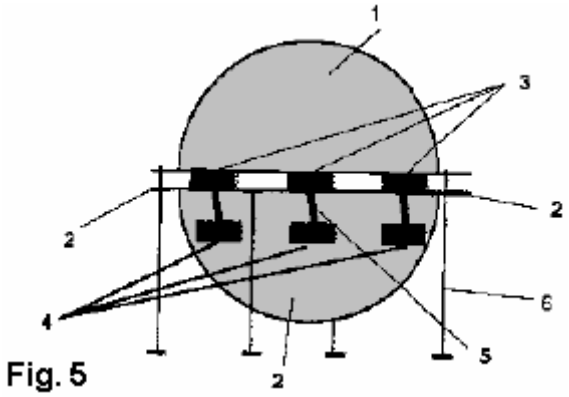

Fig. 5

Fig.5 is a side view of the free space electron-trap. It shows the two metallic hemispheres **1** and **2** (which form an imperfect sphere), and three of the coils **3** which are attached to the mounting tabs **2** and three inductors **4** which form the closed circuit itself, and which are attached by conductors **5**, and support member **6** on which are mounted coils **3** and their components.

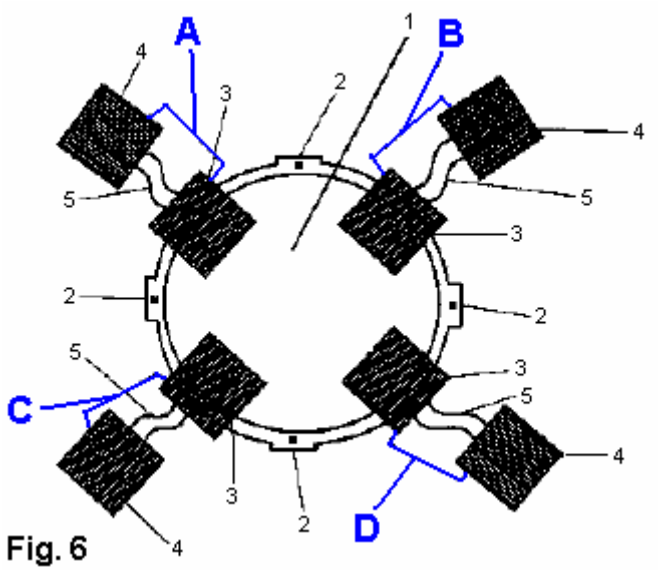

Fig. 6

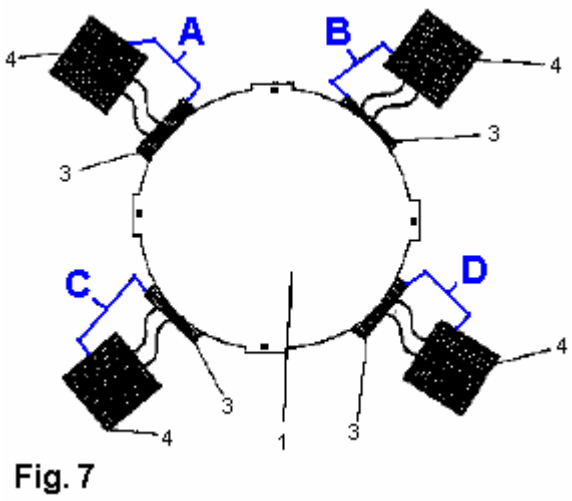

Fig. 7

Fig.6 and **Fig.7** show the top and bottom views of the metallic hemisphere **1** which accommodates four coils **3** attached to the holder **6** (not shown) which is secured to the hemisphere **1** by its mounting tabs **2**. **Fig.6** also shows the inductors or electromagnets **4** their corresponding coils **3** and their interconnecting conductors **5**. Each coil **3** and its linked inductor **4** forms a set. In **Figures 6** and **7** there are four such sets, marked **A**, **B**, **C** and **D**. The coils **3**, connected by their links **5**, each have at least one turn, and if the objective is to generate electricity, then preferably two turns, and if the objective is thermal energy, then four turns. The coils **3** may have various different shapes. The number of turns in the coil **3** are directly related to the amount of current to be generated, and the connecting links **5** may be either a single conductor or more than one conductor, the cross-sectional area of conductor **5** being selected to carry the current which is to be generated.

In sets **A, B, C** and **D**, the link conductors **5** have at least one turn around coils **3**. This winding is connected to the respective electromagnets **4** of each set (**A, B, C** and **D**) as shown in **Figures 6** and **7**. Please note that the inductors and electromagnets **4** can be any type of inductor, and other types of coil may be used.

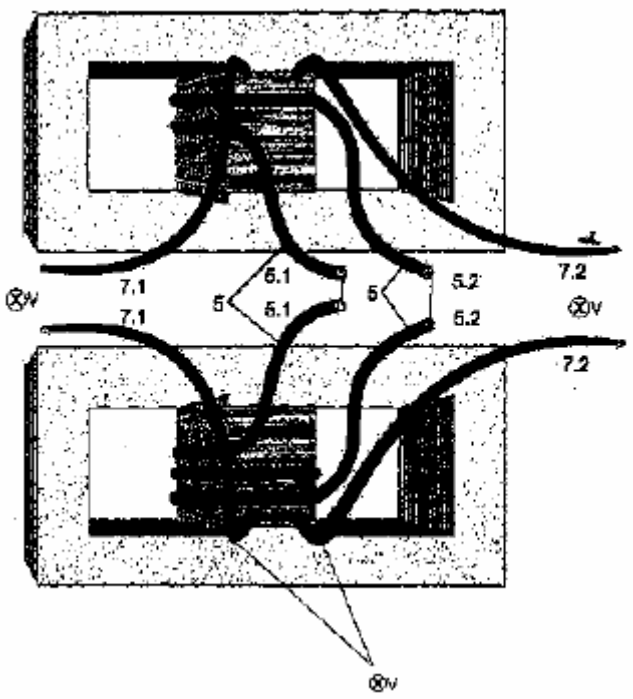

Fig.8 shows the inter-connecting coils **5** for each of the five sets **A, B, C** or **D** linking between coils **3** and **4** in each set. As shown in **Fig.6** and **Fig.7**, the link **5** makes the connection between coils **3** and **4**. This means that the wires marked **5.1** are all connected together, and the wires marked **5.2** are all connected together. Doing this, establishes the interconnection links **5** shown in the drawings. The power supply wires marked **7.1** are connected together as are the wires marked **7.2**. The wires marked **7.1** are connected to the live phase of the external power supply, while the other ends marked **7.2** are connected to the neutral of the external power supply.

In the space free-electron trap of the present invention, the coils **3** can be either single-phase, two-phase or three-phase. Also, the coils **3** may be powered by any voltage (V). The power coil **3** can be energised by any source of electrical energy such as a power grid. The electron-trap can be configured to produce alternating current or direct current. So, if the external power supply is alternating electrical current - AC, then the electron-trap provides an alternating electrical current output. If the power supply is DC, then the electron-trap provides an output of continuous electrical current - DC. The electron-trap can be configured for single-phase, two-phase or three-phase operation, with low, medium or high voltage outputs.

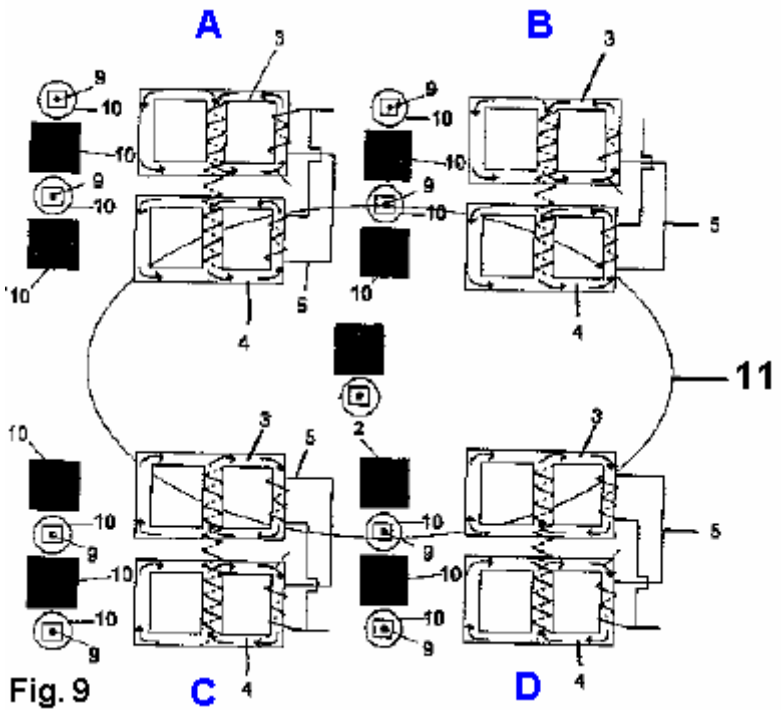

Fig.9 shows an electron-trap circuit diagram with four sets **A, B, C** and **D** of inductor coils **3** and **4**. Induction is produced around core **9** of the three sets of coils **A, B, C** and **D**. The effect of the interaction of the

electromagnetic fields **11** is shown. The induction via core **9**, causes the circulation of electric current in the links **5**, attracting the free electrons through the electromagnetic field of the trap. Then, the electrons join with the current generated by induction on link **5**, circulating between the magnetic poles north-south and south-north.

By way of example, the coils **3** are shown wound on a single phase column type core, but these can also be of any kind or shape. The electron-trap proposed by the present invention can be constructed with another type of electromagnetic field generating device which has at least one electromagnetic coil or magnet or electromagnetic inductor which can be of any kind or shape, or any combination of those, and with any number in each phase of the electron-trap.

The electron capture occurs through an electromagnetic field which is formed with the connection of coils **3** with the electromagnets or inductors **4** through the links **5** between the eight components.

This closure produces the displacement of the electrons in the coil **3** set (**A**) (for simplicity, referred to as coil **3A**), these electrons are attracted by the protons of coil **3D**, and are repelled by the electrons of the electromagnetic field of the coil **3D** itself. These coil **3D** electrons are attracted by the protons of the coil **3B**, and are repelled by the electrons of the electromagnetic field of coil **3B**. These electrons of coil **3B** are attracted by the protons of coil **3C**, and are repelled by the electrons of the electromagnetic field of the coil **3C** itself. Similarly, the **3C** coil electrons are attracted by protons of the **3A** coil, and are repelled by the electrons of the electromagnetic field of the coil **3A** itself. These coil **3A** electrons are attracted by the protons of the **3D** coil, and are repelled by the electrons of the electromagnetic field of the **3D** coil itself. Analogously, the coil **3D** electrons are attracted by the protons of the coil **3B**, and are repelled by the electrons of the electromagnetic field of the coil **3B** itself. These **3B** coil electrons are attracted by the protons of coil **3C**, and are repelled by the electrons of the coil itself induced **3C**, and then the coil **3C** electrons are attracted by protons of coil **3A**, and are repelled by the electrons of the electromagnetic field of the coil **3A** itself. That cycle continues as the sets of coils **A, B, C** and **D** are being fed by a voltage. These endless attractions and repulsions generate an electric current in the link coil **5**.

In the electron-trap, the voltage is stable. Regardless of the amount of current generated-which can be very high, the voltage will be the same in the electric circuit of the sensor, because the current moves through the attraction and repulsion of the electrons, regardless of voltage.

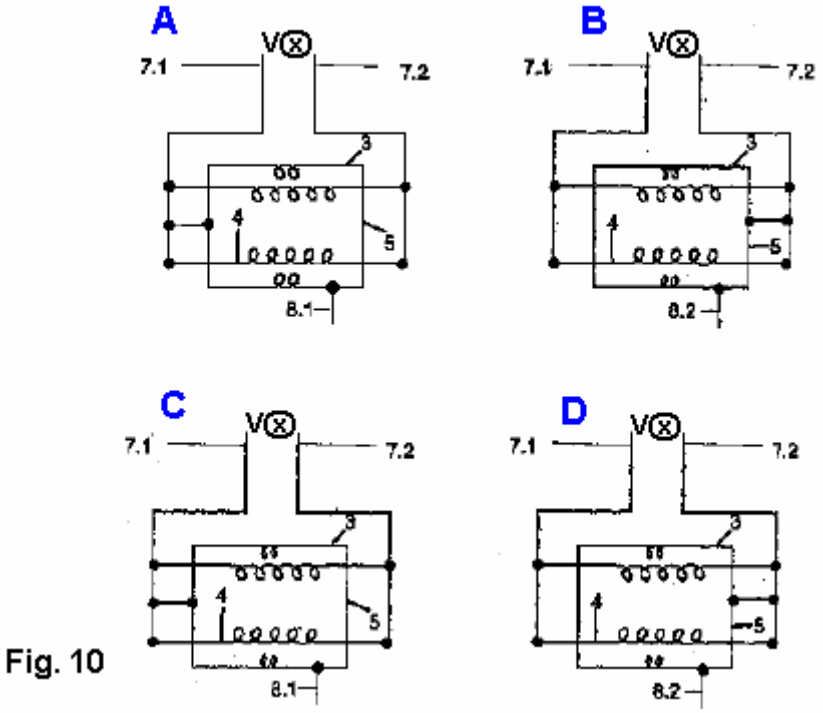

Fig. 10

Fig.10 illustrates a circuit diagram of the electrical connection between the coils **3** and **4** in sets **A, B, C** and **D**. It can be seen that the sets **A, B, C** and **D** are enclosed between the coils **3** and their associated inductors or electromagnets **4**. The supply conductors **7.1** and **7.2**, of sets **A, B, C** and **D** must be interconnected. When feeding power to the coils **3** and **4** the phase should be connected to **7.1** and the neutral to **7.2**.

The sets **A, B, C** and **D** after being fed with electric current, generate voltage through the attraction and repulsion of the electrons in the linking coil **5**, where there is at least one output load **8.1**, which should be connected joining sets **A** and **C**, and at least one load output **8.2**, which should be connected joining sets **B** and **D**. The output points **8.1** and **8.2** are the respective phases and neutral of power points **7.1** and **7.2**.

In this way, a single-phase electron-trap is created by two pairs of sets of coils/inductors **3** and **4**.

The **3/4** electromagnet coil set can be replaced by a **3/3** coil set, without any disadvantage to the electron-trap.

Sets **A, B, C** and **D**, are inserted into a hollow metal hemisphere **1** preferably constructed from - but not limited to - aluminium. The hemisphere **1**, whose function is to concentrate and maximise their electromagnetic fields, simulating an electron cloud, has a fixed support **6** connected to attachment tabs **2**, and to which the coils **3** are fixed.

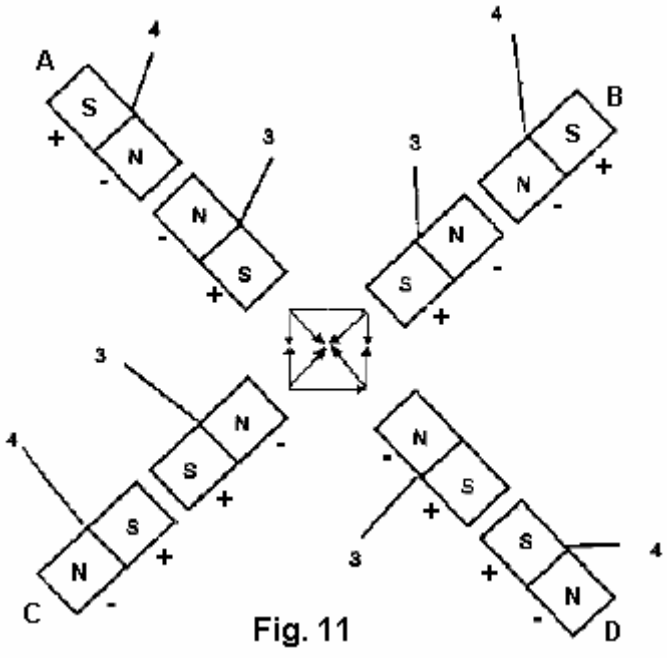

Fig. 11

Fig.11 is a diagram of the electromagnetic north and south poles of the inductor coils **3** and **4** of sets **A, B, C** and **D** of the electron-trap. The electromagnetic behaviour described for **Fig.9** is again demonstrated by the formation of the magnet assembly to the North Pole and South Pole being attracted and repelled by the lines of force of the magnet from the point "**A**" to point "**D**", point "**A**" to point "**B**", the point "**B**" to point "**C**", point "**C**" to point "**A**", and so on, as long as there is an electromagnetic field. The electromagnetic field of the space electron-trap provides that induced current in a direction similar to the variations of the magnetic flux that produced it. So, the magnetic field creates a north pole and a south pole in each of the sets **A, B, C** and **D**, as shown in **Fig.11**.

By feeding the coils **3** of the electron-trap with a desired voltage a magnetic field is generated in coils **3**, between the four sets **A, B, C** and **D**, which form a flow of electrons. This flow of electrons augments the electron flow which is circulating in the closed-loop link-coil **5**, thus implementing free electron capture from space. The electromagnetic field of the coil **3A** runs north to south, the electromagnetic field of the coil **3B** runs north to south, the electromagnetic field of the coil **3C** flows from south to north, and the electromagnetic field of the coil **3D** flows from south to north, as shown in **Fig.11**. It should be noted that the sets **A, B, C** and **D** can be formed by any combination of coil, magnet and electromagnet.

The south to north electromagnetic field induces current flow in the coil **3A**. The north to south electromagnetic field induces current flow in the coil **3B**. The north to south electromagnetic field induces current flow in the coil **3C** and The north to south electromagnetic field induces current flow in the coil **3D**. The induced current flow can have any power and it can be single-phase, two-phase or three-phase current.

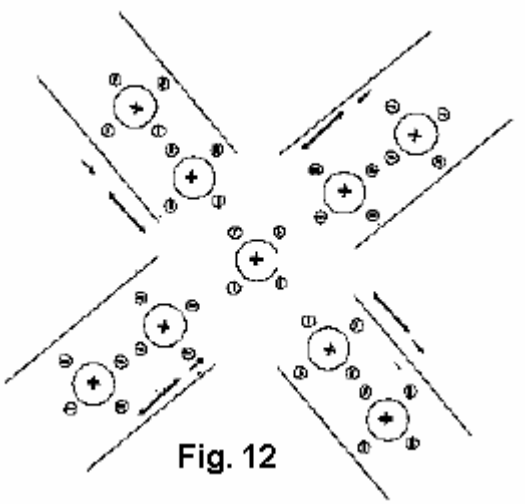

Fig. 12

Fig.12 shows the electrons being attracted and repelled by the induction coils **3** and **4**. Being repelled and attracted by electromagnetic induction, the electric current flows without resistance.

The electron-trap produces electromagnetic waves which can be used for various purposes, including signal transmission at any frequency and for any purpose. The capture is caused by these electromagnetic waves. The same physical effect can be achieved by the combination of the capture devices of other technologies, including electromechanical, electric, electronic, electromagnetic, or through the combination of a magnet or any other magnetised materials.

The space free electron-trap of the present invention is a renewable source of electrical power production and a new way of generating energy through the capture effect, generating flows of electrons, generating ordered movement of electrons - electric current - as shown in **Figures 9, 11,** and **12**. Electrons can move without any voltage difference in the continuous loop **5**. Alternatively, the loop may be biased with any chosen voltage.

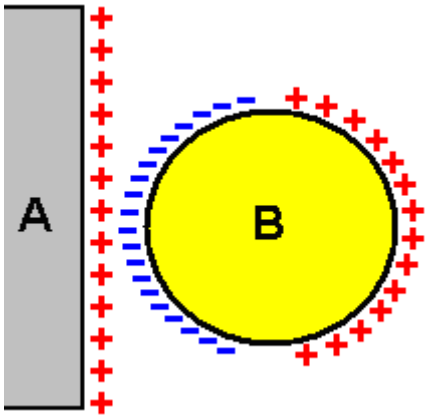
Free energy from Lorrie Matchett

The style of operation used by Barbosa and Leal looks as if it is related to the developments of Lorrie Matchett. On 16th June 2008, Lorrie Matchett published his very simple design for a device which captures usable free-energy (video: http://youtu.be/eGD9o7D4To8). His device is based on a very simple and well-know principle of static electricity. This is a principle which is taught in schools all around the world but is generally considered to be of no importance as static electricity is considered too low-power to be of any use. I seriously doubt that anyone who has been struck by lightning would consider static electricity to be “low-power” and suggesting that to them is likely to expand your vocabulary with some words which are seldom heard.

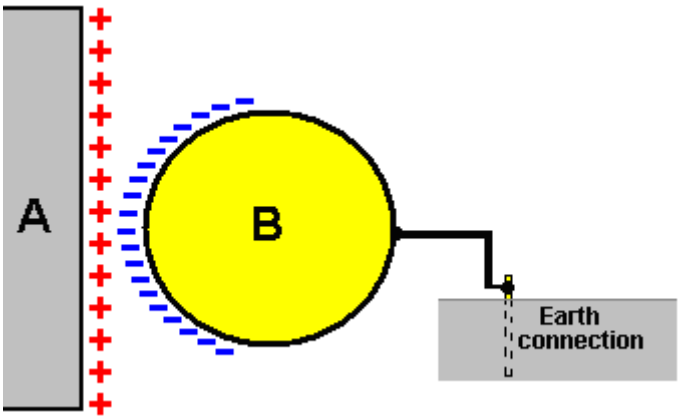
Important Note: the following details mention the use of mains voltages and so let me stress that this presentation is for information purposes only and must not be construed as being a recommendation that you construct or use any such device. Should you choose to ignore this and construct and use Lorrie Matchett’s device, then please be fully aware that you do so entirely at your own risk and nobody else is in any way responsible for the results of what you do.

The principle which is being used here is that an electrically charged object causes the migration of opposite charges on the surface of any object brought close to it. For example if a charged surface if brought close to a metal sphere, then this happens:



The ordinary metal sphere "**B**" which has no particular charge on it is very much affected by being close to a charged surface "**A**" and the closer it gets, the greater the effect. The surface of the sphere had an even distribution of positive and negative charges on its surface, giving it an overall charge of about zero, but the charged surface changes all that. The positive charges on surface "**A**" attract the negative charges on the surface of the sphere causing them to migrate towards surface "**A**". While the positive charges on surface "**A**" do repel the existing positive charges on the surface of the sphere, the migrated negative charges of the sphere itself have an even greater effect, causing the segregation of electrical charges shown above. The situation returns to normal if the sphere is moved away again.

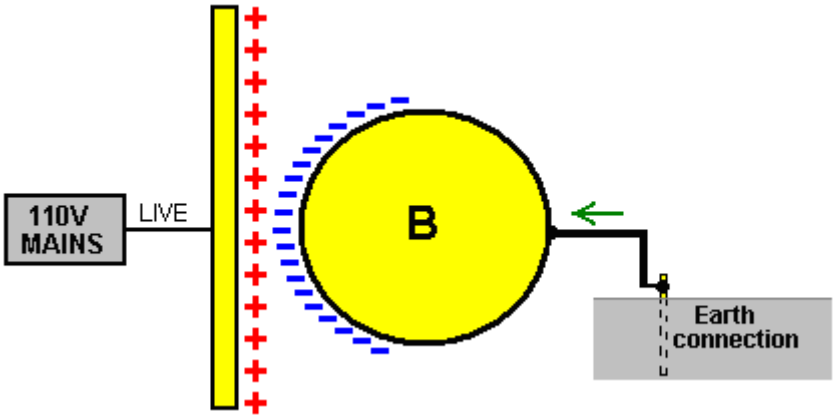
However, the situation changes considerably if the metal sphere "**B**" is connected to the ground:



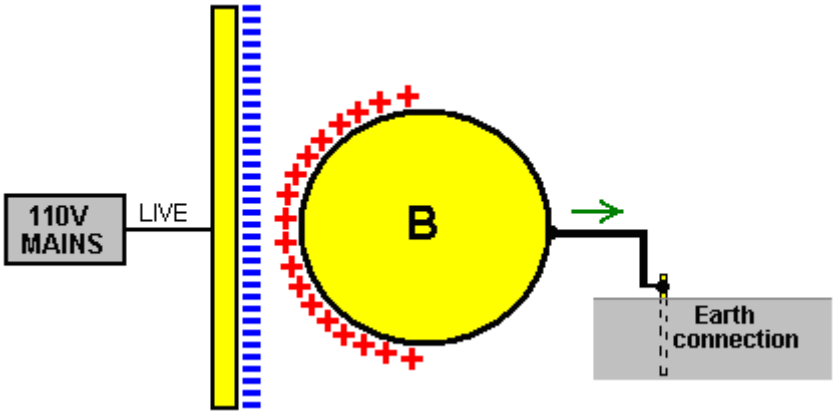
The movement of charges on the surface of the sphere is the same as before, but the Earth has millions of spare charges of both kinds and so, immediately siphons off the excess positive charges on the side of the sphere away from charged surface "**A**". You will notice that charged surface "**A**" is not directly involved in any way and no charge moves from "**A**" to "**B**".

The same effect is seen if the surface "**A**" is negatively charged (except for the fact that the sphere has positive charges rather than the negative charges shown above. The only current flow is along the wire connecting the sphere to the earth connection.

Lorrie Matchett uses this principle, and for the charged surface he connects one end of a brass rod to the 'Live' side of a 100V 60 Hz mains electricity supply. The other end of the brass rod is not connected to anything else. This produces this situation for 8.3 milliseconds:



And then for the following 8.3 milliseconds the mains reverses and you get this situation:

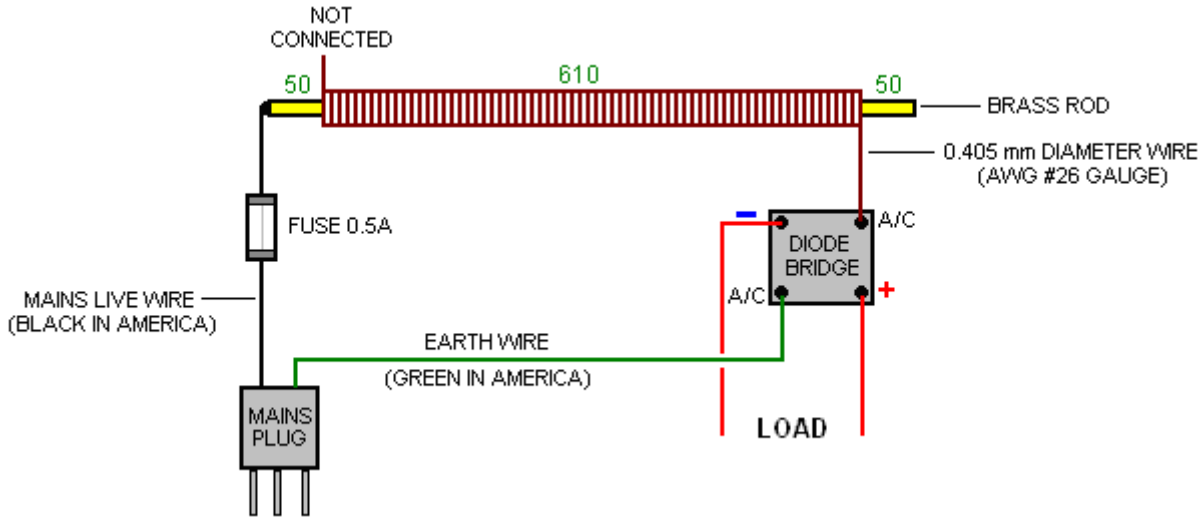


The result of this is that there is a backwards and forwards flow of static electricity along the earth connecting wire, a flow which reverses direction sixty times per second. This is not conventional electricity but is the same form of electricity which is collected by an aerial. Nikola Tesla's patents show many different ways of utilising this static electricity, as does Herman Plauson in his patent (www.free-energy-info.com/Chapter7.pdf). Thomas Henry Moray produced fifty kilowatts of continuous power from quite a small aerial. Paul Baumann of the Swiss commune produced several kilowatts from static electricity. Lorrie Matchett settles for just a few watts and he does it like this:

He connects the live wire of a 110V (RMS) AC mains supply to a brass rod 28-inches (710 mm) long and 3/16 inches (4.76 mm) in diameter. The rod is not directly connected to anything else and so does not form part of a closed loop circuit and so, no current flows from the mains. It must be stressed that the rod and connecting wire are potentially very dangerous and need to be insulated very carefully to ensure that touching them will not cause an electric shock. Please understand very clearly that as no current of any kind is drawn from the mains that this circuit is **not** "stealing electricity from the mains".

For convenience, and only for convenience, Lorrie uses the earthing system of the house mains supply by connecting a green earthing wire to the earth pin of his mains plug. It needs to be clearly understood that this has nothing directly to do with the mains supply and any good quality separate earth would be at least as good as the earthing point inside the mains plug. Effectively, there is only one mains connection.

Instead of using a metal sphere as shown in the illustrations above, Lorrie uses a coil of wire wound around the insulation layer on his brass rod, and he passes the alternating flow of static electricity, drawn from the earth, through a standard diode bridge as shown here:

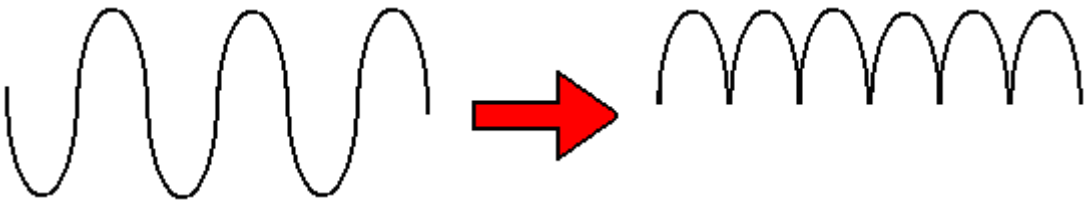


Lorrie covers the brass rod with insulation which is as thin as possible. He suggest heat-shrink tubing for the insulation and on top of it he winds 0.405 mm diameter, solid-core enamelled copper wire, covering a 24-inch (610 mm) length of the rod, placing the turns closely side by side and leaving 2-inches (50 mm) clear at each end of the rod. Thicker wire should not be used.

He also shows a 500 milliamp fuse in the mains supply line. I am not at all happy about that as that fuse can power five incandescent 100-watt mains bulbs connected in parallel, and do you really want that amount of power flowing through you if your insulation is not good enough and you touch it? If you use a fuse in that position I would suggest a 20 mm glass quick-blow 100 mA fuse (mainly because no smaller one is readily available). The fuse is not needed for the circuit and is there in an attempt to protect careless humans.

The coil wound on the insulated brass rod is only connected at one end and that end goes to one of the two "Alternating Current" tags on a 3A diode bridge. Lorrie does not specify the voltage rating for the diode bridge, but it needs to be a minimum of 170-volts if the mains is a 110V (RMS) type, and double that for a 220V (RMS) mains connection. I have no idea why he specifies a 3-amp rating, but the minimum bridge available locally at 3-amps which I would recommend is a 400V rated unit which is supplied at trivial cost.

We need to understand the effect of the diode bridge. It halves the available voltage and doubles the frequency as illustrated here:

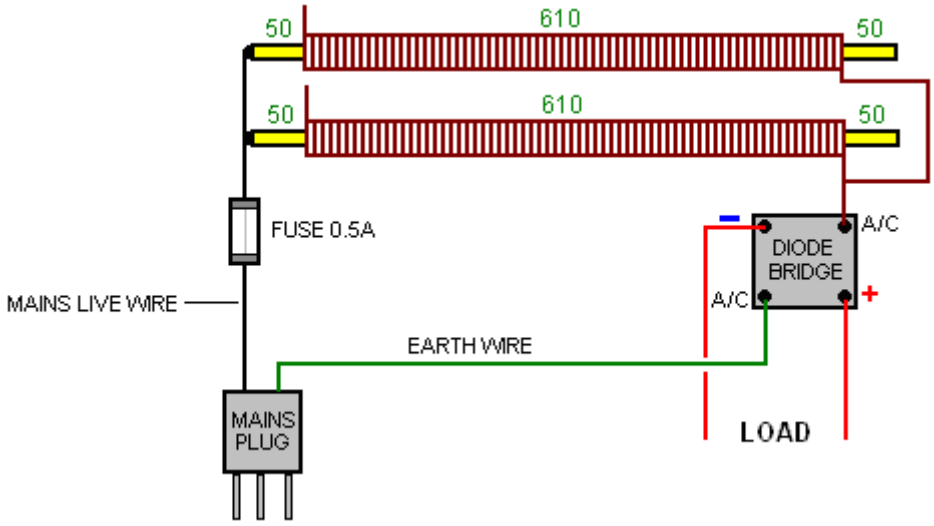


A 110V supply is supposed to swing from Minus 155V to Plus 155V and back again sixty times per second, which is an overall voltage swing of 310V. When passed through a diode bridge that changes to a voltage waveform which swings from Zero volts to Plus 154V and back again 120 times per second, which is an overall voltage swing of 154V which is an average or "RMS" voltage of 109V due to the sine wave shape.

In the rest of the world, the mains voltage is 220V (RMS) nominal, alternating fifty times per second and the Live mains wire is colour coded brown in the UK and the earth wire yellow/green stripes. In passing, the Neutral wire is white for the American 110V system and blue for the 220V system used in the UK.

This design has been brought to my attention by Jes Ascanius of Denmark who is a very able developer of all kinds of free-energy designs. He has replicated this design of Lorrie Matchett and confirms that it works. He has also taken the design further and shares some of the practical details which he has discovered through his own experimentation:

For greater power, additional rods can be used:



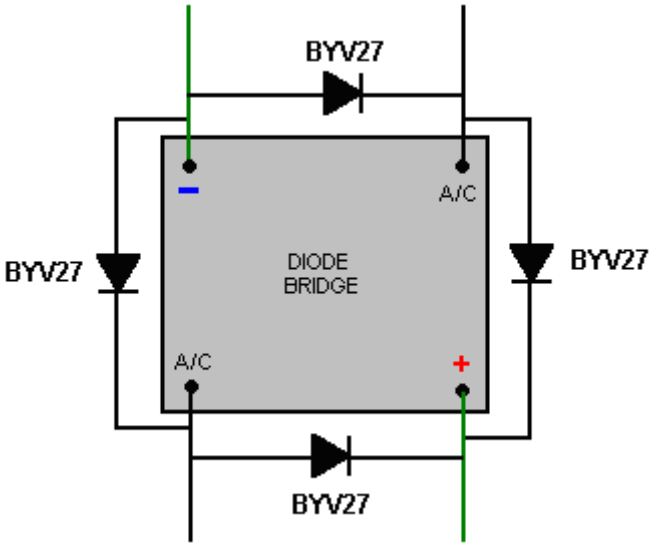
While brass is considered to be the best material for the rod, the diameter is not critical in any way and any size from 5 mm to 20 mm can be used and instead of a rod, a length of brass pipe should be quite suitable. It is also possible to use other materials for the rod but doing that reduces the output power available.

Jes has checked the output of his implementation with the mains fuse removed. The result was an output voltage of 2.6V picked up from the many 220V 50Hz signals generated by the mains wiring all around the place for lighting and sockets. When the fuse is inserted, the voltage rises immediately to 129V with two rods or 162V with five rods. When that voltage is loaded with a 7-watt LED lighting array, the voltage gets pulled down to 61V, but good lighting is being produced for zero current draw from the mains. I would expect that putting a reasonably large capacitor across the load, that the reservoir effect of the capacitor would improve the LED output. Jes has a video of this at https://www.youtube.com/watch?v=zeBqYb2QoAM&feature=player_embedded.

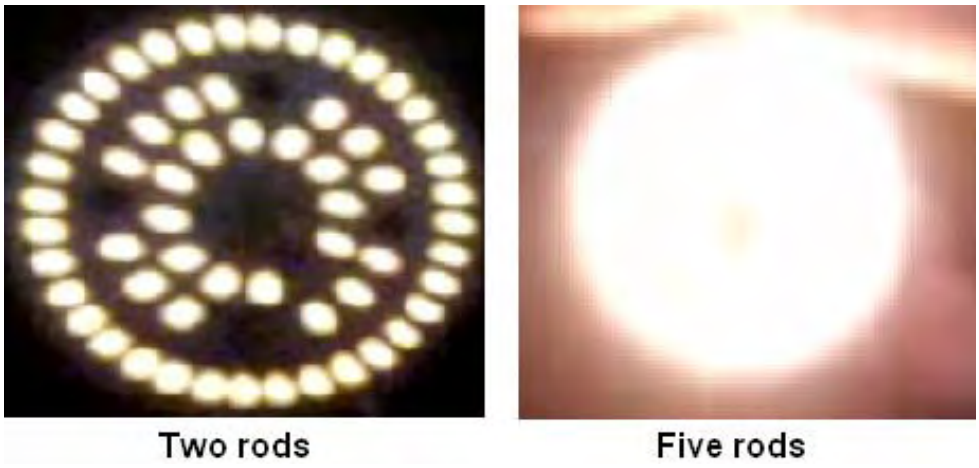
Jes initially used two long rods wound with coils:

And later, five rods. His AC ammeter is sensitive enough to show that due to inefficiencies caused by the tiny stray capacitance between the rods and the coils, there is a very slight current draw from the mains. The mains wattage is far less than the output wattage of the system.

An improvement implemented by Jes is adding four high-speed BYV27 diodes to the ordinary diode bridge like this:

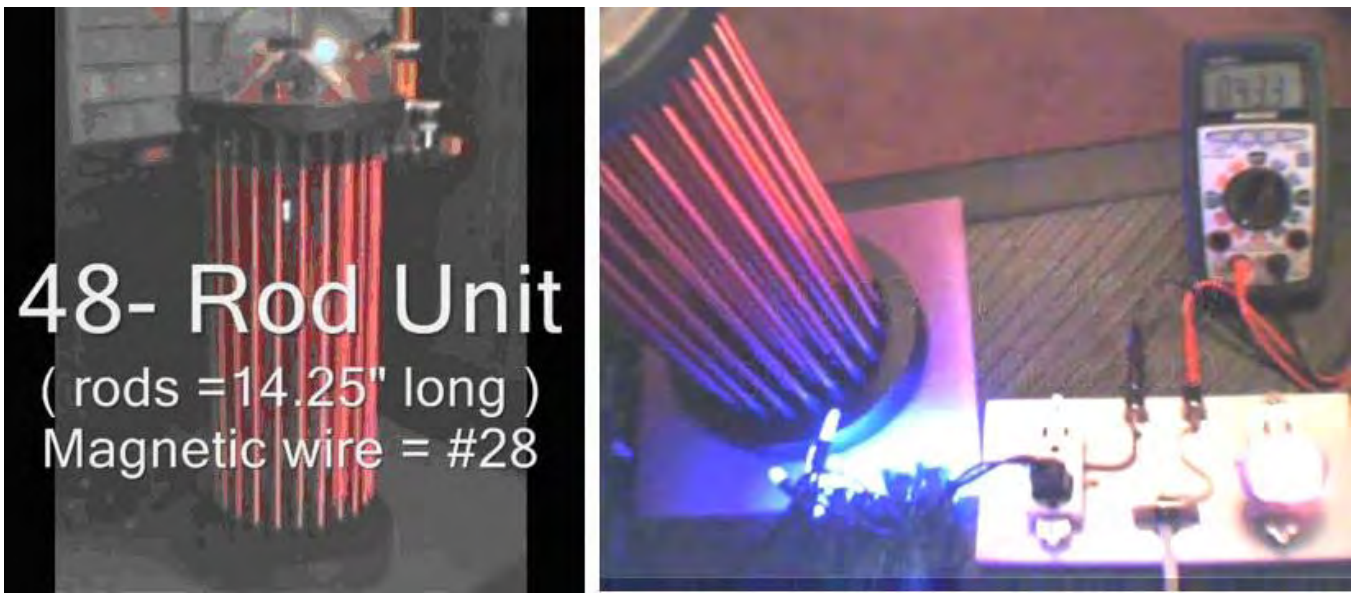


This has the effect of improving the action of the diode bridge and allows more power to extracted from each cycle of the energy flow. When using two brass rods, Jes gets his 5-watt LED array to light up like this:



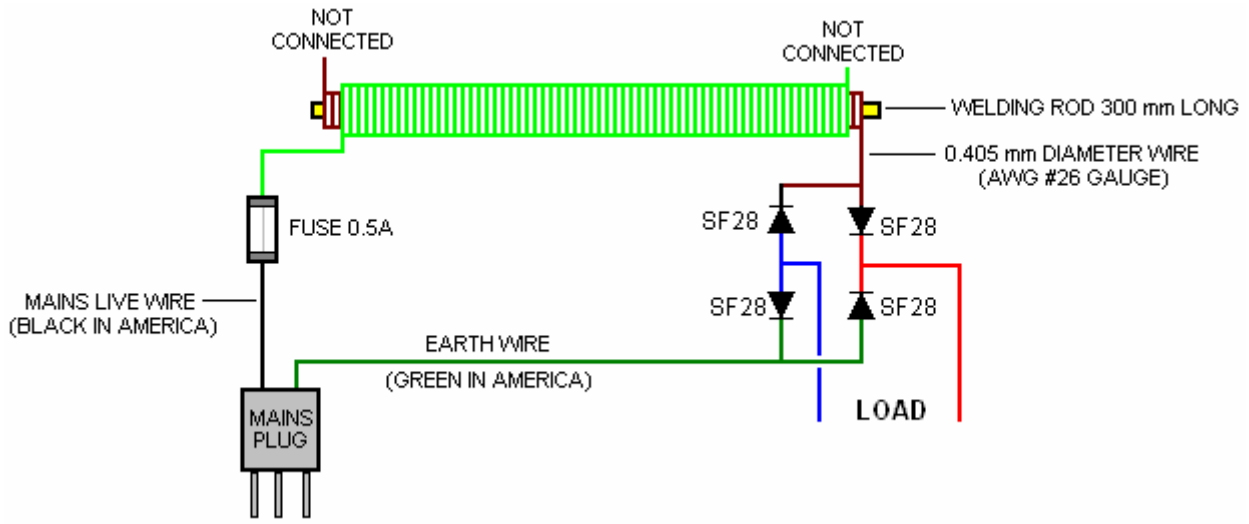
Two rods Five rods

Lorrie also extended his development to a remarkable 48 rods:



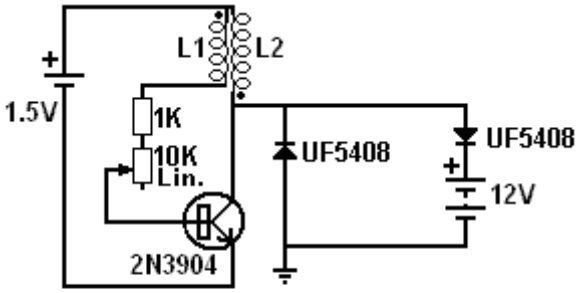
Video link: http://youtu.be/hJyZK6t9qcA The electrical output could be used to charge batteries. Adding extra turns does not increase the output voltage. If the number of turns in each coil matches the output load, then the output power will be greater.

Alexkor in Russia, who is expert in recharging batteries has experimented with this concept and he uses ten coils connected in parallel. He does not use brass, but instead uses the much shorter 300 mm long, 3 mm diameter welding rods with their chemical coating removed. Also, these rods are only used to raise the effectiveness of two separate coils wound on each rod. Each coil is 700 to 750 turns of 0.4 mm diameter wire and the connections are made to the coils and not the rods, as shown here for a single coil pair :



Alex isolates his set of 10 coil-pairs inside a short length of plastic piping:

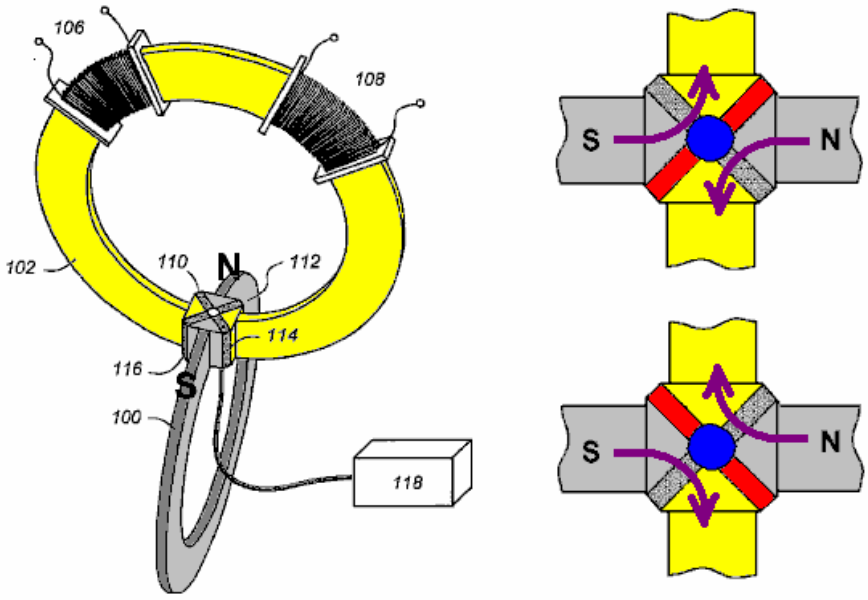
and uses them to power his battery-charging circuit:



Coils: 0.5 to 1.0mm diameter solid copper wire length: 1 to 2 metres bi-filar wound

The Solid-State Magnetostrictive System of Annis and Eberly.

Theodore Annis & Patrick Eberly have produced a variation on this multiple-magnetic-path method which is shown in their US Patent Application 20090096219. They have opted to use a motionless reluctance switch which is a solid-state device which can block magnetic flow when energised. They have arranged one of their devices like this:



The ring shown in grey is a magnet which connects to the ring shown in yellow through two diagonal ‘reluctance’ (magnetic flow) switches. The yellow ring can carry magnetic flux and the control box marked **118** switches the diagonal strips on and off in turn, causing the magnetic flux to reverse it’s direction through the yellow ring. The coils wound on the yellow ring pick up this reversing magnetic flux and pass it out as an electric current. While only one pair of rings are shown here, the design allows for as many rings as are needed to be connected together as shown here:

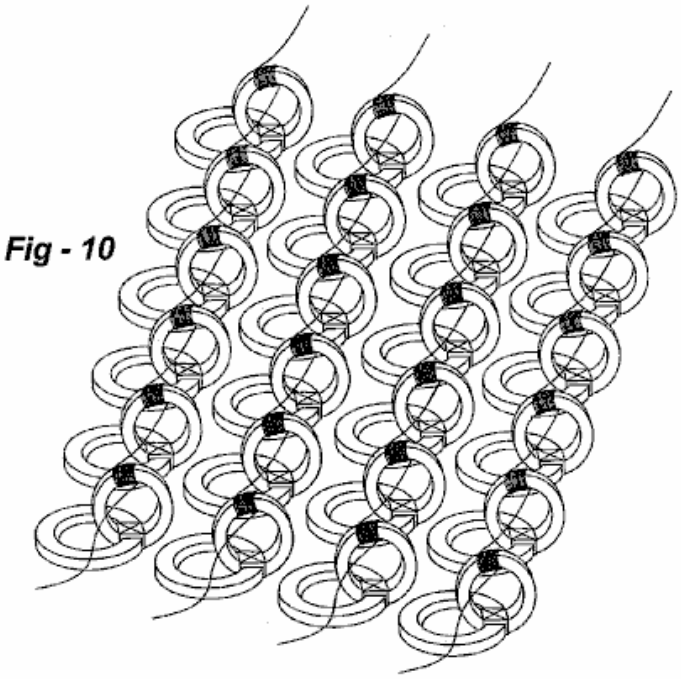


Fig - 10

The patent says: ”The currently preferred motionless reluctance switch is described by Toshiyuki Ueno & Toshiro Higuchi, in their paper entitled „Investigation of the Dynamic Properties of a Magnetic Flux Control Device composed of Laminations of Magnetostrictive Piezoelectric Materials” – University of Tokyo 2004. As shown in Fig.4, this switch is made of a laminate of a Giant Magnetostrictive Material **42**, a TbDyFe alloy, bonded on both sides to a Piezoelectric material **44**, **46** to which electricity is applied. The application of electricity causes the reluctance of the piezoelectric material to increase.

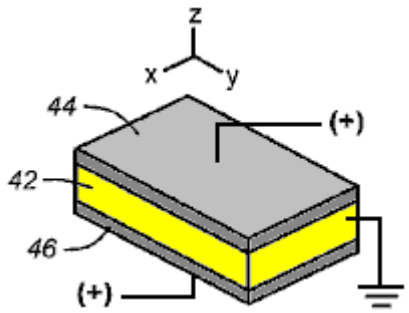

Fig - 4

This original patent application is included in the Appendix.

However, very interestingly, there is another, completely different patent application from Annis and Eberly, with the same publication date and the same number. It is not at all obvious to me how that could be, but here is the bulk of that other patent application (the original being in the Appendix).

ENERGY GENERATION APPARATUS AND METHODS BASED UPON MAGNETIC FLUX SWITCHING

Abstract

In an electrical energy generator, at least one permanent magnet generates flux and a magnetisable member forms the single flux path. An electrically conductive coil is wound around the magnetisable member, and a plurality of flux switches are operative to sequentially reverse the flux from the magnet through the member, thereby inducing electrical current in the coil. A “Figure of Eight” construction comprises two continuous loops of magnetisable material sharing a magnetisable member common to both loops. An alternative configuration uses stacked loops and a separate piece of material acting as the magnetisable member. One end of the magnet is coupled to one of the loops, with the other end being coupled to the other loop. Each loop further includes two flux switches operated in a 2 × 2 sequence to sequentially reverse the flux through the magnetisable member. A relatively small amount of electrical power is used to control the magnetic flux of a permanent magnet by switching the flux between alternate paths. The resulting power from the switched magnetic flux yields substantially more power than the power required for the input switching.

Description

FIELD OF THE INVENTION

This invention relates generally to energy generation and, in particular, to methods and apparatus wherein magnetic flux is switched through a flux path to produce electricity.

BACKGROUND OF THE INVENTION

Magnetic flux may exist in “free-space,” in materials that have the magnetic characteristics of free-space, and in materials with magnetically conductive characteristics. The degree of magnetic conduction in magnetically conductive materials is typically indicated with a B-H hysteresis curve, by a magnetisation curve, or both.

Permanent magnets may now be composed of materials which have a high coercively (Hc), a high magnetic flux density (Br), a high magneto motive force (mmf), a high maximum energy product (BHmax), with no significant deterioration of magnetic strength over time. An example is the NdFeB permanent magnet from VAC of Germany, which has an Hc of 1,079,000 Amperes/meter, a Br of 1.427 Tesla, an mmf ranging up to 575,000 Ampere-turns, and a BHmax of 392,000 Joules/meter^3.

According to Moskowitz, “Permanent Magnet Design and Application Handbook” 1995, page 52, magnetic flux may be thought of as flux lines which always leave and enter the surfaces of ferromagnetic materials at right angles, which never can make true right-angle turns, which travel only in straight or curved paths, which follow the shortest distance, and which follow the path of lowest reluctance (resistance to magneto motive force).

Free space presents a high reluctance path to magnetic flux. There are many materials which have magnetic characteristics similar to those of free space. There are other materials which offer a low or lower reluctance path for magnetic flux, and it is these materials that typically comprise a defined and controllable magnetic path.

High-performance magnetic materials for use as magnetic paths within a magnetic circuit are now available and are well suited for the (rapid) switching of magnetic flux with a minimum of eddy currents. Certain of these materials are highly non-linear and respond to a "small" applied magneto motive force (mmf) with a robust generation of magnetic flux (B) within the material. The magnetisation curves of such materials show a high relative permeability (ur) until the "knee of the curve" is reached, at which point ur decreases rapidly approaching unity as magnetic saturation (Bs) is reached.

Some of these non-linear, high-performance magnetic materials are referred to as "square" due to the shape of their B-H hysteresis curves. An example is the FINEMET® FT-3H nanocrystalline core material made by Hitachi of Japan. Other examples include Superperm49, Superperm80, SuperMalloy, SuperSquare80, Square50, and Supermendur, which are available from Magnetic Metals in the USA.

A "reluctance switch" is a device or means that can significantly increase or decrease (typically increase) the reluctance of a magnetic path. This is ideally done in a direct and rapid manner, while allowing a subsequent restoration to the previous (typically lower) reluctance, also in a direct and rapid manner. A reluctance switch typically has analogue characteristics. By way of contrast, an off/on electric switch typically has a digital characteristic, as there is no electricity "bleed-through." With the current state of the art, however, reluctance switches exhibit some magnetic flux bleed-through. Reluctance switches may be implemented mechanically, such as to cause keeper movement to create an air gap, or electrically by various other means.

One electrical reluctance switch implementation uses a control coil or coils wound around a magnetic path or a sub-member that affects the path. U.S. Navy publication, "Navy Electricity and Electronics Series, Module 8 - Introduction to Amplifiers" September 1998, page 3-64 to 3-66 describes how to modulate alternating current by changing the reluctance of the entire primary magnetic path by these means, one of which is used in a saturable-core reactor and the other in a magnetic amplifier. Flynn, U.S. Pat. No. 6,246,561; Patrick et al., U.S. Pat. No. 6,362,718; Pedersen, U.S. Pat. No. 6,946,938; Marshall, and US Patent Application 2005/01256702-A1 all disclose methods and apparatus that employ this type of reluctance switch for switching magnetic flux from a stationary permanent magnet or magnets for the purpose of generating electricity (and/or motive force).

Another electrical means of implementing a reluctance switch is the placement within the primary magnetic path of certain classes of materials that change (typically increase) their reluctance upon the application of electricity. Another electrical means of implementing a reluctance switch is to saturate a sub-region of a primary magnetic path by inserting conducting electrical wires into the material comprising the primary magnetic path. Such a technique is described by Konrad and Brudny in "An Improved Method for Virtual Air Gap Length Computation," in IEEE Transactions on Magnetics, Vol. 41, No. 10, October 2005.

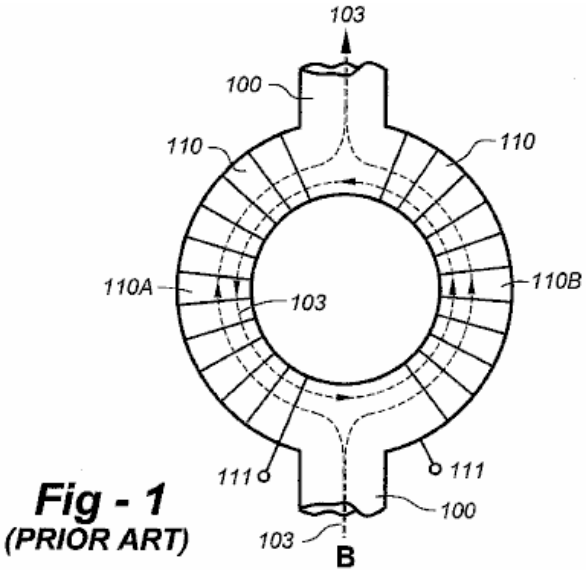

Fig - 1
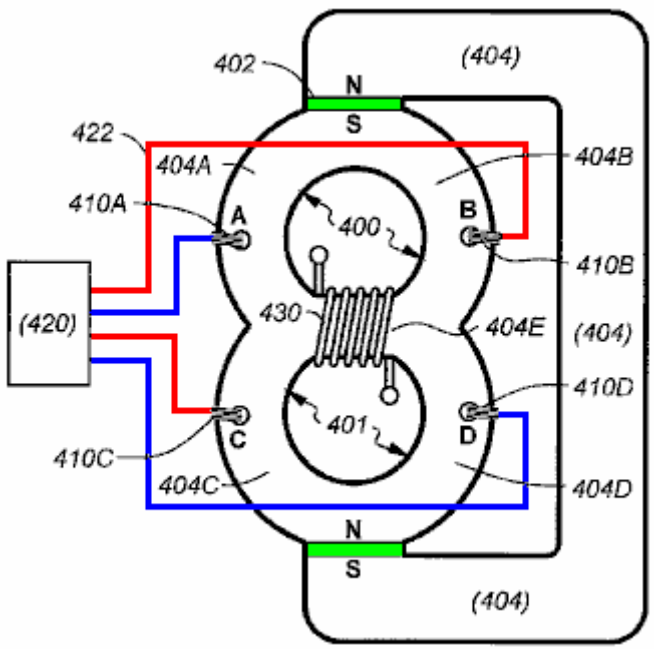
(PRIOR ART)

Another electrical means of implementing a reluctance switch is described by Valeri Ivanov of Bulgaria on the web site www.inkomp-delta.com, shown in **Fig.1**. An electric toroid **110** is inserted into a primary magnetic path (**100**), so that the primary magnetic path is divided into two sub-paths **110A** and **110B**. A net magnetic flux reduction

effect in the primary magnetic path **100** results from the combination of the effects in the two sub-paths **110A** and **110B**, each of which results from different physics principles. In the first sub-path **110A**, the magnetic flux generated by applying electrical current to the windings **110** around toroidal path **110** opposes and subtracts from its portion of the magnetic flux **103** received from the primary magnetic path **100** yielding a reduced magnetic flux, which is also further reduced by a decrease in the sub-path **110A**'s relative permeability thereby increasing the reluctance of the sub-path. In the second sub-path **110B**, the magnetic flux generated by applying electrical current to the toroid windings **111** adds to its portion of the magnetic flux **103** received from primary magnetic path **100** yielding an increased net magnetic flux that approaches or exceeds the knee of the material's magnetisation curve thereby reducing its relative permeability and increasing its reluctance.

SUMMARY OF THE INVENTION

This invention is directed to methods and apparatus where magnetic flux is switched in both direction and intensity through a flux path to produce electricity. The apparatus broadly comprises at least one permanent magnet generating flux, a magnetisable member forming the flux path, an electrical conductor wound around the magnetisable member, and a plurality of flux switches operating to reverse sequentially, the flux from the magnet flowing through the member, thereby inducing electrical current in the coil.



The preferred embodiment includes first and second loops of magnetisable material. The first loop has four segments in order **A, 1, B, 2**, and the second loop has four segments in order **C, 3, D, 4**. The magnetisable member couples segments **2** and **4**, and the permanent magnet couples segments **1** and **3**, such that the flux from the magnet flows through segments **A, B, C, D** and the magnetisable member. Four magnetic flux switches are provided, each controlling the flux through a respective one of the segments **A, B, C, D**. A controller is operative to activate switches **A-D** and **B-C** in an alternating sequence, thereby reversing the flux through the segment and inducing electricity in the electrical conductor. The flux flowing through each segment **A, B, C, D** is substantially half of that flowing through the magnetisable member prior to switch activation.

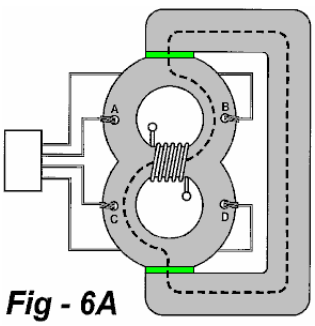


Fig - 6A

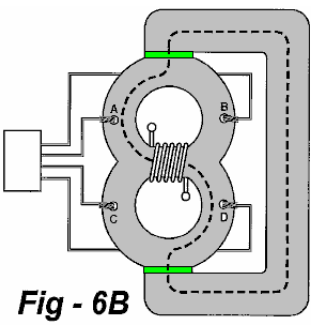

Fig - 6B

The loops and magnetisable member are preferably composed of a nanocrystalline material exhibiting a substantially square BH intrinsic curve. Each magnetic flux switch adds flux to the segment it controls, thereby magnetically saturating that segment when activated. To implement the switches, each segment may have an aperture formed through it and a coil of wire wound around a portion of that segment and through the aperture. The controller may be at least initially operative to drive the switch coils with electrical current spikes.

The first and second loops may be toroidal in shape, and the loops may be spaced apart from one another, with **A** opposing **C**, and **1** opposing **3**, and with **B** opposing **D** and **2** opposing **4**. The magnetisable member in this case is preferably a separate piece of material. Alternatively, the first and second loops may form a "Figure of eight" shape, with the two loops intersecting to form the magnetisable member.

The permanent magnet(s) and the material comprising the magnetic paths are preferably proportioned such that the material through the common segment is at or slightly below its maximum relative permeability before the electrically conducting output coil is energized. In the preferred embodiments, the power resulting from the switched magnetic flux yields substantially more power than the power required for the input switching.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE INVENTION

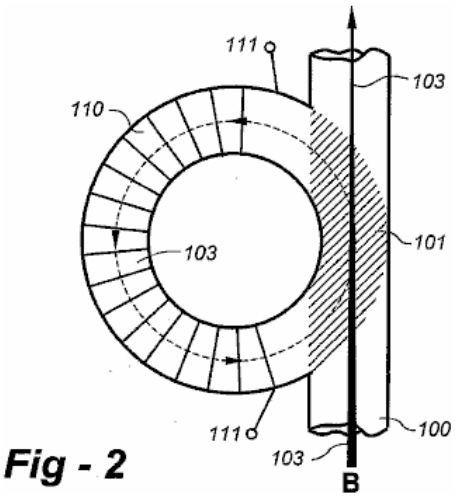

Fig - 2

Fig.2 is a detail drawing of a reluctance switch according to the invention. The reluctance switch includes the following components: a closed magnetic path **110** comprised of a high performance magnetic material (preferably a non-linear material exhibiting a "sharp knee" as saturation is approached), around which is wound a coil **111**. The closed magnetic path **110** shares a common segment **101** with a primary magnetic path **100**, in which magnetic flux **103** is induced by a permanent magnet (shown in subsequent drawings). Electric current is applied to windings **111** having a polarity and sufficient amperage so that the magnetic flux generated in the path

of switch **110** is additive to the magnetic flux **103** from the permanent magnet, such that the primary path **110** approaches or reaches magnetic saturation.

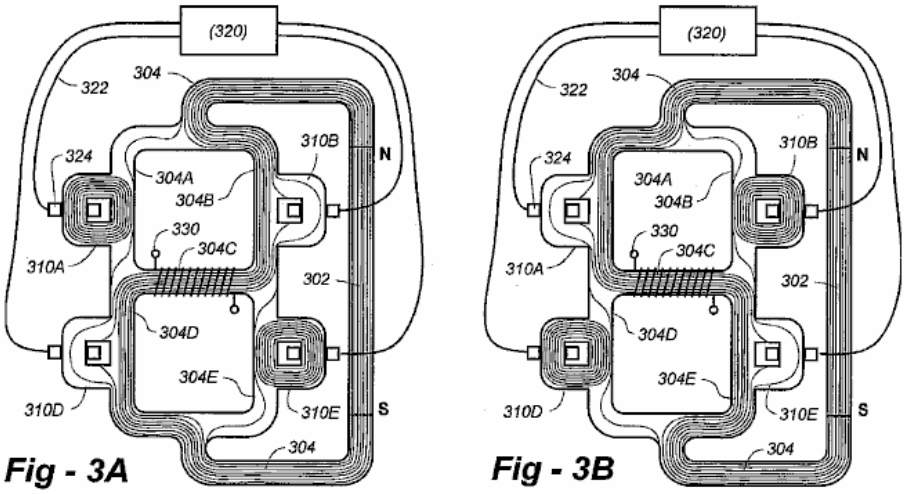

Fig.3A and **Fig.3B** are detail drawings of an apparatus which employs four reluctance switches according to the invention in a manner similar to that disclosed in U.S. patent application Ser. No. 11/735,746 entitled “Electricity Generating Apparatus Utilising a Single Magnetic Flux Path”, the entire content of which is incorporated herein by reference. In this and in all embodiments described herein, the geometry of the closed magnetic paths may be circular (toroidal), rectangular, or any other closed-path shapes . A primary path **304** carries the flux from permanent magnet **302** unidirectionally. Flux switch pairs **310 A/E** and **310 B/D** are activated in alternating fashion to reverse the flux in magnetisable member **304C**, thereby inducing electrical current in winding **330**. **Fig.3A** shows the flux flow in one direction, and **Fig.3B** shows it reversed.

In **Fig.3A**, switches **310A** and **310E** are activated by controller **320** in electrical communication with the windings on the switches such as through conductor **322** to winding **324**. The additional flux in switches **310A** and **310E** are additive with the flux that would otherwise be present in segments **304A** and **304E**, thereby saturating these paths, causing the flux through segment **304C** to be in the direction shown. In **Fig.3B**, switches **310B** and **310D** are activated, saturating segments **304B** and **304D**, and reversing the flow.

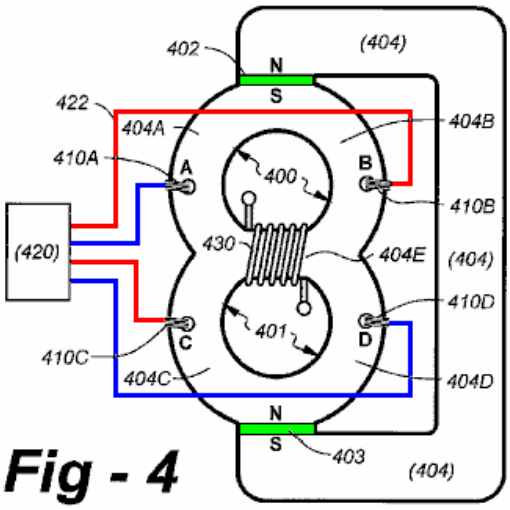

Fig.4 is a drawing that depicts an embodiment of the invention using circular toroids **400**, **401** and multiple permanent magnets **402**, **403** disposed in the primary path **404**. The two toroids **400**, **401** intersect, forming magnetisable member **404E**. A coil **430** is wound around the member **404E**, as shown.

The primary magnetic path **404** interconnects the upper end of loop **400** and the lower end of loop **401**. One of the magnets, **402**, couples one end of the primary magnetic path **404** to the first loop **400**, and another, **403**, couples the other end of the primary magnetic path **404** to the second loop **401**.

In this, and all of the embodiments described here, the permanent magnets are strong, rare-earth magnets, and multiple magnets of any length (thickness) may be used in each case. Further, in all embodiments, the loops, primary magnetic path and/or magnetisable member are preferably constructed from a high magnetic permeability

material such as the FINEMET FT-3H nanocrystalline soft magnetic material available from Hitachi. The invention is not limited in this regard, however, as alternative materials, including laminated materials, may be used.

The connections of the primary magnetic path **404** to the two loops **400**, **401** create four segments apart from the magnetisable member **404E**, the four segments including two opposing segments **A, B** in the first loop on either side of magnet **402**, and the two opposing segments **C, D** in the second loop on either side of magnet **403**.

Four magnetic flux switches are provided, each being operative to control the flux through a respective one of the four segments. A controller **420** is operative to activate the switches associated with segments **A** and **D**, and then **B** and **C**, alternately, thereby reversing the flux through the member **404E**, and so, inducing electrical current in coil **430**.

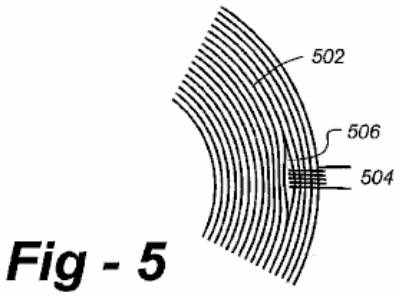

Fig - 5

Apertures may be formed through each of the four segments, with the switches being implemented by coils **410A** to **410D** which pass through the apertures and around an outer (or inner) portion of each segment. As shown in **Fig.5**, if the loops are fabricated with laminated material **502**, the laminations may be split at **506** to accommodate coil **504**. The percentage of the segment surrounded by the coil may vary in accordance with the material used, the waveforms presented to the coils, and other factors, with the goal being to magnetically saturate each segment through activation of the associated switch, thereby reversing the flux through path **404E**.

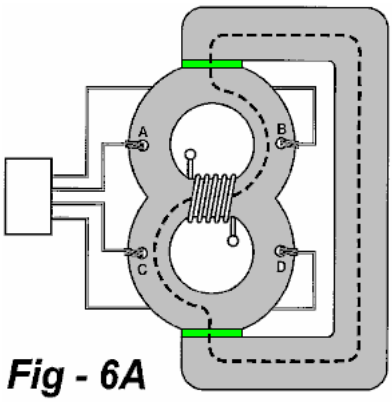

Fig - 6A

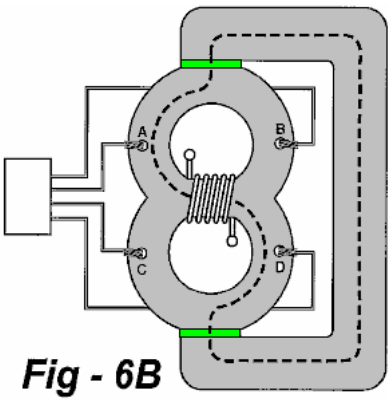

Fig - 6B

Fig.6A and **Fig.6B** show the operation of the apparatus of **Fig.4**. The primary path **404** carries the flux from permanent magnets **402** and **403** unidirectionally. Reluctance switches **410A** to **410D** are activated alternately to reverse the flux in segment **404E** which, in turn, induces electrical current in winding **430**. **Fig.6A** shows the flux flow in one direction, and **Fig.6B** shows it flowing in the opposite direction.

In **Fig.6A**, switches **410A** and **410D** are activated by controller **420** in electrical communication with the windings on the switches, such as through conductors **422** to switch **410B**. The flux provided by switches **410A** and **410D**, thereby saturating these paths, causing the flux through segment **404C** to be in the direction shown. In **Fig.6B**, switches **410B** and **410C** are activated, saturating segments **404B** and **404D**, thereby reversing the flux through path **404E**.

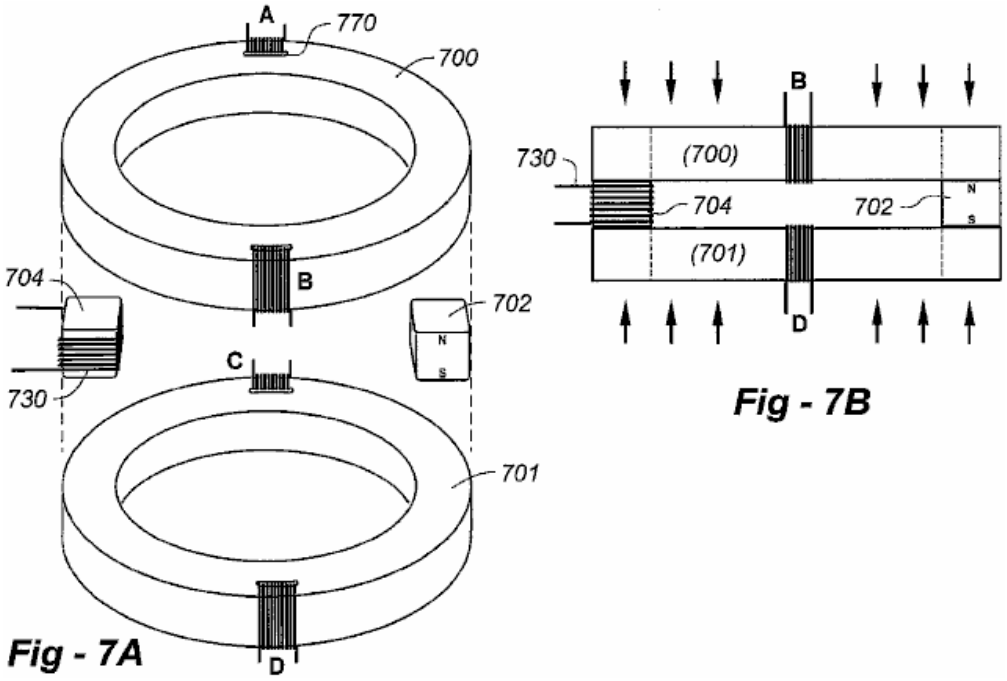

Fig.7A depicts a preferred construction of the apparatus depicted in **Fig.4**, **Fig.6A** and **Fig.6B**. Loops **400** and **401** are implemented as complete toroids **700**, **701**. This is important, since preferred high-performance magnetic materials are currently available in regular shapes of this kind. Note that, in this case, curved slots such as **770** are formed through the sides of each toroid to implement flux switches **A** to **D**. The magnetisable member in this embodiment is implemented with a block of material **704**, preferably the same high-performance magnetic material used to construct loops **400**, **401**. Permanent magnet **702**, shown at **702**, preferably has the same length as block **704**, enabling the various constituent parts to be held together with compression, shown in **Fig.7B**.

The following sections summarise some of the important characteristics of the preferred embodiments:
In terms of materials, the apparatus benefits from the use of nanocrystalline material with a “Square” BH intrinsic curve, a high Br (remanence) which is about 80% of its Bs (saturation), a low Hc (coercivity), and a fast magnetic response time to saturation. An example is FineMet FT-3H from Hitachi of Japan, which has a Br of 1.0 Tesla, a Bs (saturation) of 1.21 Tesla, a time to saturation (Bs) of 2 usec, and an Hc of −0.6 amp-turns/meter.

Modern permanent magnets are used with a square BH intrinsic curve, a Br in the range of 1.0 Tesla or more, and high Hc in the range of −800,000 amp-turns/meter or more. An example is the NdFeB magnet from the German company VAC, which has a Br of 1.427 Tesla and an Hc of −1,079,000 amp-turns/meter.

An important consideration is the matching of the magnet to the nanocrystalline material, both in Tesla rating and in cross-sectional area. The magnet's Br should be below the Bs of the nanocrystalline material. If the magnet is too “strong” for the nanocrystalline material, this may cause the nanocrystalline material to saturate at the area of contact with the magnet.

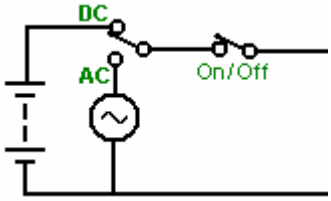
The current driving the reluctance switches in the prescribed 2 × 2 sequence should have a sharp rise in the leading edge (Tr) of each pulse with a pulse width (Pw) and Amperage value that are sustained until released at the end of the pulse width (Tf). The table below shows the effects of input current pulse rise times (Tr) on the output. There exists a narrow band of Tr, before which there is small power output, at which there are excellent power output and COPs in the range of 200 to 400 or greater, and after which there is no major increase in power output. The COP of this device without the coupling circuit is defined as “Output power/Drive Power” for the switches.

Tr	Output Power	Waveform Description
1.0E–4 secs	50 Watts	Spikes
7.5E–5	50 Watts+	Spikes with intermittent 30 Kilowatt square waves
5.0E–5	15 Kilowatts	Square waves after 3 cycles
1.0E–5	15 Kilowatts	Square waves after 1 cycle

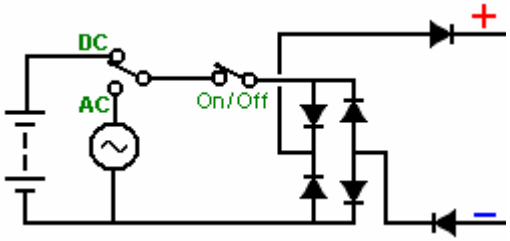
The Motionless Generator of Richard Willis.

On 28th May 2009 a European Patent application was filed by Richard Willis, entitled "Electrical Generator". During a TV interview, Richard stated that his design has COP=3,600. Available commercially from his Canadian company and sold under the name "Magnacoster", early in 2010 his advertised pricing was US $4,200 for a unit which has four separate 100 amp 12V outputs, giving a combined maximum output power of 4.8 kilowatts. A larger unit was priced at US $6,000 with four separate 24V outlets providing a 9 kilowatt combined output. The house-powering unit which is supplied with a 12 kilowatt inverter to provide mains AC power and which gets connected direct to the circuit-breaker box of the house, was priced at US $15,000. One particularly interesting statement made by Richard is that the output power is at a higher frequency than the input power. He suggests that the electrical signal bounces around inside the device, multiplying the power as it goes and giving the output higher voltage and higher current than the input. The design of the device is most interesting as it is very simple. It is shown in his patent application WO 2009065219, a somewhat reworded copy of which is included in the Appendix to this eBook. Richard's web site is http://www.vorktex.ca/page/235610203. However, while Richard's designs do indeed work, he appears to be experiencing problems with the output wiring melting due to the very high current, and more importantly, the generation of high levels of unwanted electromagnetic radiation. These problems appear to have prevented him from supplying any commercial units at this time.

The circuit is based on a pulsed coil and two magnets and it has a number of unusual features. The power supply is unusual:

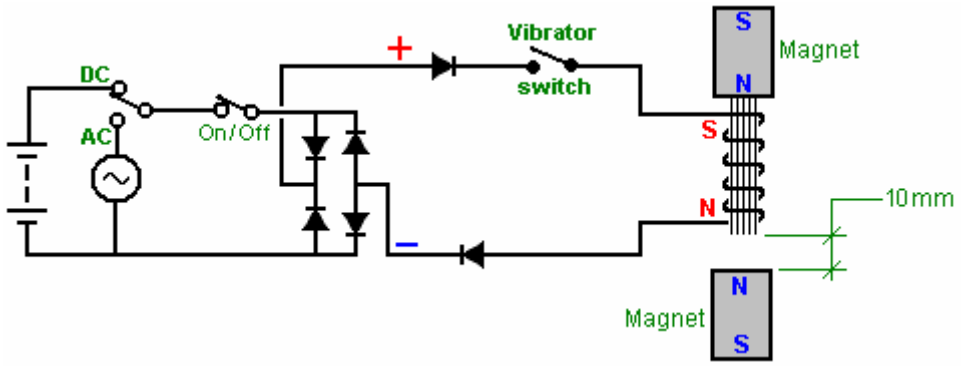


Richard arranges it like this so that either DC or AC can be used as the input power and so he follows that arrangement with a diode bridge, followed by two more diodes as shown here:



This is an interesting arrangement when the input is DC as it would be a more usual arrangement to have the diode bridge only in the AC input section and not included for the DC input where it just drops the input voltage and wastes electrical power unnecessarily. Still, that is the way it is shown in the patent, so that is the way it is shown here.

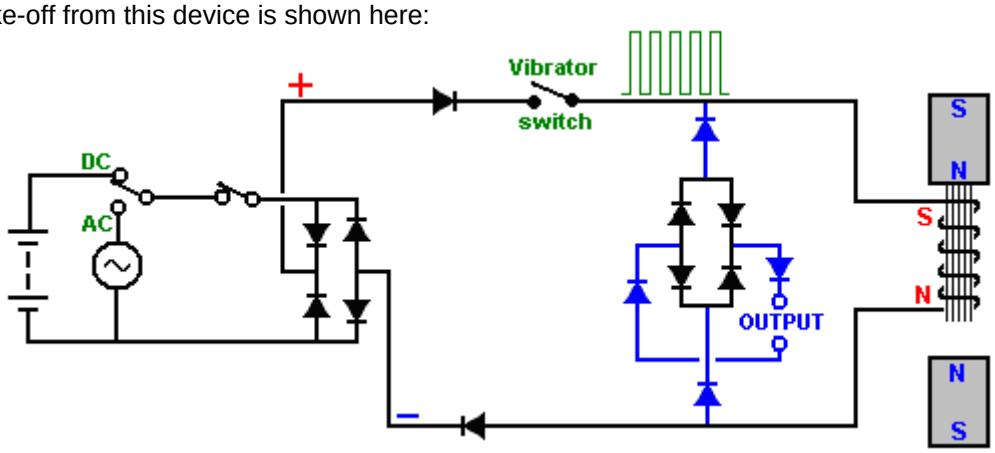
The input power supply is fed to an electromagnet but is converted into a pulsed supply by the use of an interrupter switch which may be mechanical or electronic:



As can be seen, the arrangement is particularly simple although it is an unusual configuration with the electromagnet core touching one of the permanent magnets and not the other. The magnet and electromagnet poles are important, with the permanent magnet North poles pointing towards the electromagnet and when the electromagnet is powered up, it's South pole is towards the North pole of the permanent magnet which it is touching. This means that when the electromagnet is powered up, it's magnetic field strengthens the magnetic field of that magnet.

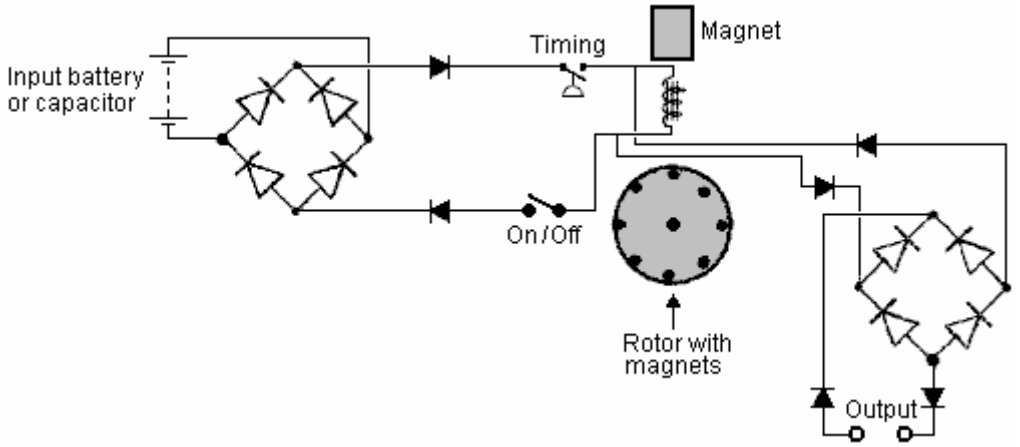
There is a one-centimetre gap at the other end of the electromagnet and it's North pole opposes the North pole of the second permanent magnet. With this arrangement, each electromagnet pulse has a major magnetic effect on the area between the two permanent magnets. In the diagram shown above, just a few turns of wire are shown on the electromagnet core. This is just for clarity and it does not mean that only a few turns should be used. The strength of the magnets, the electromagnet wire thickness and number of turns are related to each other and experimentation will be needed to determine the best combination.

The energy take-off from this device is shown here:



Richard states that the input power can be anywhere from under one volt to one million volts while the input current can be anything from under one amp to one million amps, so he clearly envisages a major range of constructions and components. The core material for the electromagnet is specified as ferrite, mumetal, permalloy, cobalt or any non-permeable metal material. It seems likely that iron filings embedded in epoxy resin is likely to be a suitable material as it can respond very rapidly to sharp pulses and it seems clear that in common with almost every other similar free-energy device, the rapidity of rise and fall of the power pulse is of major importance. Having said that, Richard states that the frequency of pulses in the output section is greater than the frequency of pulses applied to the input section. From this it seems likely that the device should be tuned so that the input pulses should be at a lower harmonic of the resonant frequency of the device. It is worth reading Richard's full description which is near the end of the Appendix.

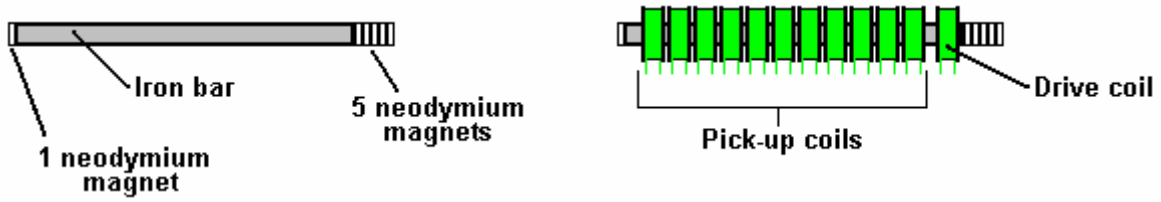
A second version of the circuit looks like a modification of the John Bedini pulsed rotor battery charging circuit with a rotor substituting for the second permanent magnet:



This enhances the operation of the Bedini device by providing an initial magnetic field in the coil.

The Generator Proposal of "Silverhealtheu".

One of the EVGRAY yahoo forum members whose ID is 'silverhealtheu' has described a simple device which appears to be not unlike the Richard Willis generator above.



The device consists of an iron bar one inch (25 mm) in diameter and one foot (300 mm) long. At one end, there is a stack of five neodymium magnets and at the opposite end, a single neodymium magnet. At the end with the five magnets, there is a coil of wire which is strongly pulsed by a drive circuit. Down the length of the bar, a series of pick-up coils are positioned. Each of these coils picks up the same level of power that is fed to the pulsing coil and the combined output is said to exceed the input power.

The Motionless Generators of Heinrich Kunel

While Richard Willis of Magnacoaster in Canada, has gone commercial with his generators, making each of the generator outputs multiples of 12V 100A, a lot of very interesting earlier information can be found in the 1982 patent of Heinrich Kunel. The patent describes four separate configurations of his basic design, a design which looks very much like that used by Richard Willis. Here is an attempted translation of the Kunel patent which is in German:

PATENT: DE3024814 28 January 1982 Inventor: Kunel, Heinrich

PROCEDURES AND DEVICES FOR ENERGY PRODUCTION

Application Number: DE19803024814 19800701
Priority Number(s): DE19803024814 19800701
IPC Classification: H02N11/00 EC Classification: H02K53/00

DESCRIPTION

The invention concerns procedures and devices for energy production, which convert the magnetic flux from permanent magnets, without the need for rotary, or any other form of motion, into temporally variable induced flux and produce large fluctuations of the induced magnetic flux into electric current, without the need for a thermal circuit, or torque or chemical process, and in such a manner that the electric current is amplified.

The energy problems of our time are sufficiently well-known in the professional world. The transformation of conventional primary energy forms into technically usable energy is relatively cost-intensive. Additionally, by doing this, precious and ever scarcer raw materials are being destroyed and pollutants are accumulated, pollutants which are able to cause the end of mankind.

In order to reduce or avoid these and other disadvantages during power production, it is suggested according to this invention, that for the production of electric current by induction, no torque is used, but instead, the magnetic flux from permanent magnets is converted into an induced flux with large rapid variations, e.g. into a rapidly changing or pulsating induced flux, which can generate an electric current.

In accordance with this invention, one proceeds from the basic arrangement where a permanent magnet is connected to an iron core via one or both of its poles, the core consisting of, for example, dynamo iron, pure iron or amorphous iron or any similar suitable material which has little or no core losses.

Following the procedure of this invention if, for example, one pole of a bar magnet touches such an iron core and is aligned with the longitudinal axis of that core, then both the magnet and the core act as a magnet.

During this initial magnetisation process of the core a magnetic flux flows in the core, which induces a current in a conducting circuit surrounding the core.

If, in addition to the permanent magnet, a coil is wound around the core, and arranged in such a way that a current flowing in that coil wholly or partially interrupts the magnetic flux flowing through the core, then this causes another modification of the magnetic flux passing through a coil wound around the core.

If this interruption of the flux flowing from the permanent magnet is large, and has the waveform of a Alternating Current, then a pulsating Direct Current is induced in the coil wound around the core.

With an AC input to the magnetic flux modifier coil wound on the core beside the magnet, the coil receives two current flow direction changes per AC cycle, and so the magnetic flux coming from the permanent magnet is interrupted once and released once during each input power cycle. In this way, a pulsating induced Direct Current is generated in the output coil caused by the pulsating magnetic flux in the core.

It was found that the induced flux from a permanent magnet achieves its full initial value of the magnetic flux density in the core also at the free end of the soft-iron magnetic core, even if there are several induction windings each with the same number of turns and the conductor cross section are appropriate as in a magnetic flux modification coil wound on the core, without changing the strength of the magnetic flux density or the remanence of the permanent magnet.

The permanent magnet is not demagnetised when used to provide the flux in the core, no energy is extracted from it, unlike an electromagnetic core, whose windings require more operating current than that produced as an output. With an electromagnetic core, as much input current is required, as is induced in the output winding, corresponding to the relationships of the well-known transformer. Therefore it is important to produce the induction flux by using a permanent magnet.

After the basic primary system, one can build e.g. energy linear generators or energy circle generators or other arising or suitable types and forms of energy generators, without the necessity of a rotor or a stator or any such mobile sections or providing torque in the generator.

The invention is so designed as to make only frequency control governed by electrical means so that the internal induction flux in the generator core is essentially caused by the magnetic field of the permanent magnet.

In the drawings constructional examples are schematically represented according to the invention:

Fig.1 shows a linear energy generator in longitudinal cross-section.

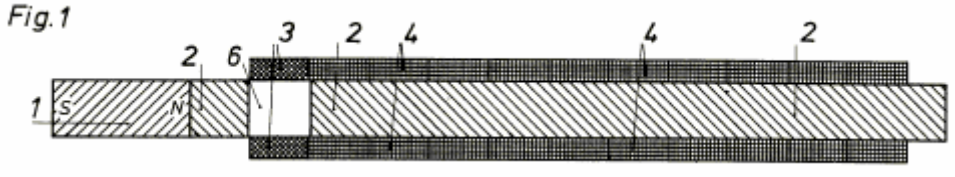


Fig.2 shows a linear energy generator in the instantaneous state of the transmission of the induction flux of the permanent magnet to the generator core and

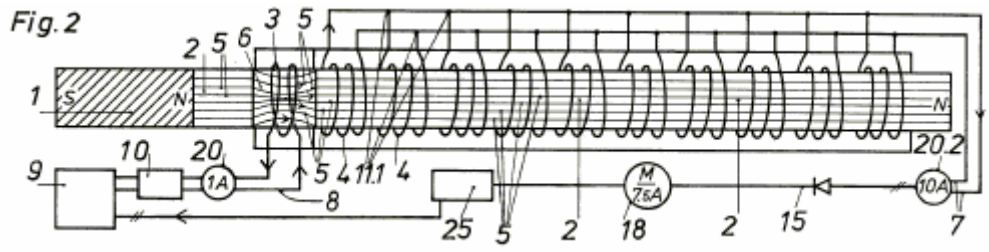

Fig.3 represents a linear energy generator at the moment of the interruption by the induced flux;

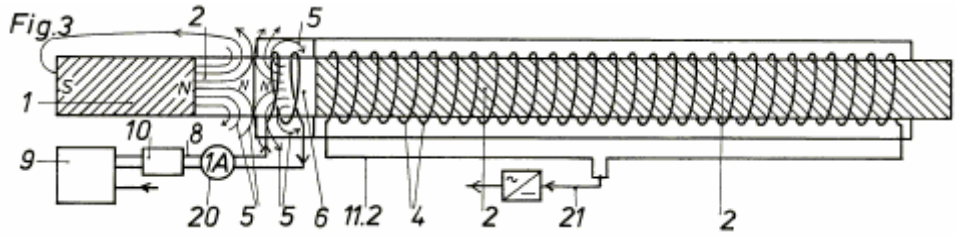

Fig.4 explains a static energy pulse generator with a closed magnetic circuit at the moment the transmission of the induction flux of the permanent magnet to the generator core block,

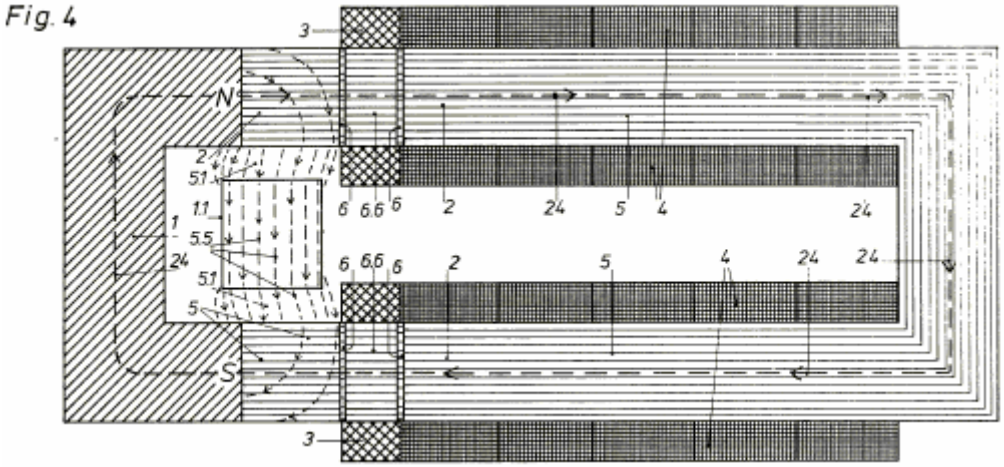

Fig.5 is a schematic diagram of the functional way in which the feedback process operates in a system according to the present invention,

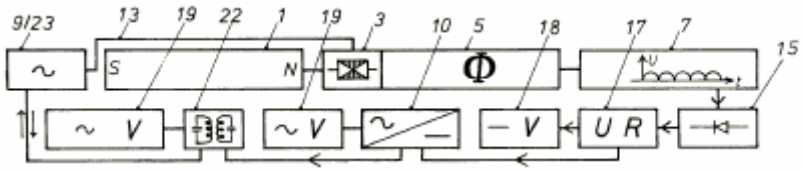

Fig. 5

Fig.6 shows a double linear energy generator with some of its sub-elements and

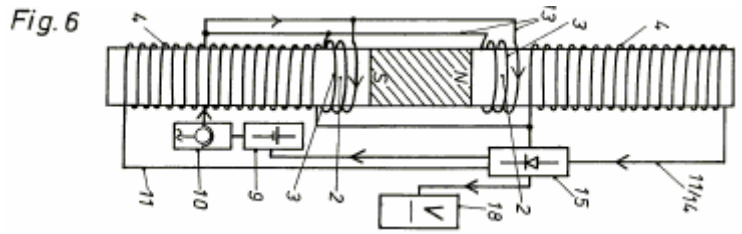

Fig.7 shows an energy generator, according to the present invention, with cyclic pulsing operation and with some of its sub-elements in and at the energy circuit.

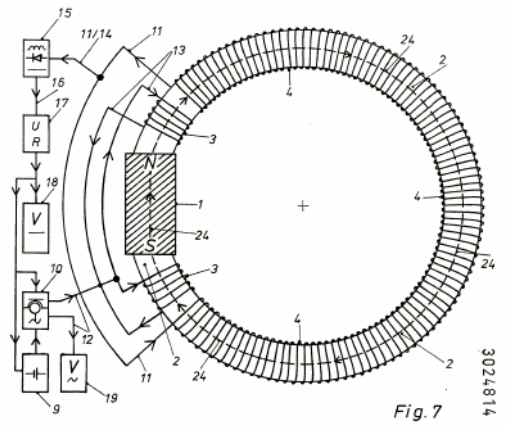
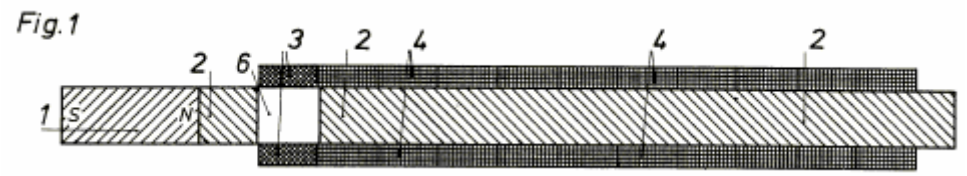
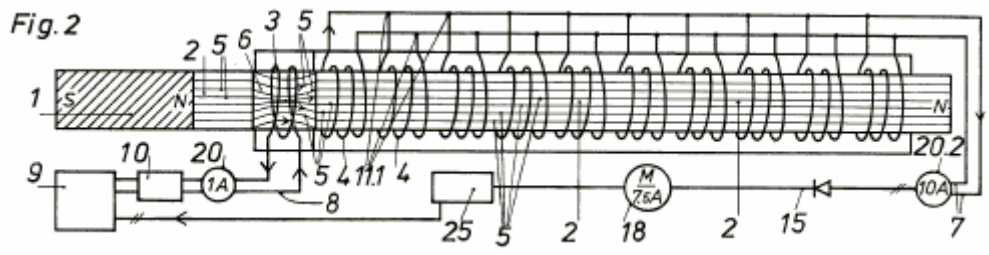




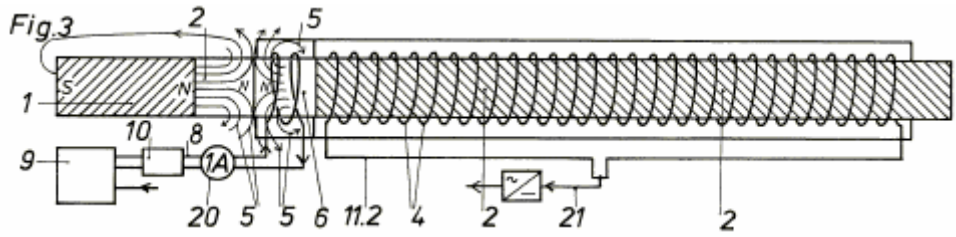
The linear energy generator shown in cross-section in **Fig.1**, consists of a permanent bar magnet **1** with a soft-iron magnetic generator core **2**, which can be a single piece, or, as shown here, divided into two sections. The magnetic flux modification coil is not directly attached to the permanent magnet **1**, so that the permanent magnet **1** is not subjected to the alternating fields produced by the magnetic flux modification coil **3**.

On the generator core **2**, following the magnetic flux modification coil **3**, there are several output coils **4**. An air gap **6** serves as a gate or circuit-breaker for the magnetic flux coming from the permanent magnet **1** and the magnetic induction flux for the induction windings **4**.



With this arrangement, an alternating current applied to the magnetic flux modification coil **3** is used to produce an alternating magnetic field in the air-gap **6**, so that, as shown clearly in **Fig.2**, with each phase of the alternating current the induced magnetic flux **5** is directed first to the core **2** and then against the permanent magnet **1**, as

shown in **Fig.3**, causing the magnetic flux **5** induced in core **2** by the permanent magnet **1**, is interrupted totally or partially, and thus experiences a modification which varies with time.



If an alternating current is supplied to the magnetic flux modification coil **3** e.g. with a frequency by 50 Hz, then the induced flux **5** in core **2** experiences one hundred modifications per second, inducing in the induction windings **4** a pulsating direct current **14** which has 50 positive maximum values per second.

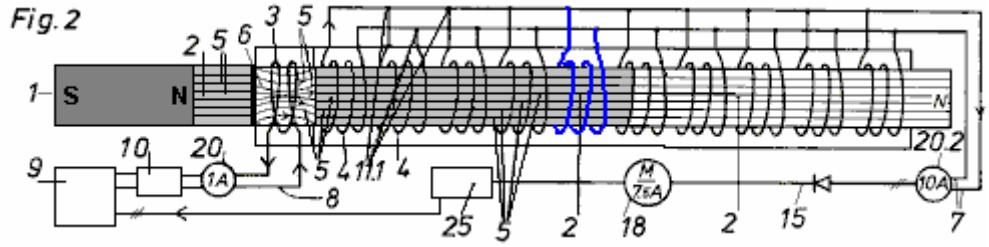


Fig.2 illustrates that on the generator core **2** several induction windings **4** are wound, **which correspond to the number of turns with same wire diameter as used in the magnetic flux modification coil 3**.

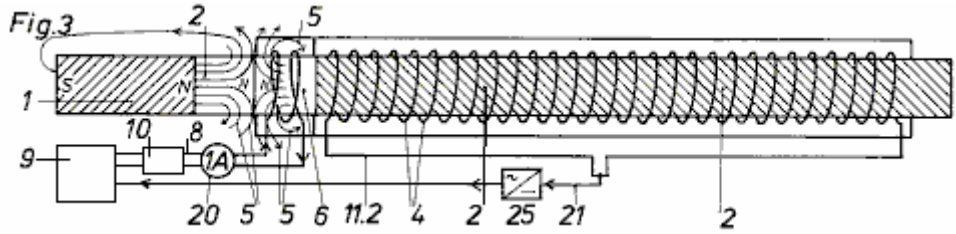
The permanent magnet **1** requires no electric current to produce its magnetic flux and nevertheless has at its North Pole end **N** of the core **2** the same magnetic saturation, as produced by the multiple number of turns of induction coil **4** of **Fig.2** or in a continuous coil **4** as shown in **Fig.3**, receives a multiple version of the input current which is needed for the excitation of the magnetic flux modification coil **3**.

From the power source **9** the energising current flows to the pulse generator **10**, the 1-amp ammeter **20** displays the intensity of the electric current. The induced current **7** or the pulsating direct current **14** is added via connections **11,1** and is measured by the 10-amp ammeter **20,2**. The rectifier **15** (not shown) produces pulsating Direct Current which is smoothed and supplied as the DC output **18**, through wire **21** to the battery charger **25**, which provides the input for the power source **9**.



The interruption of the magnetic flux by the direction change of the Alternating Current, necessary for the repeated modification of the induction flux **5**, is shown in **Fig.3**. When the induction flux **5** is interrupted, the wire coil(s) **11.2** is negative in that instant. Wire **21** provides the connection to the output power (not shown) and the input power source **9**.

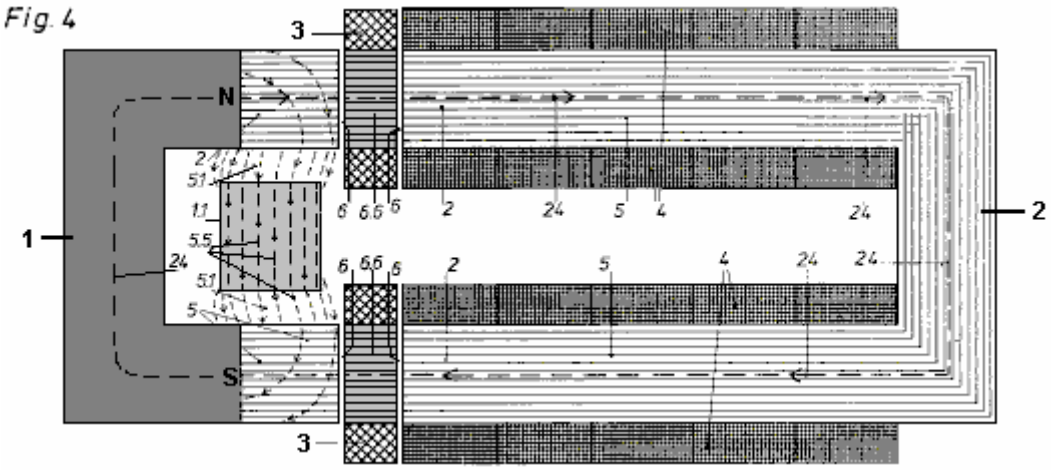


Fig.4 shows an embodiment of the above design which uses a U-shaped permanent magnet **1** and a U-shaped generator core **2** which has its two ends facing towards the poles of the permanent magnet **1**. Wound around two narrow air gaps **6** and its own narrow core, is a magnetic flux modification coil **6.6**.

Fig.4 shows the instantaneous state, when the magnetic flux **5** is transferred from the magnetic flux modification coil **3** into the generator core **2** forming a closed magnetic circuit **24**. The magnetic flux modification coil **3** here has a core **6.6**, which alternately makes and interrupts the passage of the magnetic flux **5** between two narrow air gaps **6** from the permanent magnet **1** to the generator core **2** which has the induction windings **4**, so that each pulse of the induction flux **5** induces a current in the induction windings **4**. Thus a pulsating Direct Current results which is several times larger than the input energising current.

When the direction of current flow in the soft-iron magnetic core **6.6** of the magnetic flux modification coil **3** is changed, then at that time, the magnetic flux **5** of the permanent magnet **1** flows over into the iron guidance block **1.1** and flows along the paths **5.5** and **5.1** to the South-pole of the permanent magnet **1** or to the equilibrium in the air gaps between the North-pole of iron guidance block **1.1** and the South-pole of the permanent magnet **1**. The dashed line **5.5** from North-pole to South-pole through the iron guidance block **1,1** depict the magnetic flow when it is prevented from travelling through the generator core **2**.

This steering of the magnetic flux **5** prevents leakage flux entering the generator core **2** and so the maximum RMS of the induced current is achieved, as the generator core **2** is without magnetic excitation.

PJK note: I have difficulty in accepting this as the excitation coil would appear to produce an equivalent magnetic flux into the U-shaped frame **2** as it blocks the permanent magnet flux passing across the air gaps between magnet **1** and electromagnets **3**, and to make things worse, magnetic flux flows about a thousand times more easily through soft iron than through air. However, we do know that modulating the flux from a permanent magnet with the magnetic field from a coil is very effective in producing COP>1 as has been shown by the independent replication of Lawrence Tseung's magnetic frame covered earlier in this chapter.

The following schematic diagram **Fig.5**, shows the sequence in the cyclic process e.g. in an energy generator according to **Fig.4**.

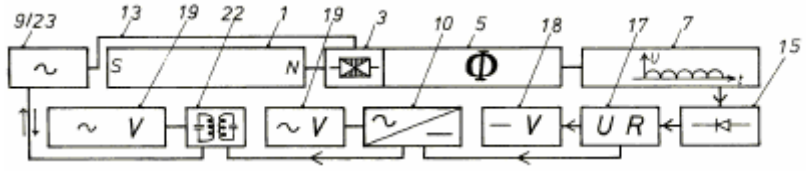

Fig. 5

The pulsating current from the power source **9** or Alternating Current **12** from the power-grid **23** flows through wire **13** to the magnetic flux modification coil **3** and produces a pulsating induction current **7** or pulsating direct current **14**, which is converted by the rectifier **15** to smooth Direct Current **16** which is passed to the voltage regulator **17**, and then on as Direct Current **16** now at the desired voltage, on to the DC output **18** and to the current transformer **10**, by which the received Alternating Current **12** is led to the AC output **19** and coupled by AC link **22** with the power-grid input **23**, whereby the AC output **19** can be supplied with current from the power-grid or from the electric output of the energy generator.

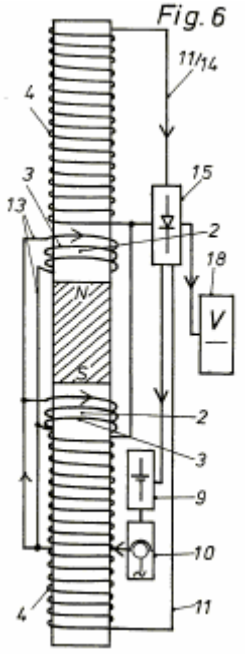

Fig.6 shows a double linear generator in accordance with the invention. On a preferably straight-line permanent magnet are fitted generator cores **2** of dynamo iron to its two poles. The magnetic flux modification coil **3** gets its working current from the power source **9** through a current transformer or from pulse generators **10** fed by the excitation circuit **13**. Through appropriate windings **4** an output of either Direct Current or Alternating Current can be obtained.

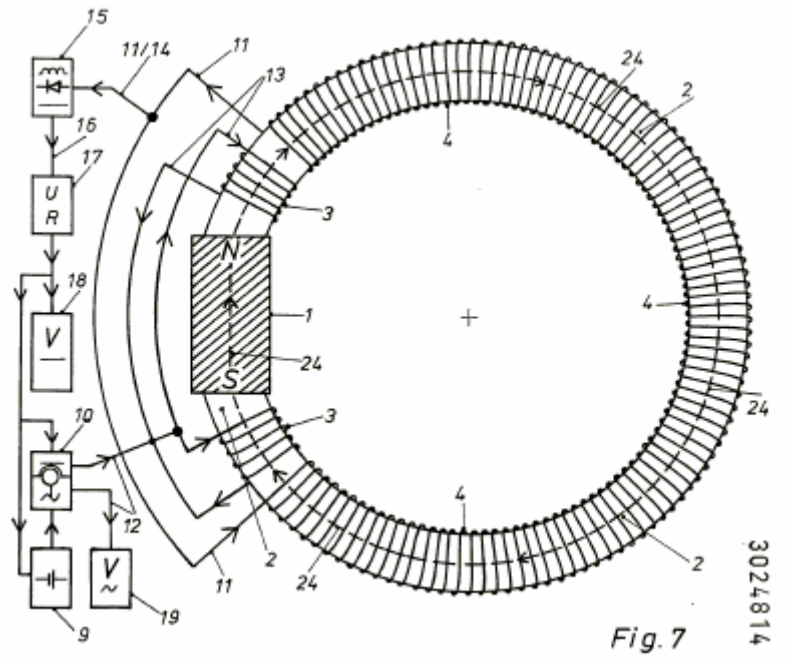
Pulsating Direct Current **14** from the induction current circuit **11** is smoothed and passed to the DC output **18** and to the input power source **9**.



A further version of the system in accordance with the invention is shown in **Fig.7**. This is also a motionless energy producer, although it has a cyclic arrangement and function. In this generator there are no mobile sections such as a rotor and the induction flux **5**, like the induction current **7**, develops from a cyclically pulsating induction flux.

The permanent magnet **1** is inserted into a circular generator core **2**. The magnetic flux modification coils **3** can be operated with pulsating Direct Current **14** or as here with Alternating Current **12**. For example, the Direct Current **16** from the power source **9** is led into a current transformer **10** converted into Alternating Current and fed into the exciter circuit **13**.

The magnetic flux modification coils are created so that the positive maximum value of the Alternating Current **12** opens and supports the natural flow of the permanent magnet flux **5** passing from the North-pole to the South-pole through the circular generator core **2** to form a closed magnetic circuit **24**.

If the magnetic flux modification coils **3** on both sides of the permanent magnet **1** carry the maximum negative value of the Alternating Current **12**, then the natural magnetic flux in the generator core **2** is constricted by induction flux moving in the opposing direction in the magnetic flux modification coils **3** and this interrupts the magnetic flux **5** either totally or partially.

In the case of temporally large modification of this sequence in the coil **4** a pulsating direct current **14** is caused, which is led by the induction circuit **11** to the electric rectifier **15**, in which the pulsating direct current **14** is reduced to a smooth DC current. The Direct Current **16** can be passed to the DC output **18** and the input power supply **9** and the current transformer **10** which supplies the AC output **19** and AC to the magnetic flux modification coils **3**.

If the induction flux **5** is restricted in the core **2** by the magnetic flux modification coils **3**, then an Alternating Current with a smaller negative maximum value is produced and the arithmetic average value during one period shifts down to zero.

According to this invention in a cyclic process an energy circle is created, with considerable energy surplus for the supply of the various outputs as well as for the maintenance of the operation of this system.

According to this invention, by avoiding the need for torque, the same induction effect is obtained by the magnetic flux modification coils and the use of permanent magnets in energy generation, as with the conventional generators which use the transformation of torque into electricity, whereby however, the energy value of the input torque is greater than the energy value of the electricity this generated.

It was found that from each pole of the permanent magnet to the two ends of a U-shaped generator core one of the magnetic flux modification or guidance coils with or without core for transmission of the magnetic induction flux has to be designated in such a manner that by alternating induction flux, which is caused by the permanent magnet e.g. in the rhythm of the phase change of an alternating current frequency of the energising current the generator core is constantly commutated, as the North-pole will be transferred alternating to one and the other open end of the core and the coils likewise leading to the core to s-pole of the permanent magnet close the reversible magnetic circuit in the core with each current pulse, which is caused by a permanent magnet.

In this way the induction flux in the core experiences its desired flux direction change and produces in the output windings of the generator an Alternating Current of the same frequency as those of the energising current, however with identical frequency to that of the input energising current.

Since the pulsating or reversible induction flux is caused by a permanent magnet, no electric current is necessary for its production also for the whole length of the generator core and its output windings, because the reversible magnetic excitation of the core takes place indirectly in each case or directly via a permanent magnet, whose remanence is changed by the magnetic excitation of the generator core in accordance with the invention.

The system according to invention for energy production and energy producer can be extremely efficient e.g. in high frequency operation with electronically controlled direct current pulse operation and it can output a multiple of the necessary input current and electricity be produced in this way, is produced without material being used up and without a thermal circuit or a torque being necessary.

If several of these generators are cascaded in graduated increasing size e.g. in a series where the second generator receives the full output from first and third generator receives the full output of the second, then with a power multiplier of 10 for each generator, the sixth generator in the chain will have a 1000 MW performance if there is a 1000 W power input to the first (and smallest) generator at the start of the series.

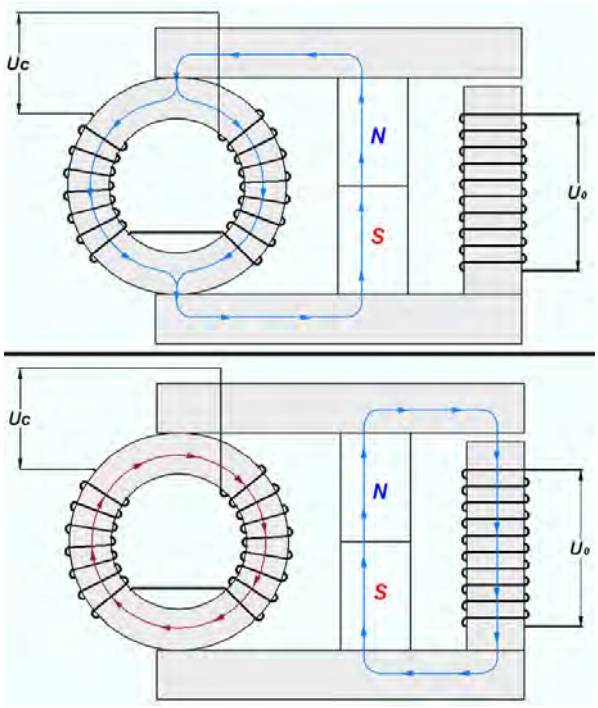
Thus it is possible to replace all well-known primary energies and procedures of the energy conversion with the systems and energy generators according to invention, for all future on economical into electricity because of their high costs, since these cannot operate in any way remotely as economically, as it is possible with the devices of this invention.

Valeri Ivanov's Motionless Generator.

There are other devices which have what appears to be a very important air-gap in a magnetic frame. One of these was displayed on a Bulgarian website and is on the web page which is located at http://www.inkomp-delta.com/page3.html, put up by Valeri Ivanov in 2007.

Valeri lives in Elin Pelin, Bulgaria and his motionless generator has COP=2.4 performance. Videos: http://www.youtube.com/watch?v=7IP-buFHKKU and http://www.youtube.com/watch?v=npFVaeSbk1Q are for his design, and it appears that he is about to go commercial: http://www.inkomp-delta.com/index.html in May 2014.

It is shown that an effective device can be constructed from a permanent magnet, a toroid and a laminated iron yoke. The arrangement is displayed like this:



When the input coil is pulsed with an input voltage, it causes a flux reversal in the frame around which the output coil is wound, generating an electrical output.

There is another forum related to this and the better known MEG of Tom Bearden's which can be found at http://tech.groups.yahoo.com/group/MEG_builders/message/1355 where that particular message states that Valeri's device can be made to work at frequencies as low as 50 Hz and can use standard laminated iron frame components and produces Coefficient Of Performance figures up to 5.4 (that is, the output power is more than five times the input power). A demo video is at http://inkomp-delta.com/page10.html but not in English. It may well be that in order to work well, the MEG needs a very narrow input coil with an air-gap on each side of it and the same may well apply to Lawrence Tseung's magnetic frame shown earlier in this chapter.

The Motionless Generators of Kelichiro Asaoka

Kelichiro Asaoka received US patent 5,926,083 some two years before the well-known MEG patent of Tom Bearden and his associates. Personally, I find it hard to understand how the MEG patent (in the Appendix) could have been awarded when the Asaoka patent was already in place. However, here is most of the content of the Asaoka patent:

US Patent 5,926,083 20 July 1999 Inventor: Kelichiro Asaoka

Static magnet dynamo for generating electromotive force based on changing flux density of an open magnetic path

ABSTRACT

A static magnet dynamo including at least one permanent magnet having different poles; a first core comprising a soft magnetic material and which couples the different poles of the permanent magnet to form a closed magnetic path; a second core comprising a soft magnetic material which couples to the closed magnetic path via a

paramagnetic material to form an open magnetic path; a magnetised coil wound around a portion of the first core where the closed magnetic path is formed; and an induction coil wound around a portion of the second core. A direction of a flux of the closed magnetic path is changed by applying an alternating voltage to the magnetised coil, generating an electromotive force in the induction coil by electromagnetic induction due changes in a flux of the open magnetic path induced by the change in direction of the flux of the closed magnetic path.

FIELD OF THE INVENTION

This invention relates to a dynamo which generates electromotive force by electromagnetic induction by changing the flux passing through an induction coil. More particularly, this invention relates to a static magnet dynamo that changes magnets that pass through an induction coil without turning the armature or electromagnet.

DISCUSSION OF BACKGROUND

Dynamos currently in practical use are so designed as to generate electromotive force by electromagnetic induction by changing the flux passing through an induction coil. Dynamos that generate power this way come in a wide variety, ranging from large models used in hydroelectric, thermal or atomic power plants to small models such as small dynamos with a diesel engine.

In all dynamo models mentioned above, the armature and electromagnet are turned, to change the flux passing through the induction coil, thus generating electromotive force in the induction coil by electromagnetic induction. For examples, the armature and electromagnet are turned by the torque of a water turbine in hydroelectric power generation, by the torque of the steam turbine in thermal and atomic power generation, and by the torque of the diesel engine in small dynamos.

Disadvantages:

Dynamos that generate electromotive force by electromagnetic induction as mentioned above are so designed that, regardless of the size of the dynamo, the armature and electromagnet are turned in order to change the flux passing the induction coil. These dynamos are disadvantageous in that the said turning of the armature and electromagnet generates vibrations and noise.

OBJECTS OF THE INVENTION

The purpose of this invention is to provide a static magnet dynamo devoid of any torque-giving means or other moving part to eliminate vibrations and noise, in order to resolve the various problems mentioned above.

To resolve the above problems, this invention is composed as described below.

The static magnet dynamo involved in this invention consists of at least one permanent magnet, a first core consisting of a soft magnetic material forming a closed magnetic path by coupling the different poles of the said permanent magnet, a second core consisting of a soft magnetic material forming an open magnetic path by being coupled to the closed magnetic path via a paramagnetic material, a magnetised coil wound around a part consisting of only the closed magnetic path of the first core, and an induction coil wound around the second core. The point of this invention is to generate electromotive force in the induction coil by electromagnetic induction by changing the direction of the flux of the closed magnetic path by applying an alternating voltage to the magnetised coil and by changing the flux of the open magnetic path induced by changes in the direction of the flux in the closed magnetic path.

Effects:

In the above configuration, the static magnet dynamo involved in this invention consists of a first core consisting of a permanent magnet and a closed magnetic path, a second core consisting of an open magnetic path via a paramagnetic material, a magnetised coil wound around the part consisting only of the closed magnetic path of the first core, and an induction coil wound around the second magnetic path. The dynamo is so designed as to generate electromotive force in the induction coil by electromagnetic force by changing the direction of the flux of the first core by applying an alternating voltage to the magnetised coil, and by changing the flux of the second core induced by changes in the direction of the flux of the first core.

This makes it possible to change the flux passing through the induction coil without a torque-giving means or other moving part and to generate electromotive force in the induction coil by electromagnetic induction, thus enabling power generation without causing vibrations or noise. This dynamo can also be downsized and made available at low prices.

Other characteristics and benefits of this invention will be made clear by the description given below with diagrams attached.

BRIEF DESCRIPTION OF THE DRAWINGS

A more complete appreciation of the invention and many of the attendant advantages thereof will be readily obtained as the same becomes better understood by reference to the following detailed description when considered in connection with the accompanying drawings, wherein:

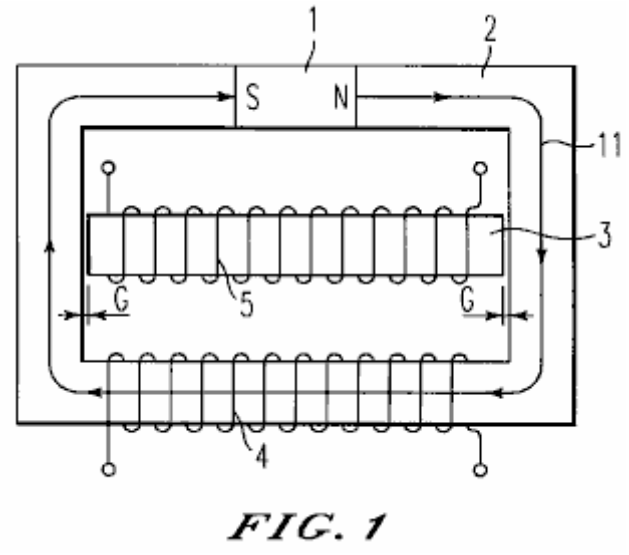


FIG. 1

Fig.1 represents a basic configuration of a static magnet dynamo with an open magnetic path involved in this invention.

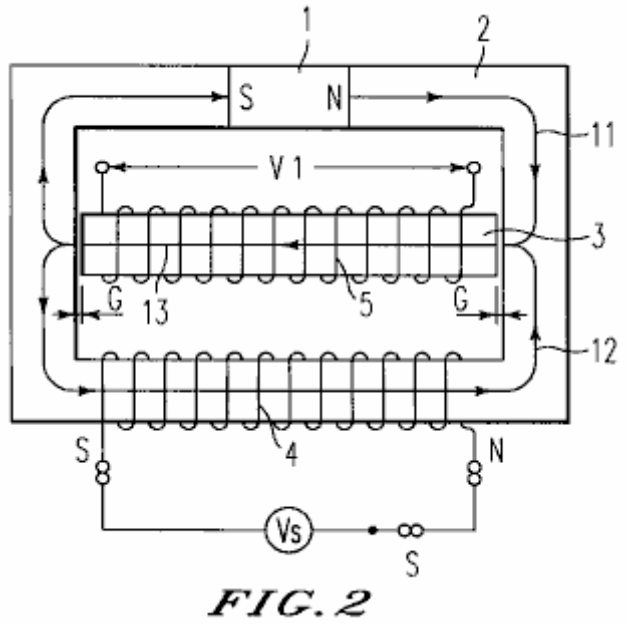

FIG. 2

Fig.2 represents how a flux in the direction opposed to that of a permanent magnet typically occurs in the magnetised coil.

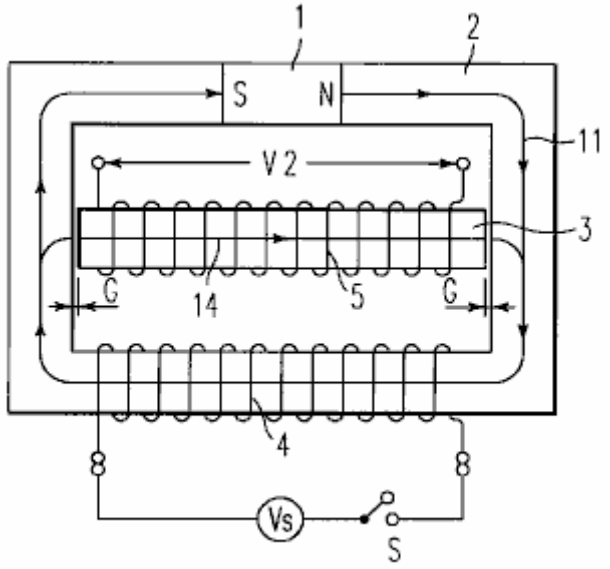

FIG. 3

Fig.3 represents how a flux in the direction opposed to that of a permanent magnet typically disappears from the magnetised coil.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to the drawings, wherein like reference numerals designate identical or corresponding parts throughout the several views, and more particularly to **Fig.1** where there is illustrated a basic configuration of the static magnet dynamo with one permanent magnet. **Figs. 2, 3**, and **4** describe how the static magnet dynamo represented in **Fig.1** generates power.

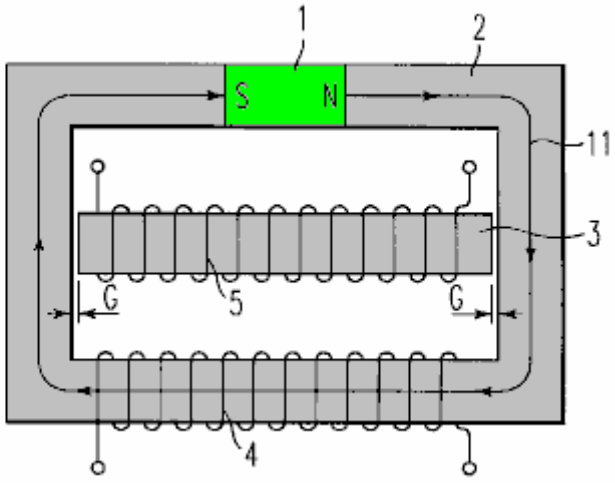

FIG. 1

As indicated in the figures, the first core **2** formed to couple the permanent magnet **1** and the different poles of the permanent magnet **1** in an annular manner, forms a closed magnetic path. This closed magnetic path is then equipped with a second core **3** via a paramagnetic material 10 μm to 5 mm thick. This results in the formation of an open magnetic path consisting of a permanent magnet **1**, part of a first core **2**, a paramagnetic material, and a second core **3**. The part consisting only of the closed magnetic path of the first core **2** is wound around with a magnetised coil **4**. The second core **3** is then wound around with an induction coil **5** designed to generate electromotive force by electromagnetic induction.

Here, the permanent magnet **1** is a magnet with a high residual flux density, a great coercive force, and a large maximum energy product for higher power generation efficiency. Typical materials used here are neodymium iron boride magnet ($Nd_2Fe_{14}B$), samarium cobalt magnet (Sm_2Co_{17}), or samarium iron nitride ($Sm_2Fe_{17}N_2$).

The first core **2** and the second core **3** are made of a soft magnetic material having a high permeability, with high initial, maximum, and other permeability levels, high residual flux density and saturation magnetisation, and small coercive force, thus making effective use of the flux of the magnetic path for power generation. Examples include Permalloy based alloys.

Applicable paramagnetic materials are those with a specific permeability comparable to that of a vacuum, such as air, copper, and aluminium. When air is used as a paramagnetic material, that is, when a gap **G** is secured between the first core **2** and the second core **3**, the second core **3** is retained with a solid paramagnetic material. The figures represent embodiments with a gap **G**, without a solid paramagnetic material designed to retain the second core **3**.

Following is a description of how a static magnet dynamo of the above configuration generates power. First, when no voltage is applied to the magnetised coil **4** of the static magnet dynamo, a first flux **11** is formed in the first core **2** in the direction going from the N pole to the S pole of the permanent magnet **1**. In this state, no flux has been formed in the second core 3 coupled via the gap **G**.

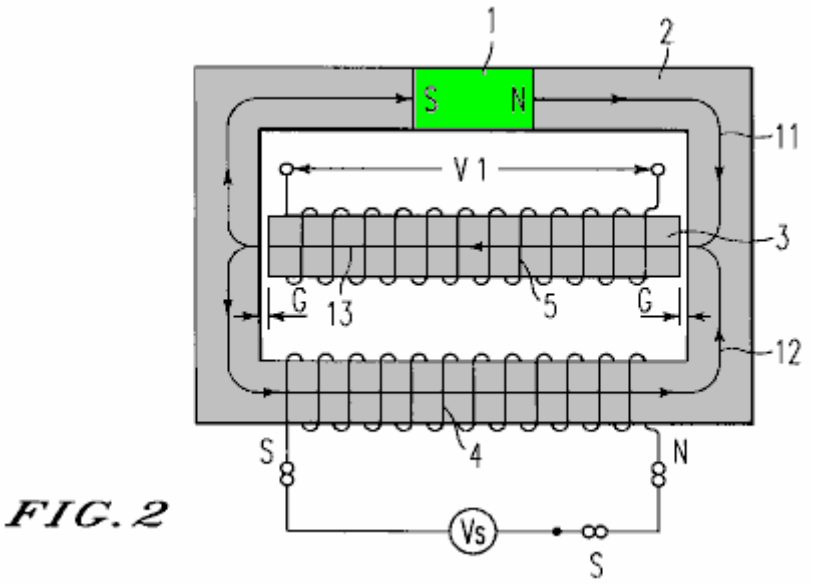

FIG. 2

A voltage can be applied to the magnetised coil **4** in three manners described below. In the first voltage application, as indicated in **Fig.2**, a DC voltage **VS** is applied to the magnetised coil **4** in the direction that the voltage repels the first flux **11** of the first core **2** generated by the permanent magnet **1**, and vice versa, that is, in such a manner that the second flux **12** occurs in the reverse direction of the first flux **11**. As a result, the first flux **11** repels the second flux **12** and vice versa, so that the flux more easily leaks from the closed magnetic path. The first flux **11** and the second flux **12**, which more easily leak from the closed magnetic path, jump across the gap **G** and enter the second core **3**, so that a third flux **13** is induced in the second core **3**. Furthermore, the induction of this third flux **13** changes the flux passing through the induction coil **5**, so that electromotive force **V1** occurs in the induction coil **5**, resulting in power being generated.

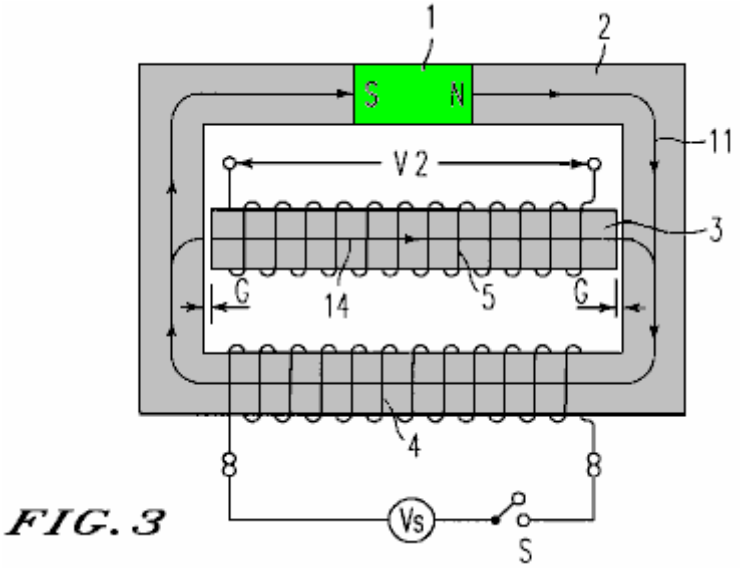

FIG. 3

Next, removing the DC voltage applied to the magnetised coil **4** prompts the first core **2** to try going back to a state where only the first flux **11** is formed as indicated in **Fig.1**. At that time, the second core **3** has a flux in the reverse direction of the third flux **13**, that is, the fourth flux **14** indicated in **Fig.3**, in order to kill the third flux **13**. Then, the induction of the fourth flux **14** changes the flux passing the induction coil **5**, so that electromotive force **V2** occurs in the induction coil **5**, resulting in power being generated.

Power generation in this first voltage application can be realised by a static magnet dynamo involved in this invention, a DC power supply to apply a DC voltage **VS** to the magnetised coil **4**, and a switching circuit that turns the DC power supply on and off. A contact-less switching circuit can be made if a semiconductor switching device, such as a thyristor, is available.

The second voltage application is the same as the first voltage application up to the point where the third flux **13** is induced in the second core **3** by applying a DC voltage **VS** to the magnetised coil **4** so as to generate the second flux **12** in the reverse direction of the first flux **11** and where the third flux **13** is induced to generate electromotive force **V1** in the induction coil **5**, thus generating power.

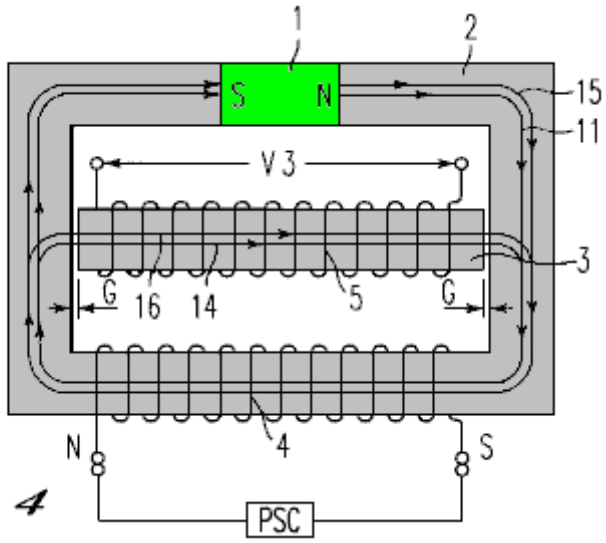

FIG. 4

Next, changing the polarity of the DC voltage applied to the magnetised coil **4** generates in the first core **2** the first flux **11** caused by the permanent magnet **1**, as well as the fifth flux **15** in the same direction as the first flux, caused by the magnetised coil **4**. Here, the first flux **11** is given the fifth flux **15**, so that the second core **3** is given the fourth flux **14** as indicated in **Fig.4**, as well as the sixth flux **16** in the same direction as the fourth flux **14**. Furthermore, inducing the fourth flux **14** and the sixth flux **16** changes the flux passing through the induction coil **5**, so that an electromotive force **V3** larger than the electromotive force **V2** is generated in the rotary coil to produce power.

This second voltage application requires a polarity switching circuit **PSC** that changes the polarity of **DO** voltage instead of a switching circuit that turns on and off the DC voltage applied to the magnetised coil **4** in the first voltage application. This polarity switching circuit can be made of a semiconductor switching device, similarly to the switching circuit in the first voltage application.

In the third voltage application, AC voltage **VS** is applied to the magnetised coil **4** instead of applying DC voltage to the magnetised coil **4** in the second voltage application with the polarity changed. The flux generated by applying AC voltage to the magnetised coil **4** becomes an alternating flux that alternates between the second flux **12** in **Fig.2** and the fifth flux **15** in. **Fig.4**. Then, the flux induced in the second core **3** is the third flux **13** in **Fig.2** when the second flux **12** is generated, and is the fourth flux **14** trying to kill the sixth flux **16** and the third flux **19** in **Fig.4** when the fifth flux **15** is generated. That is, the flux induced in the second core **3** naturally also becomes an alternating flux.

In power generation of this third voltage application, AC voltage is applied to the magnetised coil **4**, which overcomes the need for a switching circuit or polarity switching circuit **PSC**, which was needed in the first and the second voltage application, so that the device becomes simplified. Furthermore, the flux induced in the first core **2** and the second core **3** becomes an alternating flux induced by AC voltage, so that the dynamo functions also as a transformer having a gap **G** between the first core **2** and the second core **3**. It is therefore possible to increase further the electromotive force **V** generated by electromagnetic induction in the induction coil **5**.

Next, the power generation efficiency of a static magnet dynamo involved in this invention is described. The static magnet dynamo can be considered as a transformer if its permanent magnet **1** is removed and there is a gap **G**.

A transformer entails an eddy current loss **We** and hysteresis loss **Wh** of the core, and a loss **Wr** due to the electric resistance of the coil. These factors are in a relation formulated below.

Total loss **W1 = We + Wh + Wr** . . . . . .(1)

Let the input be **Win** and the output **Wo**, and the **Win** becomes equal to the total loss, so that the conversion efficiency of the transformer is

Eff = Wo / Win = Wo(We + Wh + Wr) < 1 . . . . . (2)

In reality, in **Fig.1**, the closed magnetic path consisting of the first core **2** contains a permanent magnet **1**. The flux of this permanent magnet **1** therefore contributes to power generation. Therefore, in **Fig.1**, let the input be **Win2** and the output **Wo2**, then

Wo2 = Wp + αWin2 . . . . . (3)

Where **Wp** represents power resulting from the flux of the permanent magnet **1** contributing to power generation, and **α** represents a conversion efficiency obtained when the device is considered as a transformer with a gap **G**.

Therefore, power generation efficiency is:

Eff = Wo2 / Win2 or .

Eff = (Wp / Win2) + α . . . . . (4)

Here, since **α** < 1, if **Wp / Win2** > 1, that is, if power obtained resulting from the flux of the permanent magnet **1** contributing to power generation is larger than dynamo power supplied to the magnetised coil **4**, power generation efficiency becomes no less than 1, so that the device can display its performance as a dynamo.

Thus, the inventor examined as described below how much the flux of the permanent magnet **1** contributes to the induction of the third flux **13** in **Fig.2**. First, the inventor provided static magnet dynamos of the basic configuration indicated in **Fig.1**, one with a permanent magnet **1** and another without a permanent magnet **1**. The inventor then compared the power levels needed to induce fluxes of equal flux densities to the second core **3** of each embodiment, that is, the power levels supplied to the magnetised coil **4**. As a result, an embodiment with a permanent magnet **1** required only a very low power level to be supplied to the magnetised coil **4**. It was observed that the power level required was no more than one fortieth of that of the embodiment without a permanent magnet **1**, depending on the test condition.

In a static magnet dynamo involved in this invention, therefore, **Win2** can be made sufficiently smaller than **Wp**, so that the inventor considers it possible to make **Wp / Win2** > 1.

Embodiment 1

Next, as the first embodiment, a static magnet dynamo system composed of two static magnet dynamos of the basic configuration is described based on **Fig.5**.

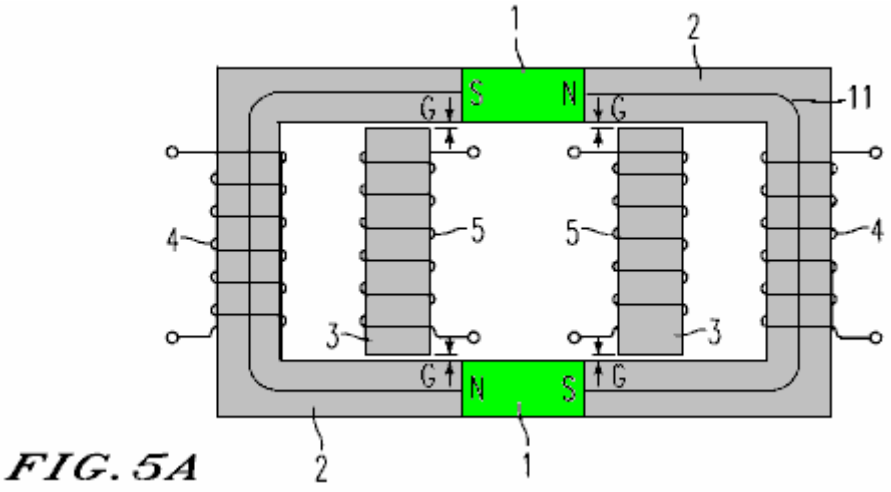

FIG. 5A

In **Fig.5A**, in a static magnet dynamo, a closed magnetic path is made of two permanent magnets **1** and two first cores **2** formed so as to couple the different poles of one permanent magnet **1** with the other permanent magnet **1** in an annular manner. This closed magnetic path is then equipped with a second core **3** via a gap **G**. This forms an open magnetic path consisting of a permanent magnet **1**, part of a first core **2**, a paramagnetic material, and a second core **3**.

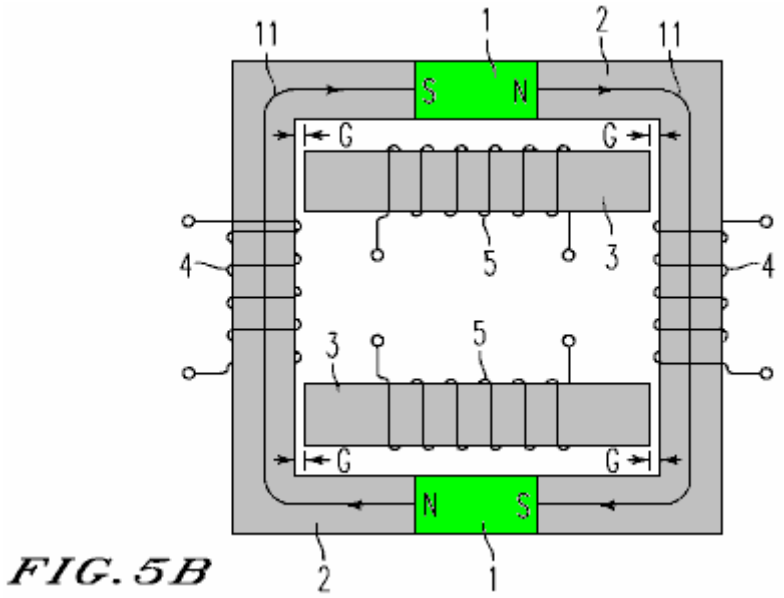

FIG. 5B

This open magnetic path can be arranged in two different ways. In one configuration, as indicated in **Fig.5A**, one open magnetic path can be made of two permanent magnets **1** and two second cores **3**. In the other configuration, as indicated in **Fig.5B**, one open magnetic path can be made of one permanent magnet **1** and another can be made of one first core **2**. The static magnet dynamos in **Fig.5A** and **Fig.5B** do not differ substantially in terms of effect results, except that their patterns forming such an open magnetic path differ.

The part forming only a closed magnetic path of each first core **2** is wound around with a magnetised coil **4**. Each second core **3** is then wound around with an induction coil **5** which generates electromotive force by electromagnetic induction.

This static magnet dynamo forms a first flux **11** in the first core **2** in the direction going from the N pole to the S pole of the permanent magnet **1**, with no voltage applied to the magnetised coil **4**. Furthermore, the action of this dynamo applying voltage to the magnetised coil **4** and generating electromotive force in the induction coil **5** by electromagnetic induction to generate power is similar to static magnet dynamos of the basic configuration. The static magnet dynamo with two permanent magnets **1** as mentioned above has well-balanced magnetic paths. Since the flux of the permanent magnets **1** can be effectively used, this embodiment achieves higher power generation efficiency than static magnet dynamos of the basic configuration.

The first embodiment is a static magnet dynamo system composed of two static magnet dynamos of the basic configuration. Similarly, a static magnet dynamo system can be made as a combination of three or more static magnet dynamos of the basic configuration (**Figs. 1-4**). In that case, similarly to the first embodiment, an open

magnetic path can be formed in two manners. One configuration is the formation of one open magnetic path by coupling all permanent magnets **1** with a second core **3**. The other is the formation of as many open magnetic paths as permanent magnets by coupling the N pole of each permanent magnet **1** to the S pole with a second core **3**.

Embodiment 2

Next, the second embodiment of the present invention is represented in **Fig.6**,

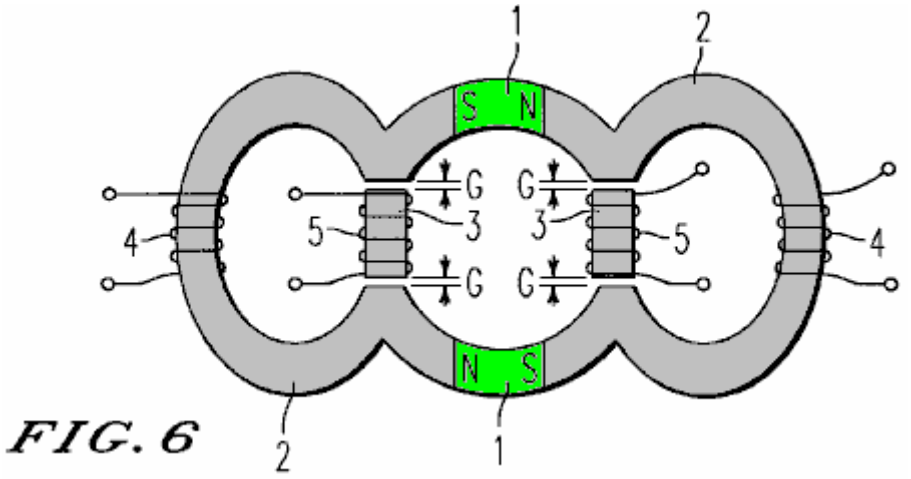

FIG. 6

the third embodiment in **Fig.7**,

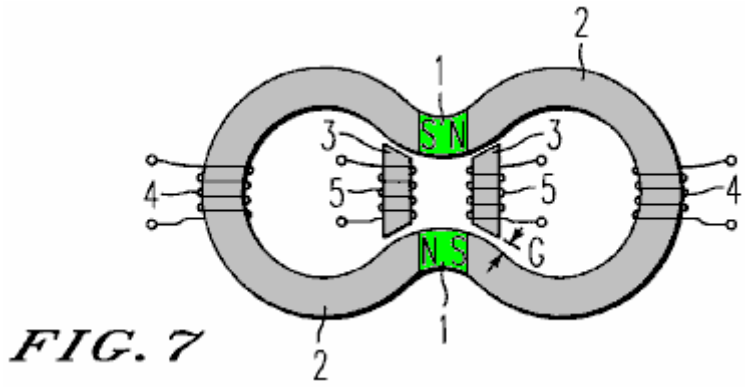

FIG. 7

and the fourth embodiment in **Fig.8**.

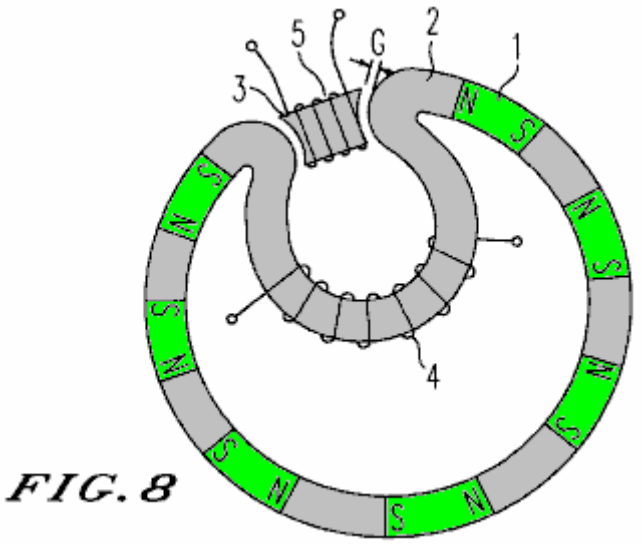

FIG. 8

In these embodiments, the action of applying voltage to the magnetised coil **4** and generating electromotive force in the induction coil **5** by electromagnetic induction is similar to that of a static magnet dynamo of the basic configuration (**Figs. 1-4**).

The second and the third embodiments represented in **Fig.6** and **Fig.7** have the same basic configuration as the first embodiment, except that the first core **2** in each embodiment is shaped quite differently.

In the second embodiment, the part opposed to the end of the second core **3** sticks out toward the end of the second core **3**. Thus, the leakage flux due to the repellence of the first flux **11** and the second flux **12** generated in the first core **2** jumps across the gap **G** and enters the second core **3** with greater ease.

Embodiment 3

The third embodiment is so designed that the part coupling the second core **3** is that part of the first core **2** which is nearest to the permanent magnet **1** and, to shorten the open magnetic path even further, the two permanent magnets **1** are close to each other. Since a flux tends to form a closed magnetic path with the shortest distance, the leakage flux due to the repellence of the first flux **11** and the second flux **12** generated in the first core **2** jumps across the gap **G** and enters the second core **3** with greater ease.

Embodiment 4

The fourth embodiment indicated in **Fig.8**, as opposed to a static magnet dynamo of the basic configuration, consists of a first loop where permanent magnets **1** with multiple closed magnetic paths are arranged circularly with the fluxes oriented in the same direction, and of a second loop which is wound around with a magnetised coil **4** and installed inside the first loop. Furthermore, the parts with their first cores **2** coupling the first loop to the second one stick out toward each other across a specified gap. The parts where this first core **2** stick out are coupled together with a second core **3** via a gap **G** to form an open magnetic path. This reinforces the flux of the permanent magnets **1** and makes it easier for the leakage flux due to the repellence of the first flux **11** and the second flux **12** generated in the first core **2** to jump across the gap **G** and enter the second core **3**.

Embodiment 5

The configuration of a static magnet dynamo involved in this invention has so far been described in terms of embodiments where an open magnetic path is connected to the first core **2** at both ends of the second core **3** via a paramagnetic material. However, this invention is not limited to these embodiments.

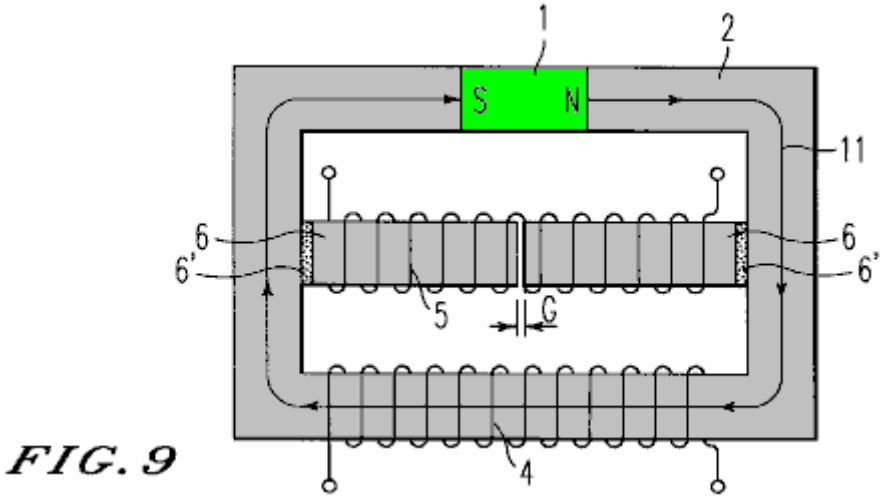

FIG. 9

That is, as indicated in **Fig.9**, the open magnetic path may be embodied by extending any two parts of the first core **2** in the direction that they approach each other, thus defining them as core extensions **6**, and coupling these core extensions **6** via a paramagnetic material **6'**. This embodiment can be applied to all embodiments mentioned above.

Embodiment 6

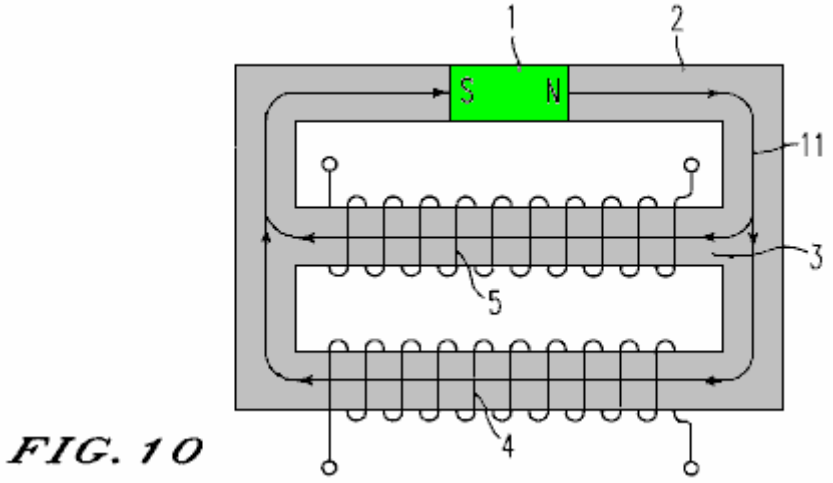

FIG. 10

As indicated in **Fig.10**, a closed magnetic path consists of a permanent magnet **1** and a first core **2** formed so as to couple the different poles of the said permanent magnet **1** in an annular manner. This closed magnetic path is then equipped with a second core **3** so that it comes magnetically in parallel with the permanent magnet **1**, so that a bypass closed magnetic path is composed of a permanent magnet **1**, part of a first core **2**, and a second core **3**.

The part consisting only of the closed magnetic path of the first core **2** is wound around with a magnetised coil **4**. The second core **3** is then wound around with an induction coil **5** designed to generate electromotive force by electromagnetic induction.

The action of a static magnet dynamo of the above configuration generating power is described below. First, when no voltage is applied to the magnetised coil **4** of a static magnet dynamo, the first core **2** forms a first flux **11** in the direction going from the N pole to the S pole of the permanent magnet **1**. In this state, a flux similar to that of the first core **2** is generated in the second core **3** as well.

Embodiment 7

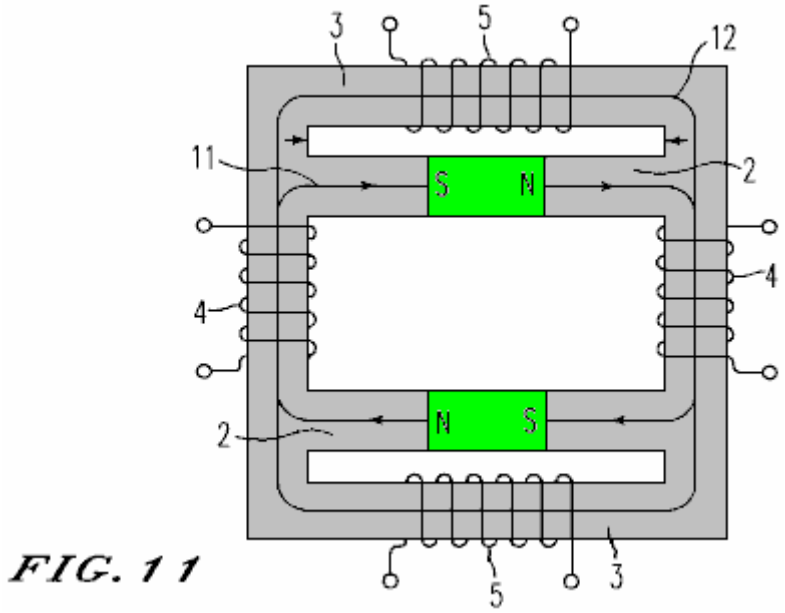

FIG. 11

The seventh embodiment is described below based on **Fig.11**, in terms of a static magnet dynamo system composed of two static magnet dynamos of the basic configuration and with the relative position of the permanent magnets changed.

In a static magnet dynamo, a closed magnetic path is composed of two permanent magnets **1** and two first cores **2** so designed as to couple the different poles of one of the permanent magnets **1** with the other permanent magnet **1** in an annular manner. This closed magnetic path is then equipped with a second core **3**. This results in the formation of a bypass closed magnetic path consisting of a permanent magnet **1**, part of a first core **2**, a paramagnetic material, and a second core **3**.

The parts where a closed magnetic path of each first core **2** alone is formed are wound around with a magnetised coil **4**. Each second core **3** is then wound around with an induction coil **5** designed to generate electromotive force by electromagnetic induction.

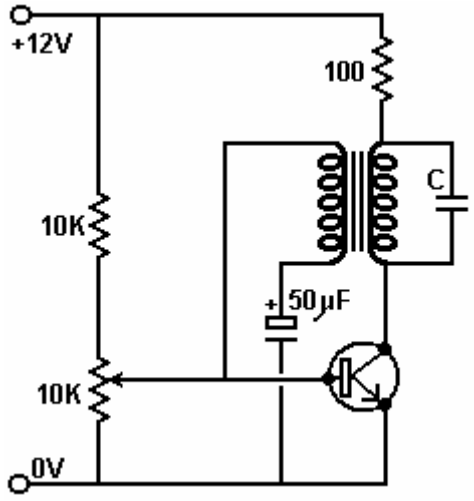
In this static magnet dynamo, where no voltage is applied to the magnetised coil **4**, a first flux **11** is formed in the first core **2** in the direction going from the N pole to the S pole of the permanent magnet **1**. The action of applying voltage to the magnetised coil **4** and generating electromotive force in the induction coil **5** by electromagnetic induction to generate power is similar to that of a static magnet dynamo of the basic configuration.

In the aforementioned static magnet dynamo incorporating two permanent magnets **1**, magnetic paths are arranged in a well-balanced manner. This makes it possible to make effective use of the flux of the permanent magnets **1**, so that power generation efficiency is higher than that of a static magnet dynamo of the basic configuration.

This invention has so far been described somewhat in detail in terms of the most favourable embodiments. Since it is clear that a wide variety of embodiments can be realised without opposing the philosophy and scope of this invention, this invention will not be limited to any particular embodiment, except for the limitations described in the attached claim.

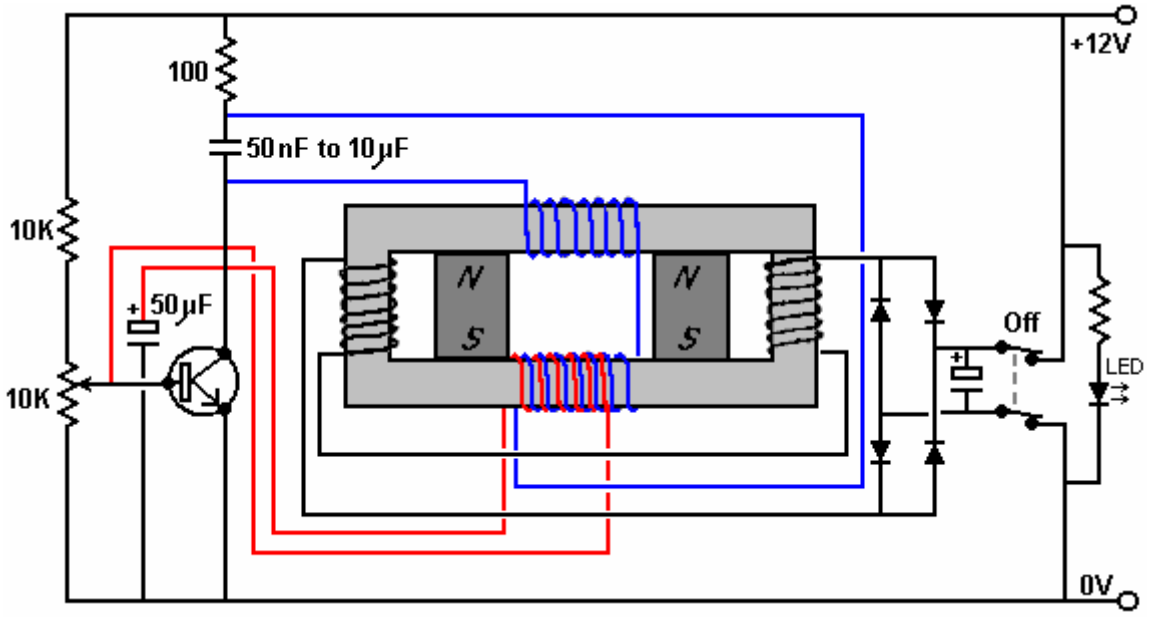
Stephan Leben's Circuits.

There is an interesting video posted on YouTube at http://www.youtube.com/watch?v=9zh_C3yvJH0 where Stephan W. Leben whose ID is "TheGuru2You" posts some really interesting information. He starts with a circuit produced by Alexander Meissner in 1913 and shown here:



Stephan states that he has built this circuit and can confirm that it is a self-resonating powering circuit. Once a twelve volt supply is connected to the input terminals, the transistor switches on powering the transformer which feeds repeating pulses to the base of the transistor, sustaining the oscillations. The rate of oscillation is governed by the capacitor marked "**C**" in the circuit diagram above and the coil across which it is connected.

Stephan suggests combining Alexander Meissner's circuit with Charles Flynn's magnetic amplification circuit. Here the transformer is switched to become the Charles Flynn oscillator winding plus a second winding placed alongside for magnetic coupling as shown here:



The transistor stage is self-oscillating as before, the transformer now being made up of the red and blue coil windings. This oscillation also oscillates the Flynn magnetic frame, producing an electrical output via the black coils at each end of the magnetic frame. This is, of course, an oscillating, or AC output, so the four diodes produce a full-wave rectified (pulsating) DC current which is smoothed by the capacitor connected to the diodes.

This circuit would be started by touching a 12 volt source very briefly to the output terminals on the right. An alternative would be to wave a permanent magnet close to the red and blue coils as that generates a voltage in the coils, quite sufficient to start the system oscillating and so, becoming self-sustaining. Stephan suggests using the piezo crystal from a lighter and connecting it to an extra coil to produce the necessary voltage spike when the coil is held close to the blue coil and the lighter mechanism clicked.

A surprising problem would be how to switch the device off since it runs itself. To manage this, Stephan suggests a two-pole On/Off switch to disconnect the output and prevent it supplying the input section of the circuit. To show whether or not the circuit is running, a Light-Emitting Diode ("LED") is connected across the output and the current flowing through it limited by a resistor of about 820 ohms.

Anyone wanting to try replicating this device will need to experiment with the number of turns in each coil and the wire diameter needed to carry the desired current. Stephan states that you need to have at least twice the weight of copper in the (black) output coils as there is in the (blue) input coils in order to allow the device produce excess power. The first page of the Appendix shows the current carrying capacity for each of the standard wire diameters commonly offered for sale. As this is a fairly recently released circuit, I am not aware of any replications of it at this time.

Floyd Sweet's "VTA" Generator.

Another device in the same category of permanent magnets in conjunction with oscillating coils, was produced by Floyd Sweet. The device was dubbed "Vacuum Triode Amplifier" or "VTA" by Tom Bearden.

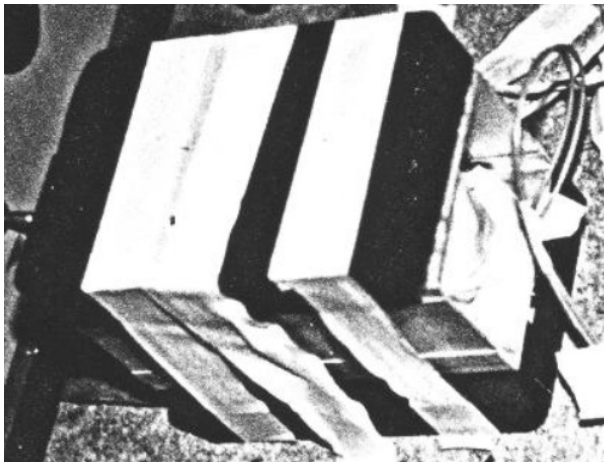
The device was capable of producing more than 500 watts of output power at 120 Volts, 60 Hz requiring less than one third of one milliwatt as input power. The output power can operate AC motors, lights, heaters and when rectified, DC motors.

Thanks is due to Horst Weyrich who has recently provided me with links to useful material which I had not seen before. This link: http://www.youtube.com/watch?v=0gM9natKIyY is to a video in which Floyd shows most of the magnet conditioning process.

Recently, some additional information on Floyd Sweet's device, has been released publicly by an associate of Floyd's who goes just by his first name of "Maurice" and who, having reached the age of seventy has decided that it is time to release this additional information. That information can be found in the Appendix. I am not aware of anybody who has succeeded in replicating Floyd's VTA, but here is as much information as I have at this time.

In the above video, Floyd talks about separating two of his conditioned permanent magnets with an "air gap" which is astonishing as he is putting them on opposite sides of a length of aluminium channel with thick walls and aluminium has a major damping effect on magnetic fields:

This arrangement which seems quite mad, is confirmed by a picture from Floyd's lab. As shown here:



This shows clearly that the open ends of the channel are not between the two magnets allowing an unrestricted magnetic field to flow between them, but instead, two channel thicknesses of aluminium are between the two magnets, obstructing the magnetic flow – quite remarkable !!

Floyd shows two coils being used to condition the magnets. The first is the large vertical coil shown here in front of Floyd:

The second coil is not seen as it is inside the vertical coil, sitting flat on the base, and consisting of an entire reel of AWG #17 (1.15 mm diameter) wire, something like this:

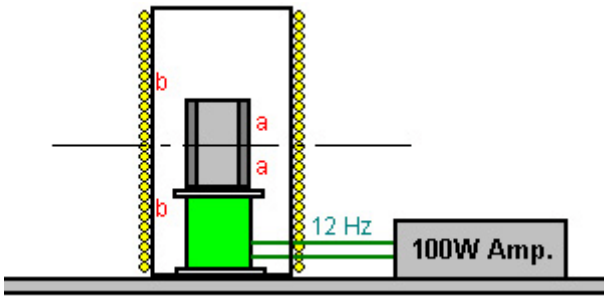
This coil operates effectively as an air-core solenoid, producing a strong axial magnetic field inside the larger coil which surrounds it. This inside coil is driven by a sine wave signal in the 10Hz to 15Hz range, boosted through a 100-watt audio amplifier which provides the current needed to impose the sine wave on this low impedance coil without distorting the waveform.

The first step is to determine the resonant frequency of each of the two permanent magnets to be used. The ferrite magnets used appear to be about 6 x 4 x 1 inch (150 x 100 x 25 mm). As they will eventually be used as a pair, one end of each is marked so that they can be aligned in the correct orientation after conditioning. That size of magnet appears to have a resonant frequency of about 12Hz, but each magnet will be slightly different.

The inside, low frequency coil is powered up at around 12Hz, the length of the magnet aligned with the Earth's magnetic field (that is, North/South), and placed on top of the vertical coil. An iron shim as used in transformer core construction is placed vertically on top of the magnet as an indication of resonating:

As shown in the video, the sine wave frequency feeding the AWG #17 coil is adjusted slowly to find the point at which the iron shim vibrates most strongly. That frequency is noted, and the same is done for the second magnet. It is not likely that the two resonant frequencies will be the same, and so the average frequency for the pair is used.

Next, the two magnets are placed in attraction mode, one on each side of the aluminium channel, with their marked ends at the same end of the channel. That is, the North pole face of one will touch the aluminium and the South pole face of the other will touch the aluminium. The two magnets and their separating aluminium channel are then placed inside the main coil and aligned so that the outer North pole faces southwards and the opposite external South pole faces Northwards. The large coil dimensions are arranged so that the centre of the magnets is at the centre of the outer coil:



While the inner coil continues to be powered up with a powerful sine wave, the outer coil is now fed a 60Hz stream of sharp voltage pulses. These are generated by charging up a 16,000 microfarad 250V capacitor and then discharging it through an SCR (Thyristor) connected to the outer coil. It is important that the spikes be sharp as they are imposing that frequency on the internal magnetic structure of the magnets. Presumably, if aiming for a European 240V version, then the outer coil would be pulsed at 50Hz rather than the American 60Hz and the capacitor would be a 450V rated type.

The working pictures of Floyd's prototype powering a load, seem to indicate that the one input coil and one output coil as described by Ashley Gray below, are the same as used by Floyd as we see wires coming out of the open end of the channel.

Horst wishes to emphasise that it is not easy to make a working replication of Floyd's design as the people at www.hyiq.org have tried to replicate it for a number of years now, without any success.

Ashley Gray of New Zealand.

In April 2014, I was sent some information about a colleague of Floyd Sweet's – Ashley Gray of Nelson, New Zealand. The version described by Ashley appears to be understandable.

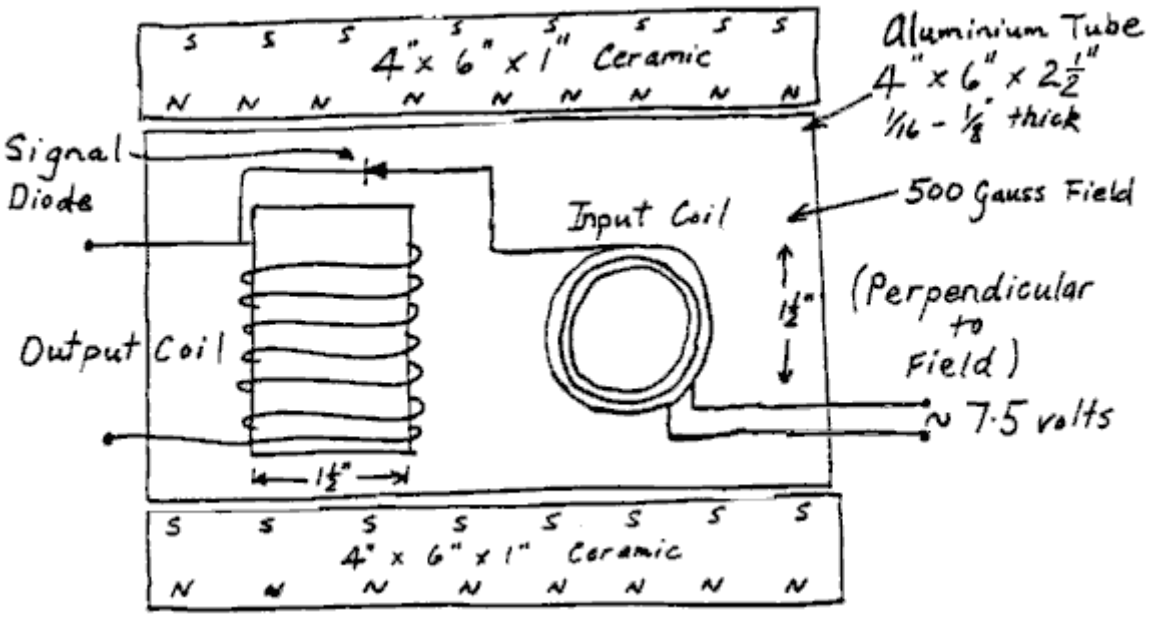
On 20th June 1994, Ashley says:

After a trip to America in 1985 when I was first introduced to Floyd Sweet, I was invited to go back and work with him. At that time he was being funded by Mark Goldes of the Aesop Institute, and Darryl Roberts was working as co-coordinator for the Institute in L.A. After working with Floyd for some time we left America for England. At that stage the "politics" had become difficult. While we were in England, we were contacted by Mark Goldes and told that Floyd had obtained some results which they would like us to verify for them.

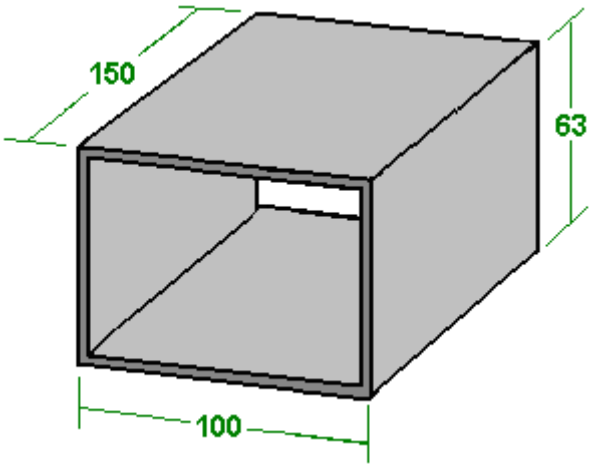
On our return to New Zealand, Darryl Roberts sent us the Lab Notes which he had recorded during the first tests of the "Space Quanta Modulator" and it's construction details. We were asked to repeat the experiments to verify the results. We constructed the device but were unable to get any results at that time. In the light of the new information which had been released, I conducted some further experiments and managed to obtain some interesting results without magnet 'conditioning' which, as far as I was aware, was not used in the original device.

The initial device which I constructed when in America, consisted of two 1-inch x 1-inch (25 x 25 mm) neodymium magnets mounted in a steel frame. There were two 'modulating' windings and one output winding. It was driven by a specially built sine-wave oscillator which was adjustable from 1 kHz to 2 kHz. We did not get any output or significant result from this device. Floyd felt that this was due to the high field strength of the neodymium magnets and the closed magnetic path. Floyd did not mention anything about magnet conditioning being necessary.

A second prototype was then built, using Barium Ferrite magnets size 6-inches x 4-inches x 1-inch (150 x 100 x 25 mm):

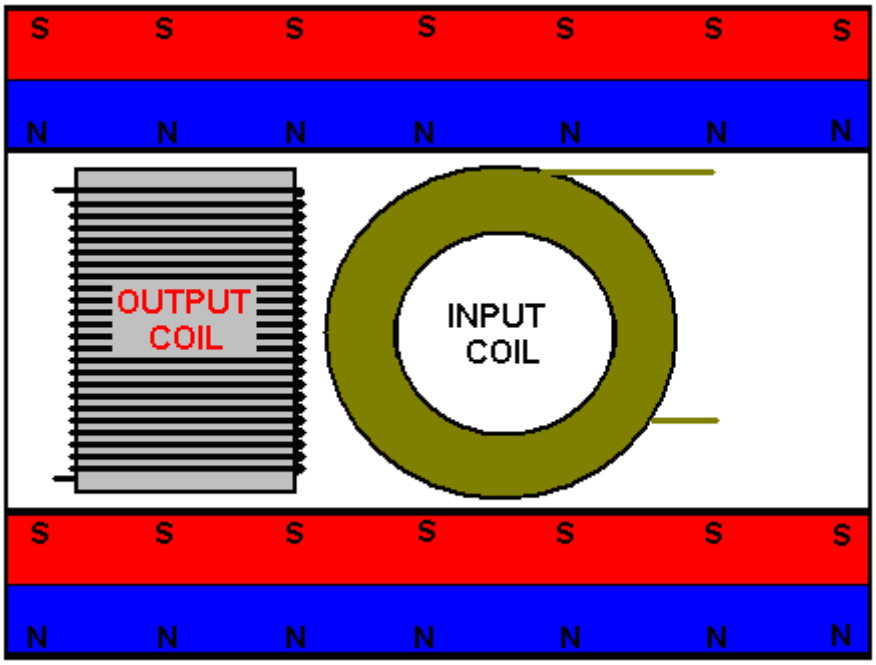


Ashley appears to be using magnets which are not 'conditioned'. Ashley has had what I consider to be very significant results from his prototype with an output power of 111 watts for an input of just 0.001 watts (a COP of 111,000). Ashley's successful build has an aluminium housing. People get the very mistaken idea that aluminium is not magnetic because magnets do not stick to it. The reality is that aluminium has a really major effect on magnetic fields and can be used as magnetic shielding if thick enough. Ashley's design uses two coils at right-angles to each other and that style of operation can be seen in other free-energy designs. Anyway, take a look at the version built by Ashley:



The aluminium enclosure is shallow. The ends are 4" x 2.5" which is 100 x 63 mm. The diameter of the input coil is 1.5 inches or 38 mm. Similarly, the output coil length has to be less than 63 mm.

The diagram below may give a slightly better idea of the dimensions involved in the construction. At the present time, magnets of that size are available for £14 each in the UK. They each have an 8 Kg pull and are very heavy.



The magnetic lines of force flow through the length of the output coil and through the width of the input coil. As you can see from the diagram, the unit is compact in spite of the very large magnets. The input needed is a good-quality sine wave. Ashley also says:

Details From Lab Notes of First Successful Tests

Original Test Setup:

A Signal Generator made by Wavetek, USA, was used to drive the input coil.

Input coil: 1.5" diameter 120 turns #20 gauge (0.812 mm diameter, overall resistance about 1 ohm)

Input = 7.5 volts at 3.l microamps = 23 micro watts

Output Coil: 1.5" diameter 12 turns #12 gauge (2.05 mm diameter)

Output = 10.4 volts sine wave at 1.84 amps = 19.15 watts at approx 400 Hz

Comments:

Frequency generally affected resistive 1.8 amp 20 watt bulb load proportionally - brightness increased with frequency, decreased with frequency except at certain points when it appeared inversely related, increasing as frequency decreased etc.

First Modifications:

The Signal generator was replaced with a purpose-built Sine Wave Oscillator of 9 volt output. The input coil was increased to 250 turns of #18 gauge (1.024mm) and the output coil was increased to 24 turns of #18 gauge(1.024 mm diameter) wire. Magnets, spacing, etc. all remained the same.

Input: 7.2 volts at 143 micro amps (0.001 watts)

Output: 24.2 volts at 4.6 amps = 111watts. Frequency 388 and 402 Hz

Comments:

By increasing the area of the wire exposed to/or occupying the fluctuating magnetic field the output was doubled. The exact proportions /ratios of the space filling volume of winding to output had not been determined at the time of writing. Magnet size seems to be less important than the volume of the windings, wire diameter, input voltage and current.

The current is only limited by the impedance of the wire which rises dramatically in the magnetic field to several hundred thousand ohms, while the impedance when outside the magnetic the field is only 2 or 3ohms @ 400 Hz. (250 turns #18 (1 mm diameter) wire).

The AC excitation current is only required to support I^2R losses as the magnetic field requires no additional power, as it is not loaded by the wires passing through the field.

The unit ran for 10 to 12 hours with no heating occurring but no longer duration tests were performed. The tests were witnessed by three people.

Technical Notes:

The quality of the oscillator is important - there should be no harmonic distortion i.e. it needs to be a pure sine wave.

The signal diode divides the current into the circuit, and being parallel - puts a small microamp current into the power coil as well as the excitation coil. This works with the magnets in such a way that there is produced a vector complementation.

When in close proximity to the magnets, the output load bulbs vibrate.

The Optical Generator of Pavel Imris.

Pavel was awarded a US patent in the 1970's. The patent is most interesting in that it describes a device which can have an output power which is more than nine times greater than the input power. He achieves this with a device which has two pointed electrodes enclosed in a quartz glass envelope which contains xenon gas under pressure (the higher the pressure, the greater the gain of the device) and a dielectric material.

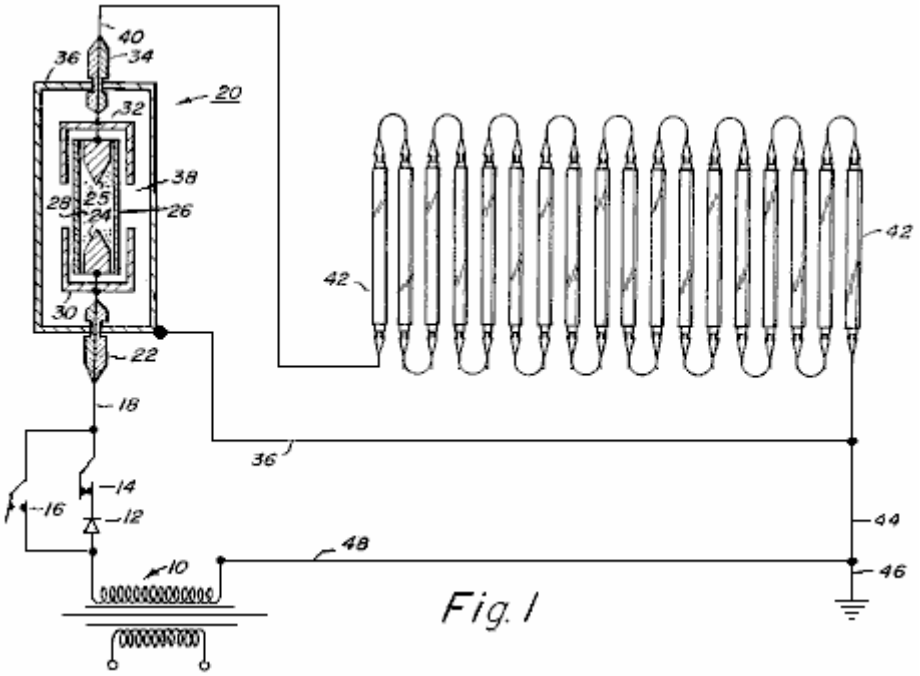


Fig. 1

Here, the power supply to one or more standard fluorescent lamps is passed through the device. This produces a power gain which can be spectacular when the gas pressure in the area marked '24' and '25' in the above diagram is high. The patent is included in this set of documents and it contains the following table of experimental measurements:

Table 1 shows the data to be obtained relating to the optical electrostatic generator. **Table 2** shows the lamp performance and efficiency for each of the tests shown in **Table 1**. The following is a description of the data in each of the columns of **Tables 1 and 2**.

Column	Description
B	**Gas used in discharge tube**
C	**Gas pressure in tube** (in torrs)
D	**Field strength across the tube** (measured in volts per cm. of length between the electrodes)
E	**Current density** (measured in microamps per sq. mm. of tube cross-sectional area)
F	**Current** (measured in amps)
G	**Power across the tube** (calculated in watts per cm. of length between the electrodes)
H	**Voltage per lamp** (measured in volts)
K	**Current** (measured in amps)
L	**Resistance** (calculated in ohms)
M	**Input power per lamp** (calculated in watts)
N	**Light output** (measured in lumens)

The results from Test No. 24 where the gas pressure is a very high 5,000 Torr, show that the input power for each 40-watt standard fluorescent tubes is 0.9 watts for full lamp output. In other words, each lamp is working to its full specification on less than one fortieth of its rated input power. However, the power taken by the device in that test was 333.4 watts which with the 90 watts needed to run the 100 lamps, gives a total input electrical power of 423.4 watts instead of the 4,000 watts which would have been needed without the device. That is an output power of more than nine times the input power.

From the point of view of any individual lamp, without using this device, it requires 40 watts of electrical input power to give 8.8 watts of light output which is an efficiency of about 22% (the rest of the input power being converted to heat). In test 24, the input power per lamp is 0.9 watts for the 8.8 watts of light produced, which is a lamp efficiency of more than 900%. The lamp used to need 40 watts of input power to perform correctly. With this device in the circuit, each lamp only needs 0.9 watts of input power which is only 2.25% of the original power. Quite an impressive performance for so simple a device!

The Michel Meyer and Yves Mace Isotopic Generator.

There is a French patent application number FR 2,680,613 dated 19th August 1991 entitled “Activateur pour Mutation Isotopique” which provides some very interesting information. The system described is a self-contained solid-state energy converter which abstracts large amounts of energy from an ordinary iron bar. This is also shown in Michel’s Czechoslovakia Patent No.284,333

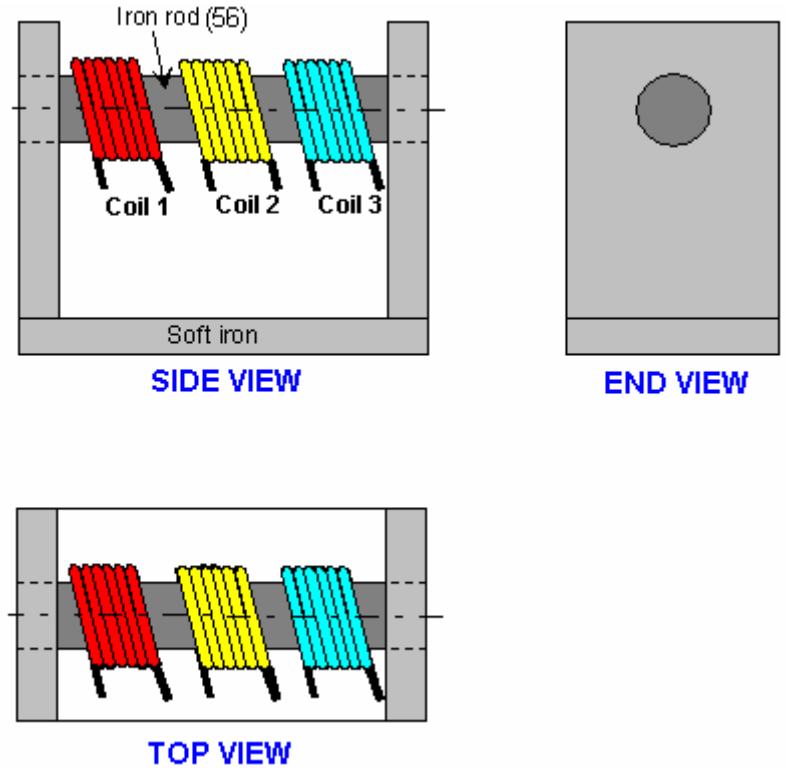
The inventors describes the technique as an “isotopic mutation effect” as it converts ordinary iron (isotope 56) to isotope 54 iron, releasing large amounts of electrical energy in the process. This excess energy can, they say, be used to drive inverters, motors or generators.

The description of the mechanism which is being used by the device is: “the present invention uses a physical phenomenon to which we draw attention and which we will call ‘Isotopic Change’. The physical principle applies to isotope 56 iron which contains 26 protons, 26 electrons and 30 neutrons, giving a total mass of 56.52 Mev, although its actual mass is 55.80 Mev. The difference between the total mass and the actual mass is therefore 0.72 Mev this which corresponds to an energy of cohesion per nucleon of 0.012857 Mev.

So, If one introduces an additional 105 ev of energy to the iron core isotope 56, that core isotope will have a cohesion energy level of 0.012962 Mev per nucleon corresponding to iron isotope 54. The instability created by this contribution of energy will transfer the isotope 56 iron to isotope 54 causing a release of 2 neutrons.

This process generates an excess energy of 20,000 ev since the iron isotope 54 is only 0.70 Mev while isotope 56 has 0.72 Mev. To bring about this iron isotope 56 conversion, we use the principle of Nuclear Magnetic Resonance."

The practical method for doing this is by using three coils of wire and a magnetic-path-closing support frame of iron as shown in this diagram:



In this arrangement,

Coil 1: Produces 0.5 Tesla when fed with DC, converting the iron bar into an electromagnet
Coil 2: Produces 10 milli-Tesla when fed with a 21 MHz AC sinewave signal
Coil 3: Is the output coil, providing 110, 220 or 380 volts AC at about 400 Hz depending on the number of turns in the coil

This simple and cheap system has the potential for producing substantial energy output for a very long time. The inventors claim that this device can be wired to be self-powered, while still powering external devices. Coil 1 turns the iron rod into an electromagnet with it's flux channelled in a loop by the iron yoke. Coil 2 then oscillates that magnetic field in resonance with the isotope 56 iron atoms in the rod, and this produces the isotope conversion and release of excess energy. Coil 3 is wound to produce a convenient output voltage.

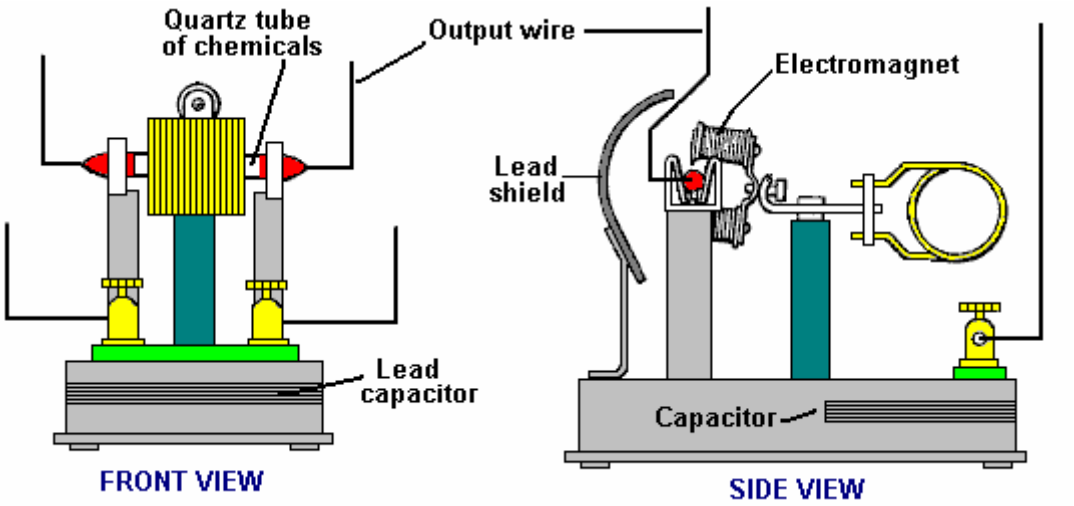
The Colman / Seddon-Gilliespie Generator.

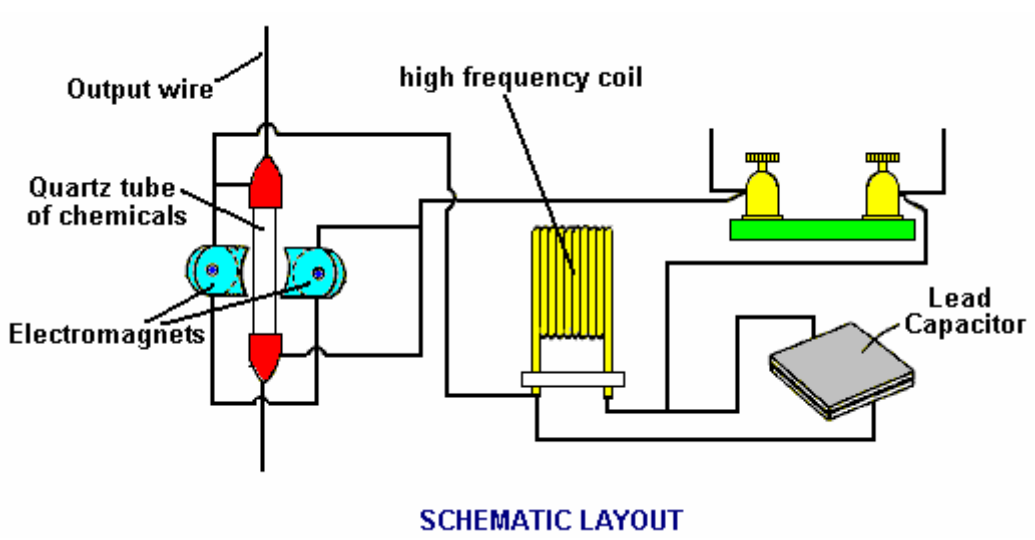
This device, patented by Harold Colman and Ronald Seddon-Gillespie on 5th December 1956, is quite remarkable. It is a tiny lightweight device which can produce electricity using a self-powered electromagnet and chemical salts. The working life of the device before needing refurbishment is estimated at some seventy years with an output of about one kilowatt.

The operation is controlled by a transmitter which bombards the chemical sample with 300 MHz radio waves. This produces radioactive emissions from the chemical mixture for a period of one hour maximum, so the transmitter needs to be run for fifteen to thirty seconds once every hour. The chemical mixture is shielded by a lead screen to prevent harmful radiation reaching the user. The patent, GB 763,062 is included in the Appendix.

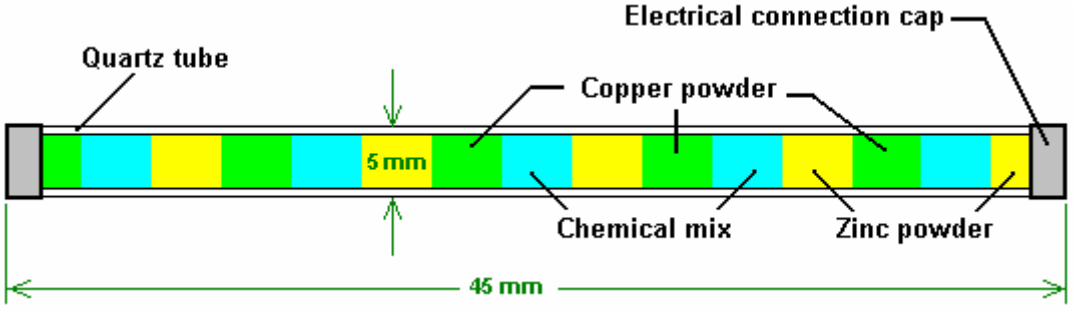
This generator unit includes a magnet, a tube containing a chemical mixture of elements whose nuclei becomes unstable as a result of bombardment by short waves so that the elements become radio-active and release electrical energy, the mixture being mounted between, and in contact with, a pair of different metals such as copper and zinc, and a capacitor mounted between those metals.

The mixture is preferably composed of the elements Cadmium, Phosphorus and Cobalt having Atomic Weights of 112, 31 and 59 respectively. The mixture, which may be of powdered form, is mounted in a tube of non-conducting, high heat resistivity material and is compressed between granulated zinc at one end of the tube and granulated copper at the other end, the ends of the tube being closed by brass caps and the tube being carried in a suitable cradle so that it is located between the poles of the magnet. The magnet is preferably an electro-magnet and is energised by the current produced by the unit. The transmitter unit which is used for activating the generator unit may be of any conventional type operating on ultra-shortwave and is preferably crystal controlled at the desired frequency.





The transmitter unit is of any suitable conventional type for producing ultra shortwaves and may be crystal controlled to ensure that it operates at the desired frequency with the necessity of tuning. The quartz tube containing the chemical mixture, works best if made up of a number of small cells in series. In other words, considering the cartridge from one end to the other, at one end and in contact with the brass cap, there would be a layer of powdered copper, then a layer of the chemical mixture, then a layer of powdered zinc, a layer of powdered copper, etc. with a layer of powdered zinc in contact with the brass cap at the other end of the cartridge. With a cartridge some forty five millimetres long and five millimetres diameter, some fourteen cells may be included.



The Devices of Don Smith.

One free-energy developer who had most impressive claims for his devices is the late Don Smith who produced many spectacular devices, generally with major power output. Don says that his understanding comes from the work of Nikola Tesla as recorded in Thomas C. Martin's book "The Inventions, Researches, and Writings of Nikola Tesla" ISBN 0-7873-0582-0 available from http://www.healthresearchbooks.com and various other book companies. This book can be downloaded from http://www.free-energy-info.tuks.nl/ as a pdf file, but a paper copy is much better quality and easier to work from.

Many experimenters have spent considerable time and effort in attempts to replicate the work which Don reports and while COP>1 has definitely been achieved, high power has not yet been reached. If you want more detail then it can be found here: http://www.free-energy-info.tuks.nl/DonSmith.pdf as a free download.

Mohamed assesses Don Smith's Devices

Late in 2014, Mohamed released the following document after two years of examining and testing Don Smith's main design. If preferred, his document can be downloaded as a separate pdf file:
http://www.free-energy-info.com/Mohamed.pdf

The Resonance Energy Device Explained

Preface

This presentation is a favour from Allah (God), the Thanks is to HIM even though it's the result of more than two years of deep thinking about the resonance energy device invented by Donald Lee Smith. I was interested in this device due to the huge amount of power which it is able to provide. The device has no moving parts and is small in size. This presentation is an attempt to explain two important sources of information about the resonance energy device; they are a document and a video:

The document is located here: http://www.free-energy-info.com/Smith.pdf

The video can be seen here: http://www.youtube.com/watch?v=cQkYAh8Qgb4

The information contained in the document is free and open to the public. I think that it is time for such information to become widely known - free energy is free because it's for everyone. Energy is everywhere in an unlimited quantity, ready to be taken with minimum effort, the resonance energy device described here is one of

the most attractive free energy devices, it depends on a multidimensional transformer which makes possible a harmonic exchange between the positive energy reality and the unseen negative sea of energy. This is possible using a spark-gap arrangement, the energetic symmetry between the positive and negative energy oceans make it preferable to use the term **ambient background energy** rather than the name **zero point energy**. The video pointed to above, is an excellent source that can be viewed in parallel with this work, and when considered together, the reader will understand both the video and this presentation.

At the start of the above video, the inventor explains the importance of the magnetic field in generating electricity. The magnetic energy upsets the background energy and that results in a separation of electrons between the two ends of a coil, this separation of electrons is a source of electric power.

The resonance energy device is based on a very important idea, namely, that magnetism and electricity are two sides of a single entity!

Matter and energy are two aspects of the same thing as Oliver Heaviside expressed in his famous energy equation $E = MC^2$. The electrical equivalent of this in our Resonance Energy Device is:

$$E = (\text{Volts} \times \text{Amperes}) \times (\text{Cycles per Second})^2$$

In this presentation, we will learn together how the device works but before any attempt to use this information, please pay attention to the following caution:

You need to read this document again and again to understand the power behind this device; this device is a power producer! You are near a power production factory but in a small size, this special coil only needs voltage and when we oscillate that voltage, the voltage turns into real current !!

This means that even a short-circuit isn't permitted in the collection system if you plan to use HV capacitors. This is not the place for amateurs, please do not attempt to implements or use the information shown here unless you are experienced and skilled. Neither the publisher nor the author makes any representations as for the completeness or the accuracy of the information contained here and disclaims any liability for damages or injuries resulting from your actions.

Let's examine how a magnetic field generates a voltage in an ordinary coil and why our coils lack the energy key that Donald Smith has found!

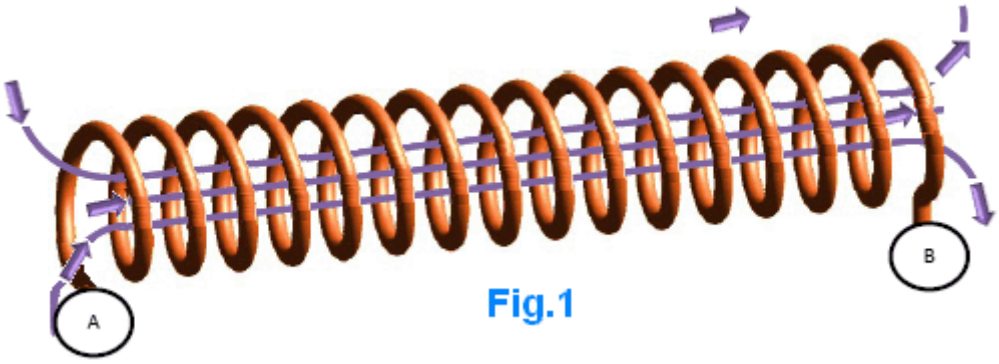

Fig.1

When a magnetic field penetrates a coil, the induced rotating electric field generates additive elementary voltages along the coil. Every turn in the coil receives the same voltage, we extract the power along the length of the coil,

but we miss the power available in the area inside the coil !! To understand this, let's examine the induced electric field:

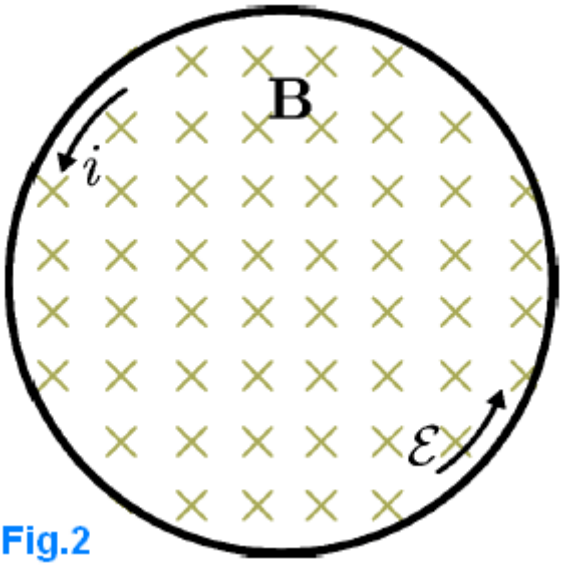

Fig.2

If we examine Fig.2, which represents a single turn of the coil shown in Fig.1, we see that the magnetic field penetrates all of the area inside that ring. This magnetic field will be transformed to a voltage because it will drive a rotating electric field, this field is able to induce a voltage and this induced voltage will cause the current to flow due to the different of voltage between the two points **A** and **B** in Fig.1.

The important, generally forgotten thing about the induced electric field, is its availability inside our coil as shown in Fig.3:

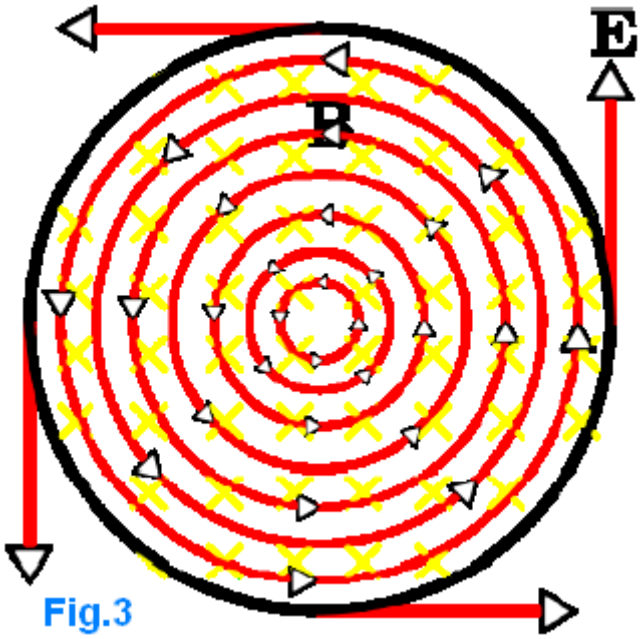

Fig.3

The induced electric field exists independent of the conducting loop. In other words, an induced electric field permeates all of the space within the region of the changing magnetic field, as indicated by the red field lines in Fig 3. What about this field? It is wasted power. It is wasted power at point **A**, as well as all of the distance between the two points **A** and **B**.

If we want to achieve power amplification we have to combine the magnetic field with the induced electric field in such a way as to conserve the non-conservative electric field! The induced rotating electric field will remain non-conservative but we could play with the induced voltage created by that field using a Tesla Bi-filar Coil ("TBC").

We need to extend the capacitive side of a Tesla bi-filar coil in order to benefit from the induced E field to a reasonable degree, if we try to use a flat TBC we will face the same problem in our solenoid coils where we concentrate between two points… The heart of the Resonance Energy device is based on an extended Tesla bi-filar coil (Fig.4)

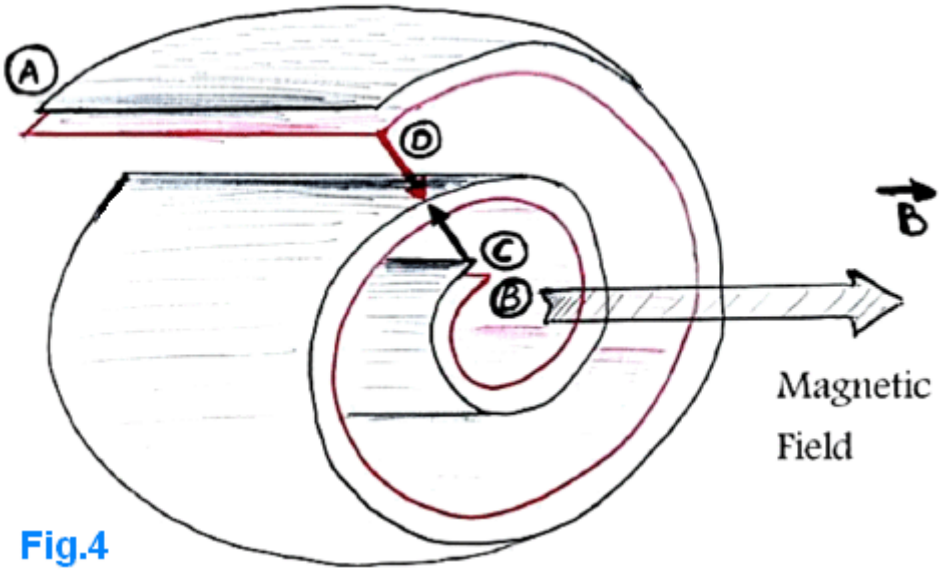

Fig.4

During my search for the specification of Tesla bi-filar coil I wasn't able to find a lot of information such as the resonance frequency of this special coil as if it has been forgotten, although it has been known since 1894!

I felt it's without advantage; fortunately at that time I successfully built a new type of asymmetrical capacitor that has four plates rather than three plates, I was able to replicate my source voltage, I gave it the name C1/C2 system, when I fed C1 with high voltage I was able to take the voltage from C2 without direct contact, the device is based on the electric field interaction between C1 and C2.

The C1/C2 system opened my mind to the possibility of charging a capacitor without the need of direct contact; with the device. I began thinking in a different way, wondering how I could combine the two side of electricity in just one device. The device shown in Fig.4 can be simplified as shown in Fig.5:

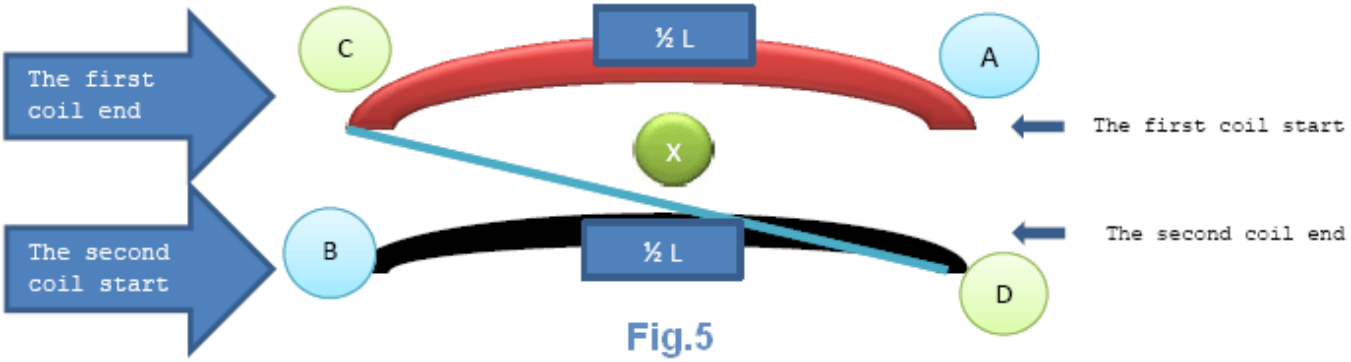

Fig.5

The magnetic side is the path from **A** to **B**, it is the path which the current will follow, and then the magnetic energy will be formed and concentrated inside our coil, the magnetic side is the hidden side of electricity because we can't conserve this state for a long time as we do in the capacitors. This side is directly related to the ambient background energy or zero point energy. (Later we will see why Donald Smith prefers the name of ambient background energy as opposed to ZPE)

To make things easier we could take the permanent magnet as an example, the permanent magnet appears to create the magnetic field all the time without requiring us to provide any visible power for which we have to pay.

The electric side of this amazing coil is the most difficult thing to understand. The capacitor in our extended Tesla bi-filar coil is just one point! It's the point "**X**" but from a static perspective, we say that it is between points **C** and

D. The path from **C** to **D** is the way to conserve the direction of current needed to build the coil and ensure the maximum voltage is generated between the two plates of the capacitor. This capacitor is a dynamic capacitor and not a static capacitor. In this capacitor the displacement current is absent... because it gathers the two polarities of electricity in one device. The magnetic side is the current side where the current starts from point **A** and flows to point **B**. The electric side is the point at which the maximum voltage between the two plates exists. I think that this is the most difficult point to understand in the Tesla Bi-filar Coil, because we see it as just a coil and not a coil with a built-in capacitor!

Back to 1894 and take a look at what Mr. Nikola Tesla said about his bi-filar coil:

> **My present invention has for its object to avoid the employment of condensers which are expensive, cumbersome and difficult to maintain in perfect condition, and to so construct the coils themselves as to accomplish the same ultimate object.**

Let us start by analysing how the extended Tesla bi-filar coil works. Imagine that the following drawing is a charged, extended Tesla coil with the positive and negative parts, shown as red and black plates respectively.

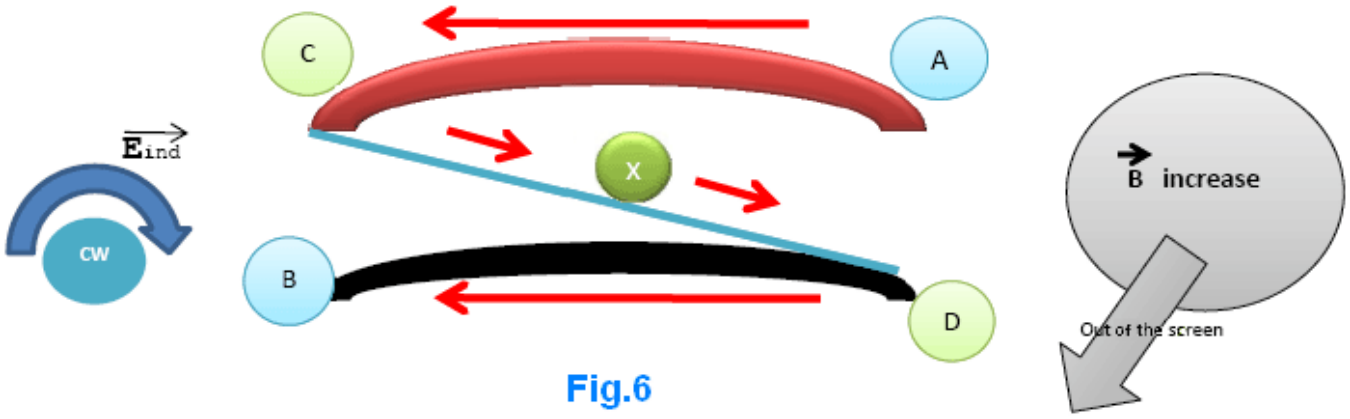

Fig.6

When we connect these two plates by their points **C** and **D**, an electric current will flow from point **A** to point **B** as shown by the red arrows. When the induced electric field finds a coil which is wound counter-clockwise ("CCW") – the red plate - versus another coil wound clockwise ("CW") – the black plate - this electric field will generate an induced voltage which will tend to recharge the capacitor again!

The rotating electric field will start to build an induced electric voltage from point **B** which will be 0V in this case because the induced electric fields rotate in a clockwise direction. When the magnetic field increases, the electric current will flow counter-clockwise and so the direction of the magnetic field will be out the screen as indicated in Fig.6.

In this case we achieve a cost-free voltage difference between adjacent plates. This situation attracts electrons which were not previously available, to become incorporated and produce a very large net gain in potential, this gain is real !!

The induced rotating electric field flows in closed loops but this design causes it to build a voltage difference between adjacent plates. This fact prevents the voltage difference between the adjacent plates from dropping and it makes the replication of electric power with radio frequency a practical operation.

Because of this, we can understand why resonance can't produce the power but it replicates the power with radio frequency and this is the secret of the huge power which this device is able to give with the equation which Don Smith gave us:

$$\text{Power in one second} = \tfrac{1}{2} C V^2 F^2$$

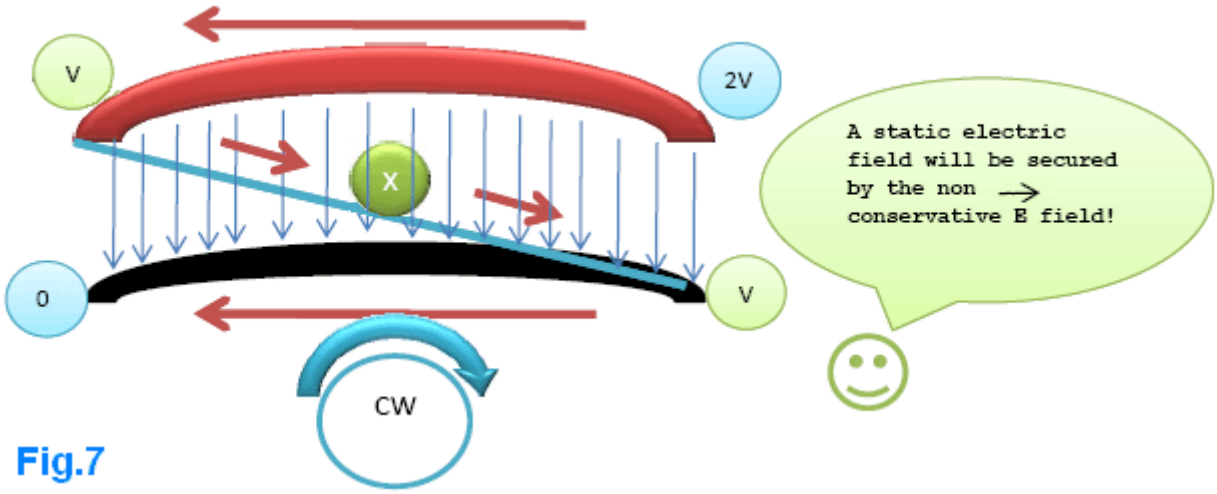

Fig.7

The induced rotating electric field will build induced elementary voltages; **B** is the starting point for that field, so it will have 0V but when we arrive at point **D** it will have V volts, which same voltage will be available at point **C**. The induced rotating electric field will continue it's rotation producing a value of 2V at point **A** !! (Fig.7).

A question arises: where is the capacitor if **C** and **D** both have the same voltage?

The capacitor in our extended Tesla bi-filar coil (TBC) is a dynamic capacitor, it will be formed only when the coil oscillates. When that happens, the induced electric field will give **C** and **D** the same value of voltage but every adjacent turn will receive the same difference of voltage needed for attracting ambient electrons which weren't originally in the system but now are incorporated in large numbers, providing the excess power. This capacitor appears due to the junction **CD**, and from a dynamic point of view, it is the point **X**.

This device treats the magnetism and electricity as if they are the same thing. When this happens both sides help the other side. The displacement current is absent here because it appears when we separate electricity and magnetism. When we do that, we fill the gap by introducing something isn't real. The displacement current does not exist !!

When you move a permanent magnet in the air, **an induced electric field will appear regardless of the presence of a coil.** The electricity is there, it comes from the background energy and returns to its background level, both electricity and magnetism have the same origin, the magnetism is the energy side (magnetic field), the electricity is the physical side (electrons).

The physical side appears when we place a conducting coil in an area where there is a changing magnetic field. The magnetic field causes the electrons to rotate CCW and produce voltage and rotate CW and produce current, voltage electrons appear to be more negative because they are more active, current electrons appear to be less negative. We seek the number of electrons separated by the changing magnetic field. The current (I) is the energy killer because it absorbs the power of the voltage electrons!

In this system, the magnetic field penetrates inside a special capacitor coil where both sides of **electric power** are found in a unified state. We discussed the phase when the capacitor discharges across itself, and now it is time to see how the coil will charge the capacitor with a reversed polarity.

It's important to review the resonance in a normal L/C circuit to understand the work of the extended TBC. Imagine that you have a charged capacitor, when connected to a coil a current starts to flow, when the current reaches its maximum value, this means that the capacitor was totally discharged, the magnetic field will have the greater value and start to decrease and induce a voltage which will charge the capacitor again with the opposite polarity.

The same will happen in our extended TBC, when the magnetic field reaches its maximum value it will then decrease and induce a voltage which will charge the capacitor again, the complexity here is to understand the positions of coil and capacitor.

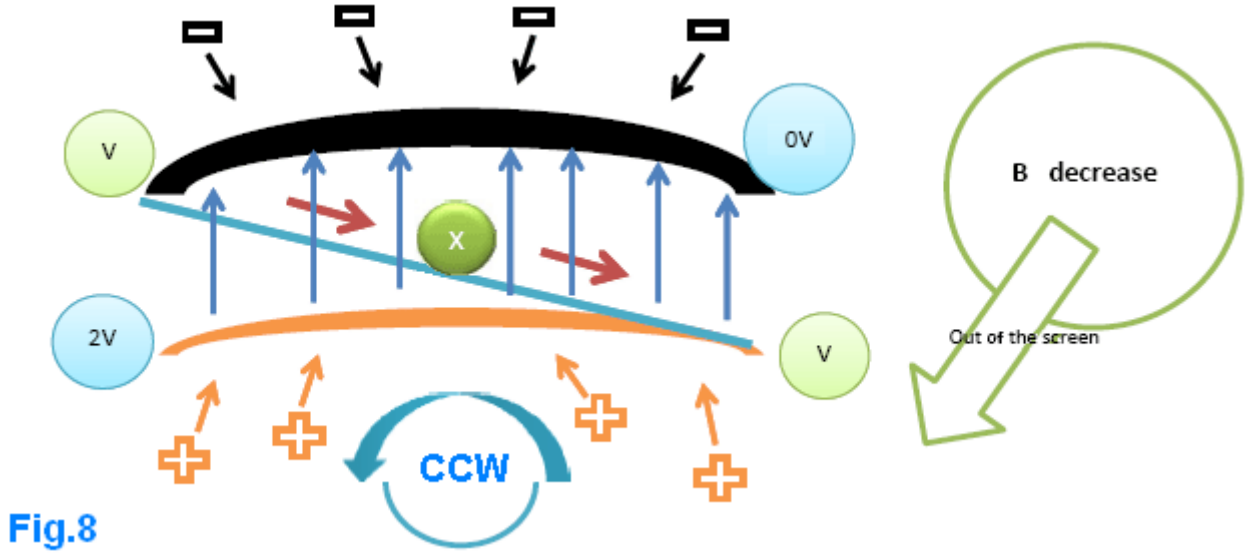

Fig.8

In a dynamic perspective the coil sees the capacitor in the **X** position, the coil situated between **A** and **B**, comparing this to what happens in a normal L/C circuit at this phase the coil has to drive a current **outside its region**, the outside region between **A** and **B** has to be position **X**. when the magnetic field induces a current to recharge the capacitor between **C** and **D**, the induced electric field will do this job because it will change the direction of rotation to be CCW (Fig.8), and this behaviour will tend to keep the current at a high value while the voltage increases! The position of the capacitor in this device has to be the position of a spark gap. A spark gap in this position will improve the performance **dramatically** and amplify the power gain.

The Resonance Energy device works with radio speeds above 20 kHz. The ambient background electrons are usually found in a dormant or inactive state and this makes the drawing-in of ambient electrons a difficult operation. For this reason, we need an earth connection to improve the performance of this system, later in the video, Don Smith talks about something new, the earth connection isn't needed because there is something called **air grounding**.

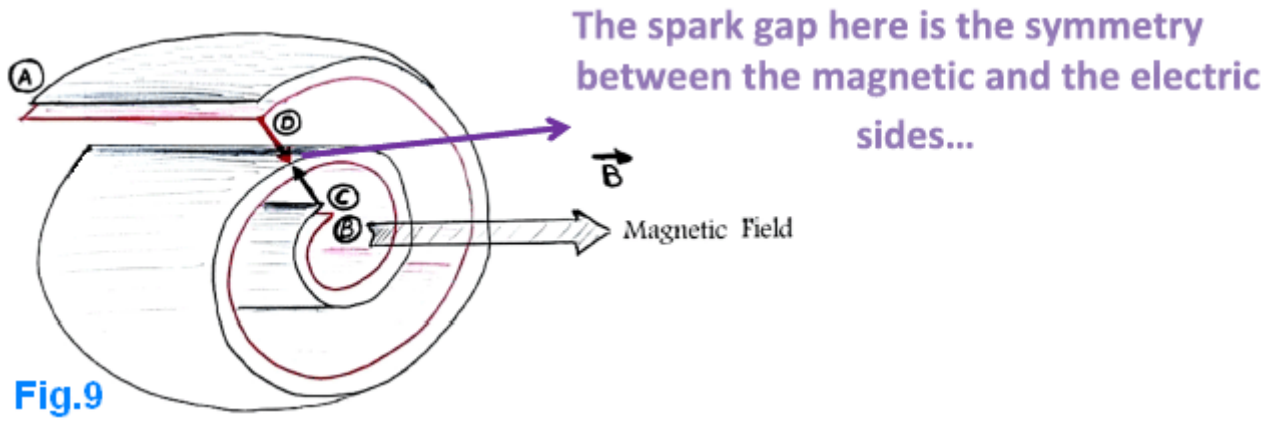

Fig.9

To activate air electrons effectively we need another source of power, actually this source of power exists as a negative energy but before we go further, we have to see the symmetry between the electric and magnetic sides. When we start from **A** to **C** we have **half coil-capacitor** while from **D** to **B** we have **capacitor-half coil**.

To understand how our extended TBC receives negative energy, it is better to see the way in which the device oscillates. There are two methods of feeding this coil:

The direct method

Here we have to know the resonant frequency of this coil or alternatively, we need to have the resonant frequency covered by our feeding circuit. This method is the best because we don't need lots of power, because when we achieve resonance our extended TBC will have a very high impedance, and so, a maximum voltage will be available between **A** and **B**, and fewer turns will be needed in the **reactant coil L2**.

The indirect method
Here we don't have to know the resonant frequency, if we feed this coil from **A** and **B** the capacitor will charge. The spark gap has a very high resistance and it will not fire until there is a voltage difference between points **C** and **D**, at that moment a spark will occur, and when that happens, the resistance of the spark gap drops from a very high value to very low value and that short-circuits any power coming from the power source until the natural coil resonance finishes!

When the capacitor is fully charged, the maximum voltage appears between points **A** and **B** which is the coil side, **when the spark occurs the capacitor will transform into a coil which has a capacitor built into it!**
This operation provides the natural resonance needed without causing any problems.

Caution!

When we feed this coil from point **A** to point **B** and then disconnect it from the power source, you would then expect to discharge it by short-circuiting point **C** to point **D** (usually from the location of spark gap). If you do this and then touch the coil **you will definitely receive a substantial high voltage shock!** Even if you see the spark, the spark will not discharge this capacitor immediately but it will cause the coil to oscillate again and recharge itself. This device isn't a simple capacitor because when you short-circuit the spark gap it will transform the electrical energy into electromagnetic energy capable of recharging the capacitor again.

If you try to short-circuit points **A** and **B** in an attempt to discharge the extended TBC, then these two points will **transform** into electric points (due to the symmetry). From a static perspective, the capacitor can take an **AB** position as well!

The solution is to short circuit **C** to **D** permanently and then short circuit **A** to **B** at the same time.

As I mentioned before, there is a need for extra energy in order to activate air electrons effectively. In reality, this is not exactly what will happen as the arrangement is complicated. The negative energy enters this device in an unusual way. The extended Tesla Bi-filar Coil will supply reactive energy in enormous amounts because there are common characteristics between reactive energy and negative energy. Reactive power is a kind of electrical power, measured in volts-amps-reactive ("vars") which cannot do work in its present form. For sinusoidal waveforms, the formula for reactive power is

$$\textbf{Reactive power} = \mathbf{V} \times \mathbf{I} \times \sin(\theta)$$

The reactor coil in our system is a shortened version of a normal parallel L/C circuit. The output energy received in the reactant coil has to be a reactive energy because of the presence a coil in parallel with a capacitor. The phase angle between current and voltage is 90 degrees, and so, the active energy in this case will be zero.

$$\textbf{Active power} = \mathbf{V} \times \mathbf{I} \times \cos(90 \text{ degrees}) = 0$$

The system acts like a negative resistor, it's a **non-dissipative** system because it's an energy absorbing system:

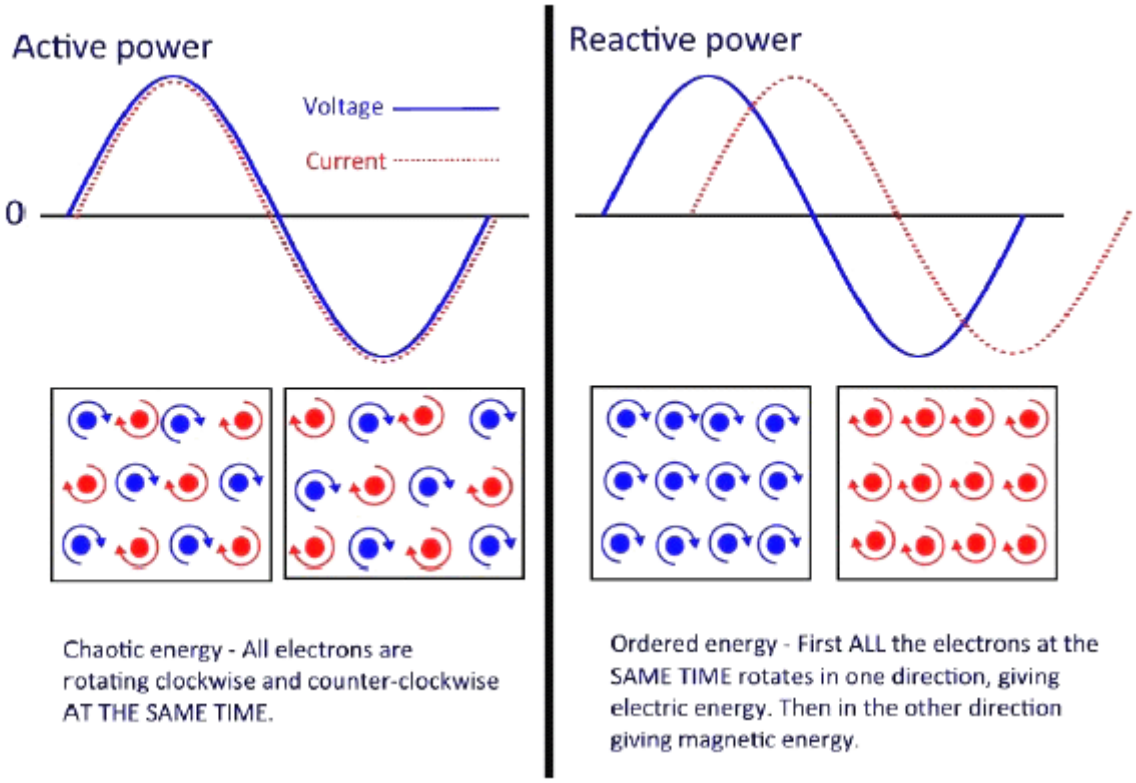

Fig.10

The reactive energy in this system is an advantage. The energy is ordered and so we can easily achieve **super-conductivity** at room temperature!

As shown in Fig.10, active energy is a **chaotic energy** and so it is not easy to get rid of resistance. The important point where we need to focus our attention is where the voltage has a maximum value the current will be totally absent. Negative energy is a kind of electric **power** obtained when sparking (on-off) from a high voltage direct current (Fig.11).

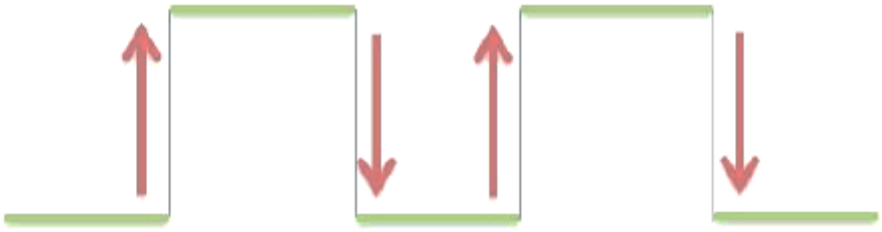

Fig.11

This is why we need a high-voltage diode in our power supply circuit. The resonance in a normal parallel L/C circuit does not require this.

If we connect a spark-gap between point **C** and point **D**, then the negative energy will be drawn into our system with the same speed as positive energy! The symmetry between the magnetic and electric sides in our positive energy reality will open the correct door for the undetectable negative energy reality!

Initially, when the capacitor starts to discharge, the current increases but the induced rotating electric field will tend to keep the voltage at a high value. The capacitor discharge through the spark-gap (which requires a large amount of voltage), the current flow does not start immediately. Initially, the current increases but the spark does not occur. This pushes the voltage up higher (behaviour which is known in parallel L/C circuits), then the current increases to a high value very quickly, while the voltage is drawn down to a level which cannot sustain the spark. When the capacitor is totally discharged the current flow through the spark-gap is at its maximum value. Consequently, the extended Tesla Bi-filar Coil produces a square wave rather than the expected sine-wave which is produced by an ordinary parallel LC circuit. The square wave produced when the spark occurs, contains waves of all frequencies and so, even if the time during the spark is short, there will still be thousands of oscillations in that time. I know that it is not easy to visualise this, but it is what actually happens.

This special genius design solves the most difficult problems in cold electricity, due to it's reversed behaviour compared to hot electricity. Cold electricity prefers to flow along materials which we consider to be insulators while hot electricity prefers to flow along materials which we consider to be conductors.

According Tom Bearden, with negative electricity the capacitor performs in the way that a coil does with hot electricity, and the coil will perform like a hot electricity capacitor (Fig.12).

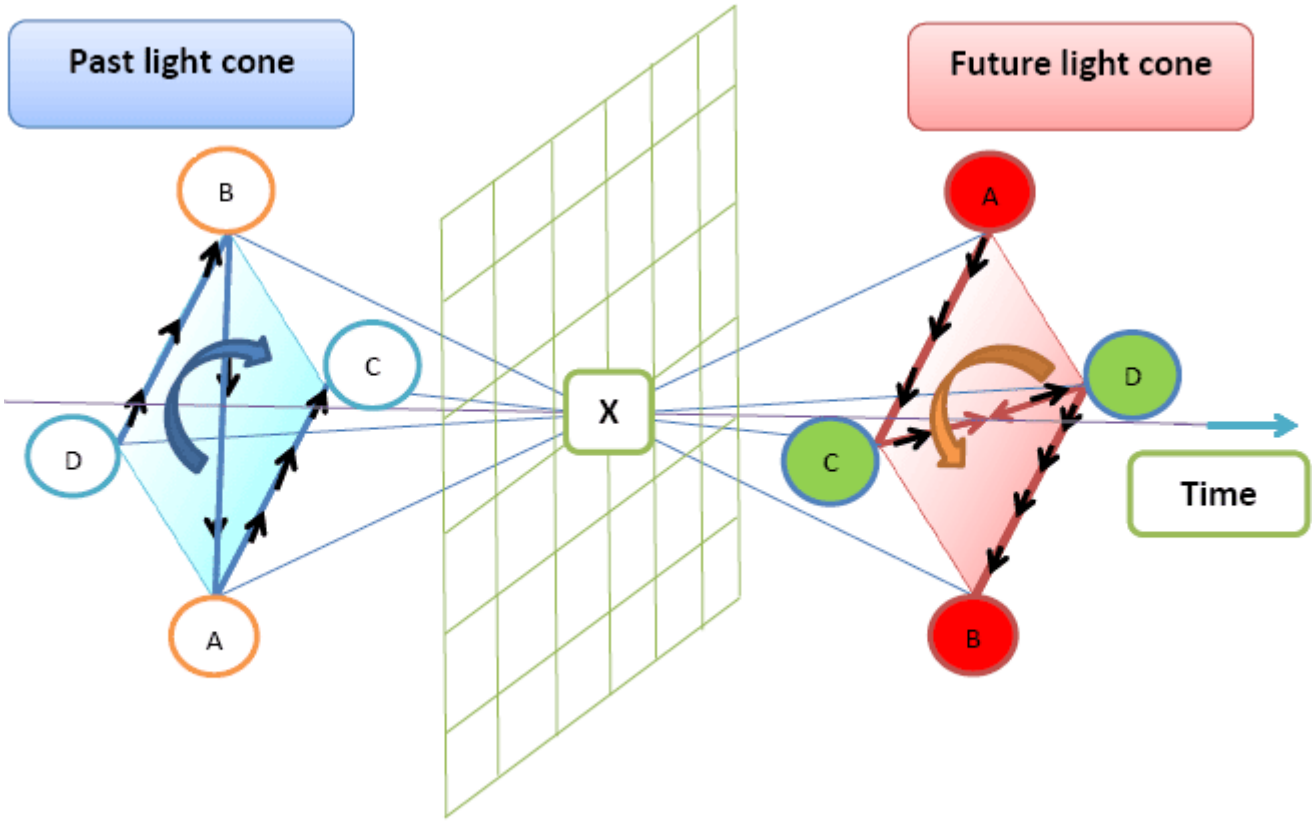

Fig.12 (the capacitor is discharging across itself)

the above illustration is an attempt to understand how cold electricity work but it's better to take a look at Floyd sweet explanation of his VTA device in the Appendix (page A-1209) :

it is important to note that so long as positive energy is present in a **positively-flowing time regime**, then unity and over-unity power gains are not possible. The summation of the losses due to resistance, impedance, friction, magnetic hysteresis, eddy currents and windage losses of rotating machinery will always reduce overall efficiency below unity for a closed system. The laws of conservation of energy always apply to all systems. However, **the induced motional E-field changes the system upon which those laws need to be applied**. Since the vacuum triode operates in **more than four dimensions** and **provides a link between the multi-dimensional reality of the quantum state and the Dirac Sea**, we are now dealing with an open-ended system and not the "closed system" within which all conservation and thermodynamic laws were developed. To achieve unity, the summation of all magnetic and ohmic losses must equal zero. To achieve this state, **negative energy and negative time need to be created**. When this is achieved, **all ohmic resistance becomes zero and all energy then flows along the outside of conductors in the form of a special space field**.

The above explanation describes the VTA device but also demonstrates the work of the Resonance Energy device of Don Smith !!

The correct model of capacitor is the extended Tesla Bi-filar Coil because it provides a link between the multi-dimensional reality of the quantum state and the Dirac Sea of negative energy. From a positive energy perspective, **AB** describes the coil while **CD** describes the capacitor, **but** the coil will transform into capacitor **AB** in the region of negative energy; and in the same area the capacitor will transform into the coil !!

How can we explain this physically!?

The energy equation and Dirac's equation call for both positive and negative energy. Thus they are symmetrical with respect to energy, as are the forces of physics positive repulsive forces increase positive energy, while negative attractive forces increase negative energy. According to the modern kinetic theory of mass-energy, negative energy would merely be a **vibration of charges at right angles to our ordinary dimensions in an "imaginary" direction**. (Fig.13).

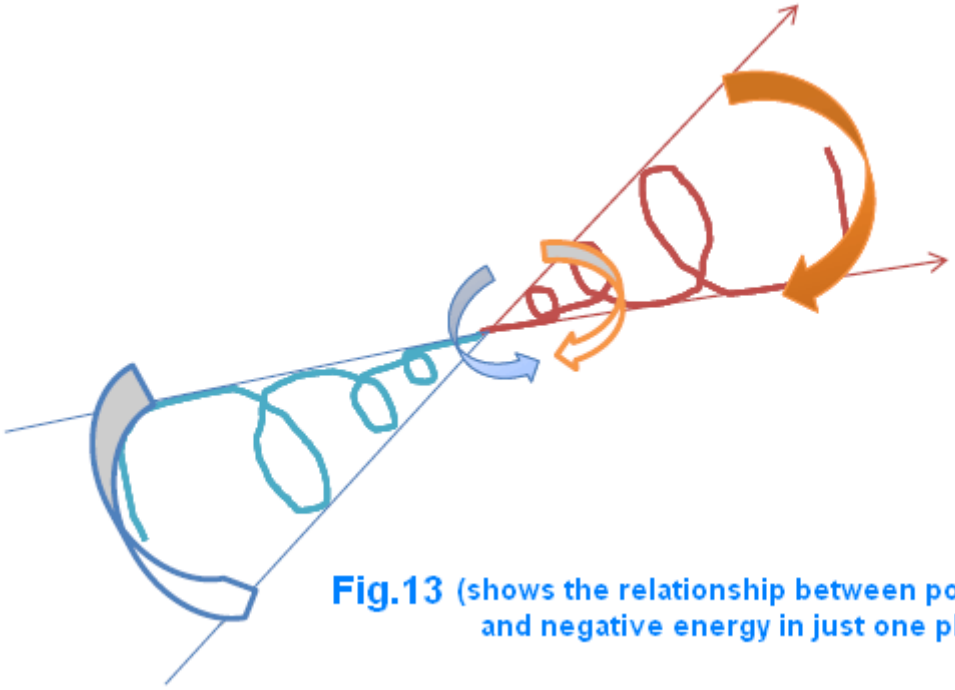

Fig.13 (shows the relationship between positive and negative energy in just one phase)

To understand Fig.13 correctly, we need to remember that we are confined by our positive energy reality; in our extended Tesla Bi-filar Coil we need the negative energy in our positive side, the spark gap in CD position is the flexible place for both positive and negative energy to be combined.

Tom Bearden has an important book entitled "Energy from the Vacuum". The following text is on page 236 where he explains the specification of a true negative resistor:

The true negative resistor is an open dissipative system ***a priori***, and equilibrium thermodynamics therefore does not apply. Instead, the thermodynamics of open systems far from equilibrium applies. The negative resistor freely receives energy from outside the system (from the environment), and "dissipates" it in interception and collection actions inside the system, to freely increase the available potential energy in the system.
In circuits, the main characteristic of a negative resistor is that the environment freely furnishes some excess energy to (i) power the load, and/or (ii) move the current back against the voltage, particularly when shunted across the back emf region of the source dipole. The *operator* does not have to furnish this excess energy dissipated to propel the current backwards or dissipated to power the load!

The true negative resistor in our system is the blue extended TBC where negative energy moves the current back against the voltage; this power will charge the coil electrically if it's acting as a capacitor!

The electric current in the negative energy region (past light cone) works in a reverse manner compared to the electric current in positive energy region (future light cone), the symmetry between the magnetic **energetic** side

and the **physical** electrical side will curve space for the negative energy power to enter our device through our **flexible** spark-gap zone which represent a one dimensional capacitor **X**, the negative energy which can be represented by attraction forces will find its way through the spark-gap to increase the electric energy through **AB**, the system will continue its divergence and the clockwise rotation of the negative energy current will increase the counter clockwise rotation of the hot electric current (potential energy), this tends to amplify the power between point **A** and point **B** which represents the voltage gained by this virtual current!

We are examining the first instant when the capacitor discharges across itself (transform into coil), the curved **AB** space will transform into one point in the negative energy sea which is the capacitor in our imaginary extended TBC.

Similarly, when the magnetic field collapses and charges the capacitor across **CD**, the magnetic field returns to its background level, the space-time continuum is reversed by the fields which are produced in the presence of excited coherent space flux. These quanta have been attracted from, and ultimately extracted from, the virtual vacuum, the infinitely inexhaustible Diac Sea (from Floyd Sweet papers in the Appendix)

Like charges have repulsion behaviour on the positive energy side, while they attract each other in the negative energy region. This information is essential for an understanding of the nature of the negative energy sea.

When the turn comes (second time period) for our capacitor to be charged again with opposite polarity, the system will diverge toward negative energy space to close the loop in that space !! The current passes from **C** to **D** to charge the capacitor but in the virtual dimension it starts from **D** and finishes in **C**. This power will charge the capacitor magnetically if it's a coil.

As you see there is positive real energy and undetectable negative real energy. I think that Don Smith preferred the name *ambient background energy* as opposed to *Zero Point Energy* because there are two regions from which we can take power, namely, over ambient background energy and below ambient background energy.

At this point, we can understand why cold electricity prefers insulators rather than conductors. This kind of power is capable of running in an imaginary dimension **parallel and reversed** relative to our ordinary, familiar dimension. But… according to Floyd Sweet; when run in parallel with positive energy however, cancellation (annihilation) of **opposing** power types occurs. This has been fully tested in the laboratory.

This applies to the chaotic positive energy flowing regime time when voltage electrons (ccw rotation) and current electrons (cw rotation) run together at the same time, our Reactive Energy resonance system works in harmony with negative energy, our previous study allows us to draw us some important conclusions:

For the first time period, we have (C discharging across L);
+ energy increase magnetic energy ---- I
- energy increase electric energy ---- V

For the second time period we have (L charging C);
+ energy increase electric energy ---- V
- energy increase magnetic energy ---- I

since magnetic energy is the current and electrical energy is the voltage and because they are out of phase (reactive energy), positive energy will work in harmony with negative energy and no cancellation will appear.

Our extended TBC is a very important device not only because it can supply unlimited electric power but it give us an exceptional opportunity to understand the way that energy flows inside our universe!

When the device oscillates it produces cold electricity and hot electricity, this means that the device is able to relate to both positive and negative energy. The flow of energy has two directions; from positive to negative and vice versa. Let's think about the physical way in which things work.

In this analysis I'm trying to explain some deep physical aspects about positive and negative energy. As illustrated in Fig.12 and Fig'13, it is important to consider energy flow in relation to time. These two pictures just represent my thoughts and understanding of the subject.

Cold electricity has the ability to produce an electric response when it interacts with metal surfaces. This can also be seen in the Casimir Effect where two non-magnetic metal plates, which are not carrying an electrostatic charge, are suspended very close to each other. The plates do not hang straight down but move towards each other.

Cold electricity has the ability to produce an electric response when contacting metal surfaces because it's able to ionise empty space. In our extended TBC, when the spark occurs, we are actually colliding the space-time field through one point (the spark-gap).

The space-time field is, in my opinion, the space where negative and positive energy exist together, they exist together but cancel each other out due to a constant ratio. If we take a mass with a gravity field around it, and we move the mass and create a mass current, a new field is also created. It is a different kind of gravity field with no source and no sink, when the speed of the mass increases, then the created gravity field increases also. If the mass reaches the speed of light, then this means that it has the value $E = mC^2$ as a positive energy. mC^2 is the maximum value exchange between positive and negative energy admissible by zero point fluctuation (ZPF) for that mass to exist the way it does in its time-space field, the mass has two options to reach the speed of light:

1. It will transform into exotic matter.
2. It will break the time-space structure.

The only places which provide these two conditions are black holes. Black holes exist in the centre of galaxies which provide the rotational energetic symmetry between the mass and gravity field - see Fig.14, Fig.15 and Fig.16.

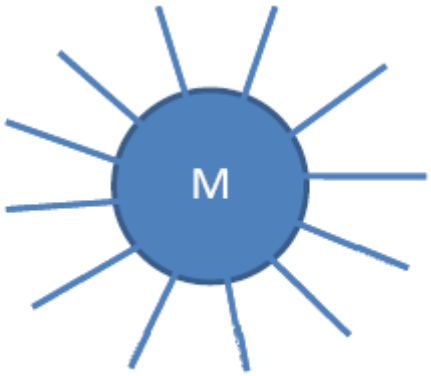

Fig.14 GRAVITATIONAL FIELD

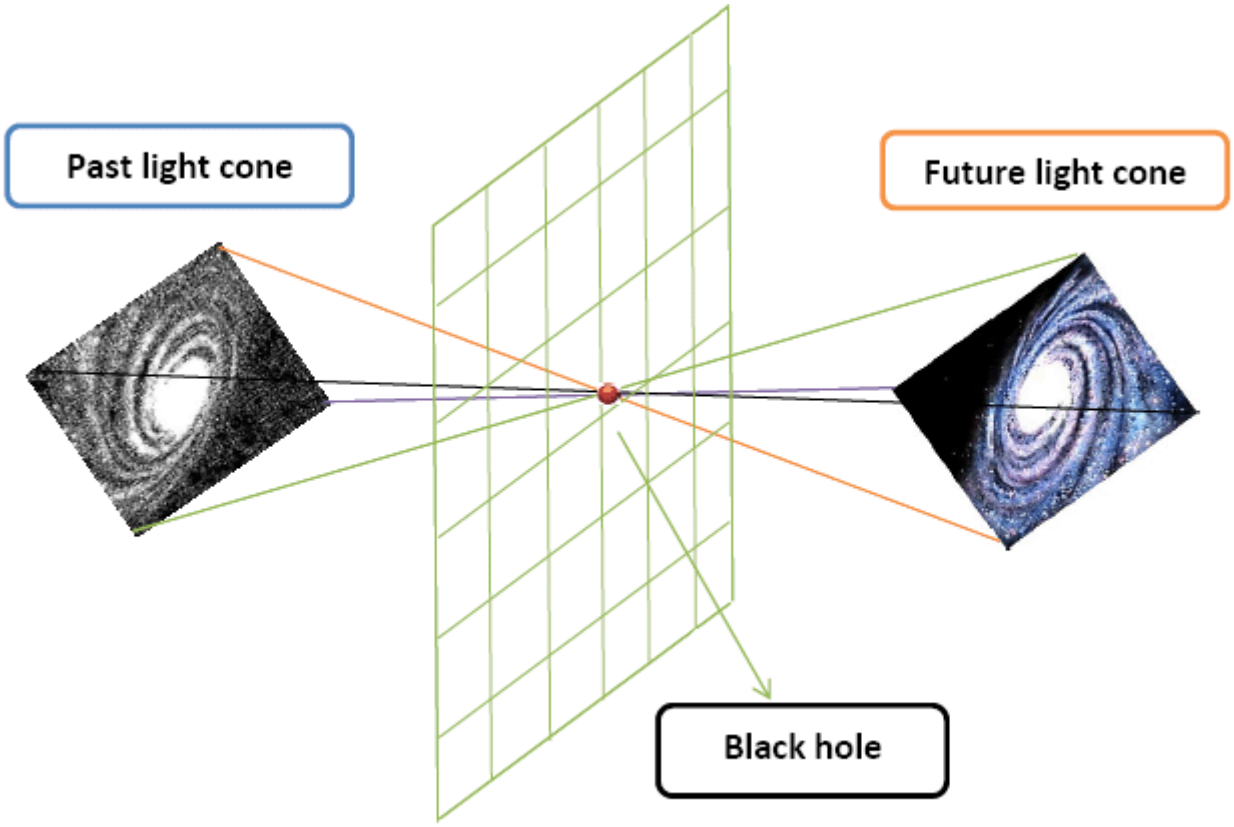

Fig.15 notice the similarity between the black hole and the spark gap

Fig.16 The massive spiral galaxy NGC 1365 has a huge black hole in it's heart, spinning at nearly the speed of light

For a spiral galaxy to maintain its shape with cosmic dimensions (the diameter of galaxy may exceed 100,000 light years) there is a need for a negative energy to be the underlying energy for space-time throughout all of that galaxy. That negative energy has to transport virtual particle instantly! The transformed physical matter (including space-time!) provided by black holes furnishes an excess of positive energy in the galaxy, providing stability and symmetry. Black holes are not a fracture in space-time but they are essential.

The above explanation will help to clear the way for a better understanding of the nature of electric energy. This explains why a sharp positive-going DC electric pulse interacts with negative energy to produce cold electricity which is an instant response from the negative energy sea. This response does not start from the spark-gap, but it ends in it!

The negative energy will rotate to finish in the spark gap, this will squeeze the space-time to provide excited coherent virtual particles which in turn produce electronic responses when contacting a metal surface. From my point of view, the electronic responses created in metal surfaces have a magnetic angular momentum. Cold electricity is able to charge a capacitor to a much higher voltage than the capacitor's voltage rating, even if the capacitor's rated voltage is low. The question which springs to mind is; do electric fields inside a capacitor charged with cold electricity really exist?

If the answer is yes, then why isn't the capacitor destroyed? In my opinion, it is because the electronic responses caused by cold electricity have magnetic angular momentum instead of electric field lines. I suggest that the presence of magnetic field lines between the positive and negative plates of a capacitor charged with cold electricity are actually as shown in Fig.17.

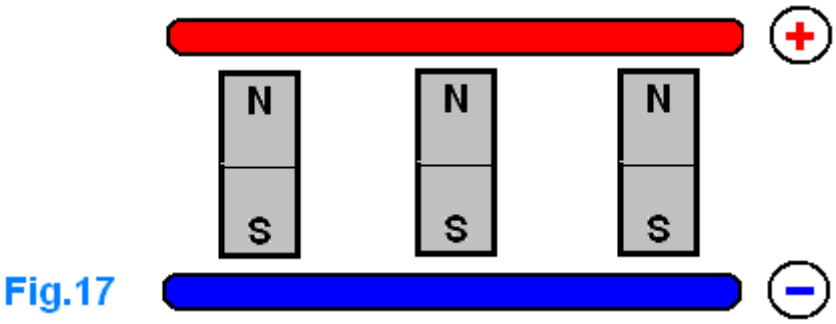

Fig.17

When the spark gap impacts on space-time (that is, when the spark occurs) the response from the negative energy sea looks as if it should neutralise the excititation created in the positive energy side (Fig.18). We can't detect the movement of negative energy, and so we only see the impact which it has in our positive energy reality.

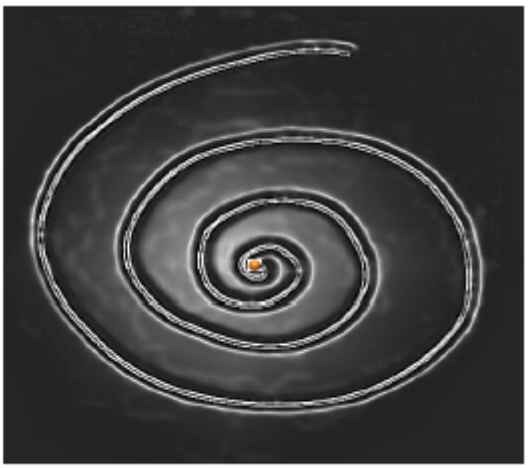

Fig.18

The small red ball in the above drawing, is the spark gap which is the door for negative energy to enter our positive energy reality; the negative energy sea will react both before and after the spark occurs.

Referring back to Fig.14, before the spark-gap fires the negative energy will rotate starting from the spark-gap to neutralise the excitation created in the positive energy side (Fig.19a) and when the spark-gap finishes firing, the negative energy will end in the position of the spark gap (Fig.19b).

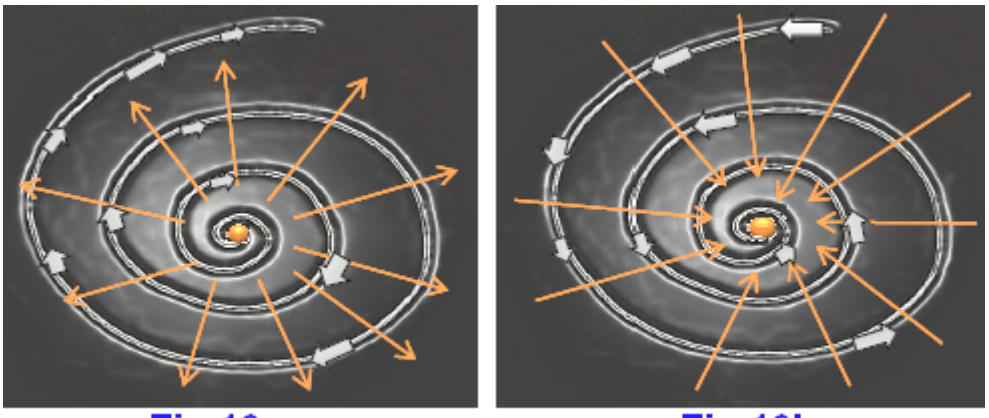

Fig.19a Fig.19b

The Bloch wall area in an ordinary permanent magnet, is the area of electron separation. Let's see how this happens in our extended Tesla Bi-filar Coil. During the first time period, when the capacitor starts discharging across itself to become a parallel L/C circuit, point **A** will provide a maximum voltage while point **B** is the maximum current. The current flow starts from point **A** and finishes at point **B**. The system is now producing magnetic energy and because of the magnetic field increase, the electrons will start from point **B** and flow to point **A** which causes clockwise rotation to neutralise the counter clockwise spin of the voltage electrons, and cold electricity will charge the coil electrically if it is acting as a capacitor, and it will push the current to go back against the voltage by providing a magnetic angular momentum (the clockwise rotation shown in Fig.19a) at point **X** the result is to turn back the voltage electrons, causing strong initial potential electrical energy which increases the electrical energy. Current in cold electricity is the equivalent of voltage in hot electricity. The Bloch wall is the place where negative energy interacts with our E-TBC, in other words when the spark-gap fires, the current will not start immediately because the negative energy will supply a virtual current by providing a CW rotation in the Bloch wall area **X**. This virtual current is a compensator of the real current but it will not absorb the power from the voltage electrons which increase the available potential electrical energy. All this happens before the real current increases to provide the magnetic energy.

Caution: Please be aware that high voltage capacitors have dielectric recovery which stores the electric field for a long time. High voltage capacitors need 5 minutes or more to discharge completely.

Energy is everywhere and in enormous amounts ready to be taken for free. When we do that, we do not reduce the available power because the universe is full of energy, the energy in our universe is the source, physical matter is the energy in a visible form and the energy is in invisible matter form.

The presence of the negative energy sea beside our positive energy reality, raises an important question, namely, why they are separated when they could be united? They are separated to let our universe exist in the way that it does. Negative energy serves our existence because it's designed to be the **under** background energy level for our **foreground** positive energy reality. Our existence is a thin part between those two energetic oceans. Negative energy is extremely active until the point when it appear to be nothing!

We now need to explain another important behaviour of our extended Tesla bifilar coil, namely, it's super conductivity at room temperature.

One of the puzzles in this device is its capability to equal the voltage with the current. The wire of the coil **AB** can receive ambient electrons because it's the surface for the capacitor **CD**; let's examine this surface in Fig.20:

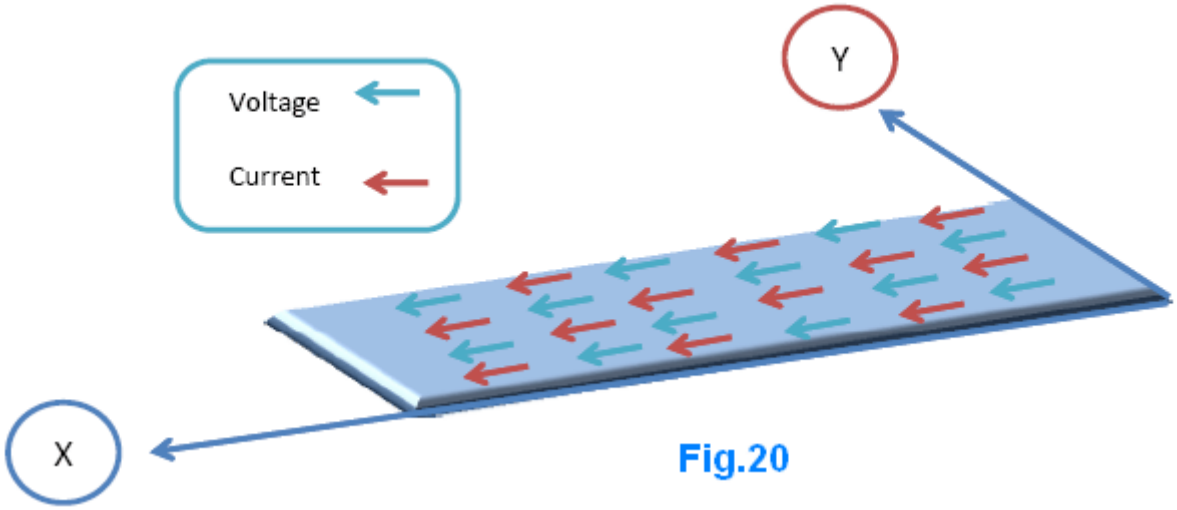

Fig.20

When the capacitor discharges across itself to become a parallel L/C circuit, the induced rotating electric field (with the help of negative energy) creates a difference of voltage between adjacent plates, this voltage according the Gauss law causes **new electrons** to be present in the system.

$$\oint \vec{E} \cdot d\vec{A} = \frac{Q_{enclosed}}{\varepsilon_0}$$

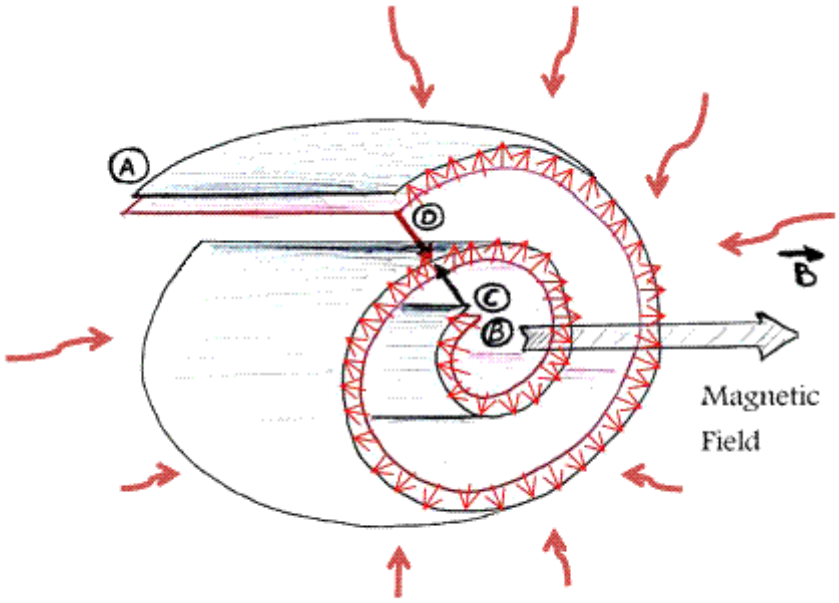

Fig.21 (ambient electrons can be taken from the other plate as one of them has to lose electrons)

When ambient electrons enter our system (Fig.21), they increase the power gain across the Y axis (Fig.20). When the current flows inside the extended TBC, parallel currents will be added while parallel voltage will be the same in the Y axis, while in the X axis serial voltage will be added while serial currents will be the same!!

On the Y-axis: sum (I) equals (V)
On the X-axis: sum (V) equals (I)

This system treats the voltages and currents in the same way, the voltages and the currents are physically equal.

When this happens the device squares the electromagnetic flux and becomes a near-unity system in every process which will replicate the electric power according to the working frequency. This is a near-unity system due to the super conductivity at room temperature where the electrons don't face the usual reduction encountered in an ordinary parallel L/C circuit.

A normal L/C circuit cannot produce the super conductivity at room temperature because the exchange between the electric power and the magnetic power must lower one of them in each process. In our extended TBC they are combined in such a way so as to amplify the power in every process, and so the total available electrical energy in each cycle is twice the power available in a charged capacitor which can be seen from the following relationship:

$$\textbf{Power} = 0.5 \times C \times V^2$$

(consider the similarity between the magnetic and electrical energy in a resonating parallel L/C circuit)

Here, I need to explain the importance of the reactive electric power in the Resonance Energy device, in an alternating electric system where the voltage and current go up and down at the same time (Fig.10). Only active, real power is transmitted and when there is a time shift between current and voltage both reactive and active power are transmitted. When this time shift is 90 degrees (π/2 degrees) the transmitted real power will be zero as discussed above. This does not mean that there is no power, but it does mean that **we cannot use this power in this alternating form,** we have to transform it into Direct Current so that both current and voltage are united.

Reactive power looks like a skipping rope (Fig.22):

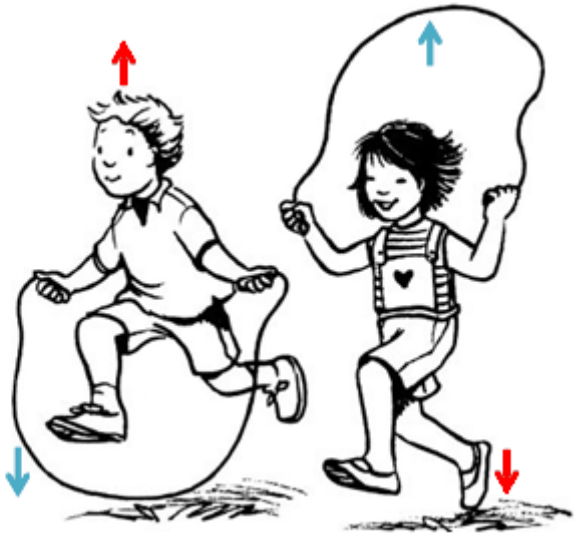

Fig.22

Imagine the **voltage** to be the rope and the children's bodies are the **current**. Reactive power looks like a skipping rope, the active power will not let the kids' bodies move correctly. Reactive power is an essential part of the Resonance Energy device, and a skipping rope is good example which shows how kids go up and down without any problem. This sort of movement exists in our device.

The separation between voltage and current in the Resonance Energy device is crucial for producing and cloning electric power at radio frequency speed. A proper method of collecting and converting the huge available electric energy is needed.

The example given in Fig.22 is important when planning to collect and convert the available electric power. If we simply use a step-down transformer it is highly likely that we will alter the current which will reduce the gained power. With reactive energy, when the voltage is high the current is low. A step-down transformer will lower the voltage but it can't amplify the current as expected! In a normal transformer we amplify the current depending on the available active power (V x I):

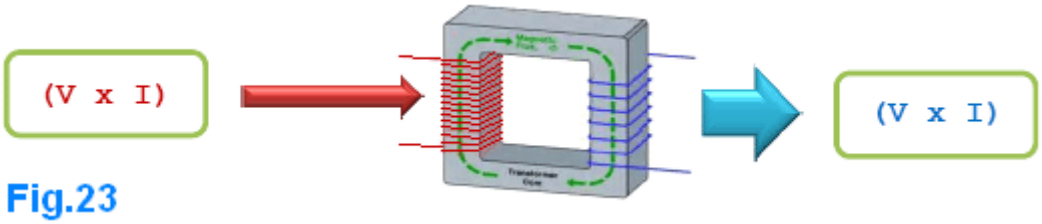

Fig.23

Physically (Fig.23) the **electromagnetic flux** inside the transformer has two components, the electrical component **V** and the magnetic component **I**, for successful transfer of electric power from the primary to the secondary, both of them are needed at the same time. In our case, when **V** is high the product (**V x I**) is low due to the time shift, even if the available power could achieve megawatts!

Another factor which we have to take into consideration, is the high-speed needed to replicate the power, using a transformer to lower the voltage imposes the need for a special transformer core which is able to respond at radio frequencies. These facts have to be taken seriously if we want to collect the available energy effectively.

Fig.24

Personally, I prefer to improve on the use of high-voltage diodes as shown in Fig.24. It is better to use a diode bridge constructed with **fast recovery** high-voltage diodes. Fast recovery diodes have the ability to return to their blocking state very quickly, making it possible for the other half-oscillation to be accumulated in the high-voltage capacitors, each cycle (**up** and **down** in Fig.25) will give power similar to the power available in a charged capacitor given by the following equation **½ C V^2**.

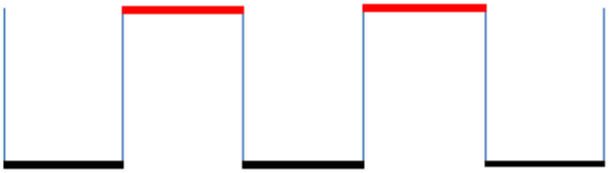

Fig.25

The amazing, energetic behaviour of the extended Tesla Bi-filar Coil make it totally different from an ordinary parallel L/C circuit. Our extended TBC gives twice the frequency of an equivalent parallel L/C circuit. This means that if you form the same inductance with the same capacitance in an ordinary parallel L/C circuit, then that will produce only half the frequency that the same combination produces with an extended Tesla bifilar coil form!

I have not been able to verify this because I don't have an oscilloscope or a frequency meter. That, of course, is no excuse for not thinking about how the device will act, so the following analysis is an attempt to imagine the energy equation given by Mr. Donald Smith as:

$$\textbf{Power in one second} = 0.5 \times C \times V^2 \times F^2$$

To simplify things, let us analyse only the voltage. When the capacitor discharges across itself to become a complete parallel LC circuit, at that instant, the magnetic field reaches it's maximum value. What makes this system different, is the induced rotating electric field. This field will instantly charge the capacitor with the opposite polarity before the induced current resulting from the collapsing magnetic field can do it. As we learned before, this is the key to energy amplification.

Resonance is the key for energy multiplication, our extended TBC acts like one device, so the passage from the positive cycle to the negative cycle takes no time. In other words, the device has the ability to change it's direction of charge instantly. The yellow zone in Fig.26 is absent (compared to a normal parallel L/C circuit), when the energy cycles up and down (Fig.25) the device gives twice the power available in the capacitive side of the extended TBC.

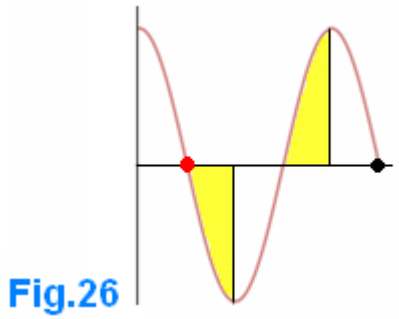

Fig.26

(the cycle in an ordinary L/C circuit is from the red point to the black point. In our device, that is only half of the time which explains why an E-TBC produces twice the frequency when compared to an ordinary parallel combination)

The power is each cycle will be given by:

$$\frac{1}{2} C V^2 \times 2 = C V^2 \ldots\ldots\ldots\ldots\ldots\ldots 1$$

Since the frequency will affect both the voltage and the current we will examine the equation number 1 as follows:

CV x V, the product CV is the quantity of charge available in a charged capacitor, if we divide it by 1 second this will give us the current since Q/T is the current in one second. Let us suppose that the frequency is 3 Hz.

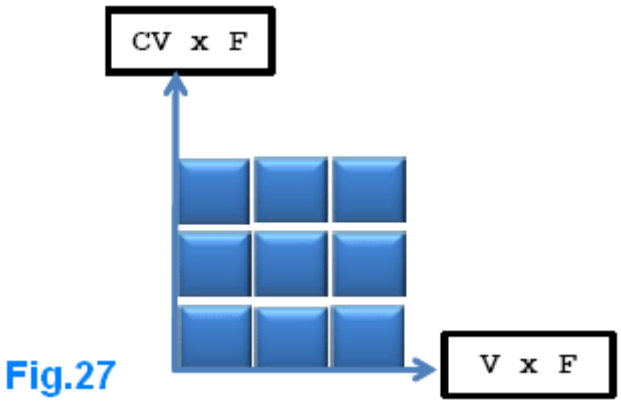

Fig.27

From Fig.27 we can see that the total available power is proportional to 9 which is the square of the given frequency. Each cycle has the power of C V^2, the number of cycles in one second gives us the frequency; the frequency will replicate CV which is the current and this will give us CV x F and replicate the voltage by the product V x F, this analysis is the best explanation of why the voltage equals the current in this system, because CV x F is the available current and V x F is the available voltage! This seems strange; how could the product V x F be the available voltage since the result is very high since we are working with radio frequencies above 20 KHz?

The example given in Fig.23 will help us understand this. The energy formula gives the available DC power when converted from its alternating state; the **electromagnetic** flux will be squared causing amplification of both **current** and **voltage**. In each second, the available power is **CV x F** x **V x F**, the power obtained depends on the number of turns in coil L2, and the limiting factor is the product **V x F** which is a very high number in practical systems. Below this factor, the current is very high being the product **CV x F**!! This explains why a megawatt sized unit can fit quite easily on a breakfast table and it explains why this device is able to give any required level of energy.

The energetic formula of our extended TBC can now be written as follows:

$$\textbf{Power in one second} = C \times V^2 \times F^2$$

This equation gives the available power in watts when converted into high-voltage Direct Current. When the device oscillates the power obtained is **pure reactive energy, Volt-Ampere-Reactive (VAR) is present while active electric power (W) is absent in this dynamic state**, Fig.28:

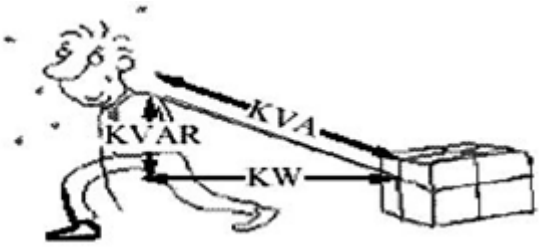

Fig.28

(this explains why reactive energy isn't capable of doing real work in it's alternating state - when KW=0 then KVAR has no effect)

In practical terms, the extended TBC is just a high-voltage capacitor which has the ability to let the current penetrate inside itself, so it has both magnetic and electric specifications.

Practical section

A free-energy device is something which is fascinating, being hasty in wanting to build and test one is common, but that is not good. **High-voltage with high current isn't a game!**, your first mistake may well be your last. If you decide to build this device in your house it is a good idea to use locks and keys and sticking a high-voltage warning symbol on the device is a sensible action.

I am not encouraging you to actually construct the device described here; the above theoretical information provided is the most important section. When the device is fully understood, then taking care when near it will be automatic. This device is a very special Tesla coil, when increasing the voltage in a normal transformer the current drops, **but here the current increases in the same manner as the voltage does!** This device has current equal to the voltage. Resonance will impact both the voltage and the current. The special geometrical design of the extended Tesla Bi-filar Coil, including the flexible position of the spark-gap, produces the needed rotational energetic symmetry between positive and negative energy. As we have already seen, the spark gap opens the door for a massive inflow of electrical energy to be present. **I personally got shocked indirectly from the L2 coil and I certify the risk of this device**.

For construction, the first thing we need is a source of high-voltage. The device can be fed using two different methods as described here. The first is the direct method where the high-voltage power source has the same frequency as the natural resonant frequency of the extended Tesla Bi-filar Coil. The second method is the indirect method; where there is no need to know the frequency of the reactor (active) coil.

The high-voltage power source is needed to feed the extended TBC which is the reactor coil (active coil), Fig.29 shows an easy to build oscillator:

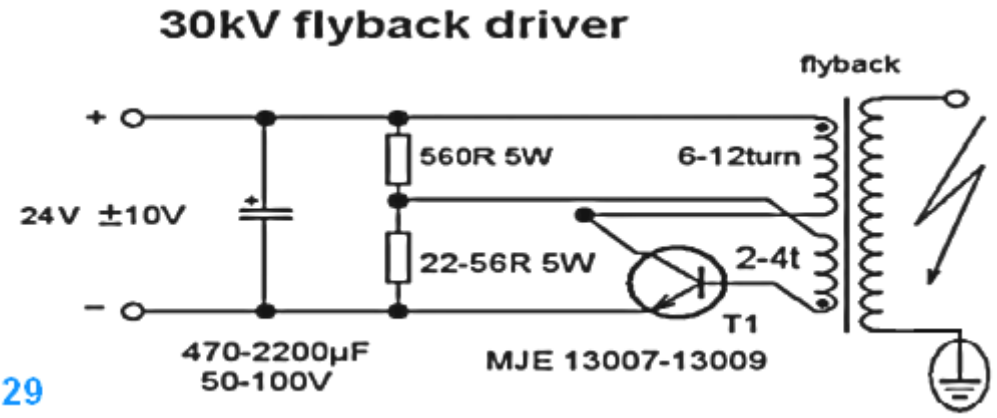

Fig.29

It's better to use a flyback transformer which has a high-voltage diode built into it. Flyback transformers are readily available and cheap. The above circuit diagram is for a flyback transformer, where a high-voltage power source enter our reactor coil via points **A** and **B** (Fig.30):

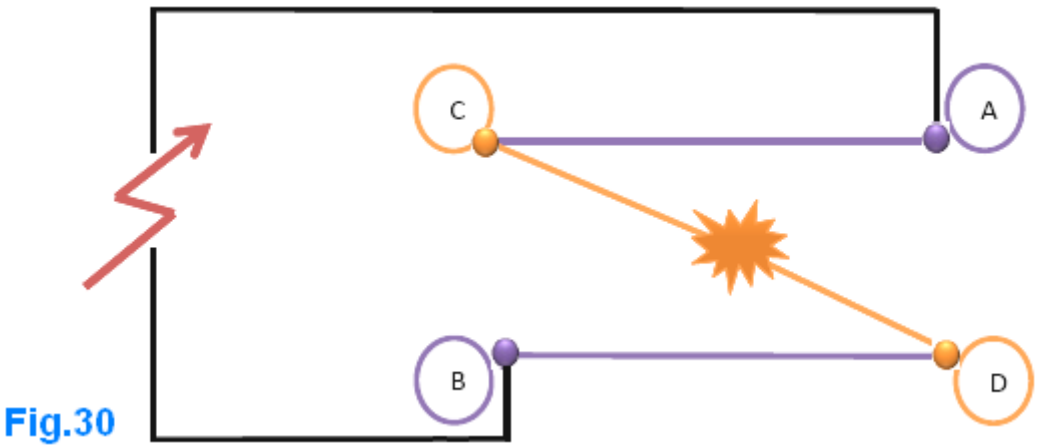

Fig.30

Initially, the capacitor charges up to the value needed by the spark-gap. When the voltage across the electrodes of the spark-gap reaches a high enough value, a spark occurs causing the resistance of the spark-gap to jump from a very high value to a very small value, short-circuiting any power coming from the power source until the natural resonance finishes. The capacitor transforms into a complete coil which has its capacitor built into it. The natural resonance of the TBC is assured when using this method, but it does have some disadvantages. The frequency produced by power supply/spark-gap combination has to be high enough to allow more power to be produced and this calls for a powerful power source. On the other hand, the voltage between the reactor coil **AB** will be **limited** by the distance between the electrodes of the spark-gap. This imposes the need for a large number of turns in the L2 coil.

The output current obtained is directly related to the available voltage between the capacitor plates which form the device between **A** and **B**. We need to bear in mind that the capacitor incorporated inside our extended TBC operates in a dynamic fashion where no displacement current exists.

The direct method of feeding the reactor coil with its own exact natural frequency is the best way to get the most available power, but this creates a real problem as it is not at all easy to find a high-voltage power supply adjustable over the range of frequencies which we want, especially frequencies above 200 KHz. We may require our extended TBC to work above 200 KHz, and for that, we may need impedance-matching capacitors (Fig.31).

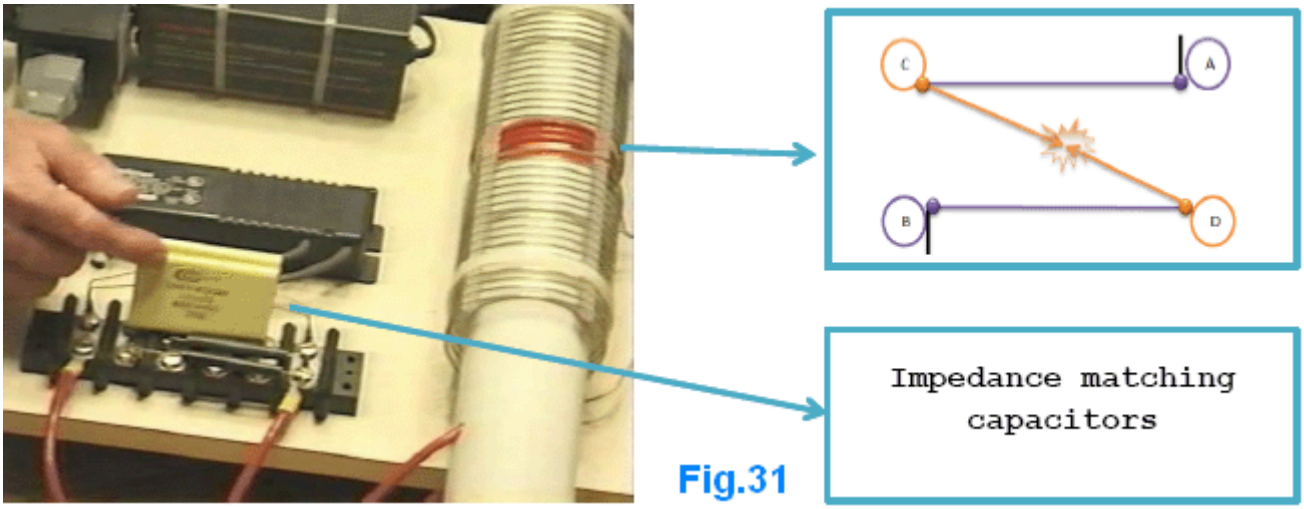

Fig.31

The two yellow capacitors seen above are for impedance matching since the working frequency in Don Smith's device was very high, requiring a neon-tube driver to supply it.

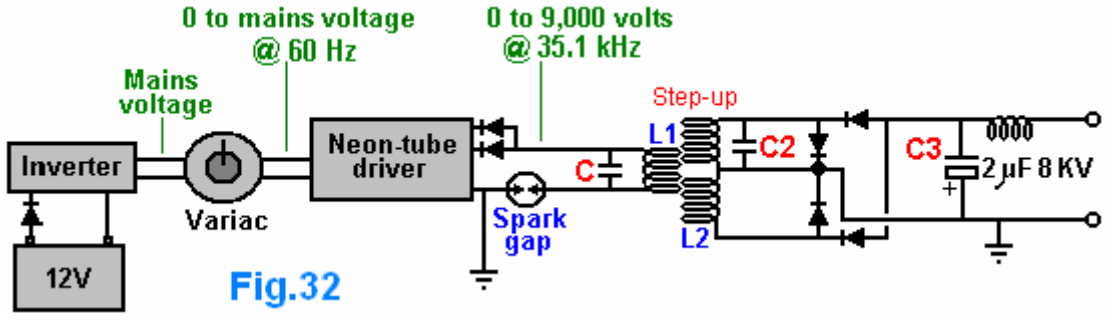

Fig.32

Impedance matching is simply the process of making one impedance look like another; in our situation it is necessary to match the load impedance to the source. For example, if the extended TBC resonates at 2.4 MHz, (this is the load), and the neon-tube driver operates at 35.1 KHz (this is the source) we need to add parallel capacitors to our extended TBC in order to make it resonate at 35.1 KHz.

In practice, you need to short-circuit the points **C** and **D** and measure the inductance of the E-TBC (L2 has to be in place for this measurement). After that, remove the short-circuit and measure the capacitance of the E-TBC. This gives you two values "C" and "L".

The resonance of the Extended –Tesla Bi-filar Coil is given by:

$F^2 = 1 / (\pi^2 \times LC)$ …… (a) The resonant frequency of an E-TBC is double

When you add a capacitor for impedance matching to the extended TBC, the resonance frequency will decrease with the following relationship

$F^2 = 1 / (4\pi^2 \times L(c+c^*))$ …… (b) where F is the frequency of the source

I believe that we can use the above equation to calculate the value of c* which needs to be added in order to achieve resonance. From equation (b) we could write

$$\frac{1}{F^2} = 4\pi^2 LC + 4\pi^2 LC^* \qquad \text{and so we have}$$

$$C^* = \frac{1}{4\pi^2 \quad L}\left(\frac{1}{F^2} - 4\pi^2 LC\right) \ldots\ldots\ldots\ldots\ldots\ldots \quad (c)$$

Using equation (c), we will be able to calculate the needed capacitor for impedance matching; the value obtained is in Farads, and that equation the frequency is in Hz and the inductance in Henries.

When you have the correct C* value and you power your device up (Fig.33), resonance will not be achieved instantly because the spark gap forms the full L/C parallel circuit only when it fires!!

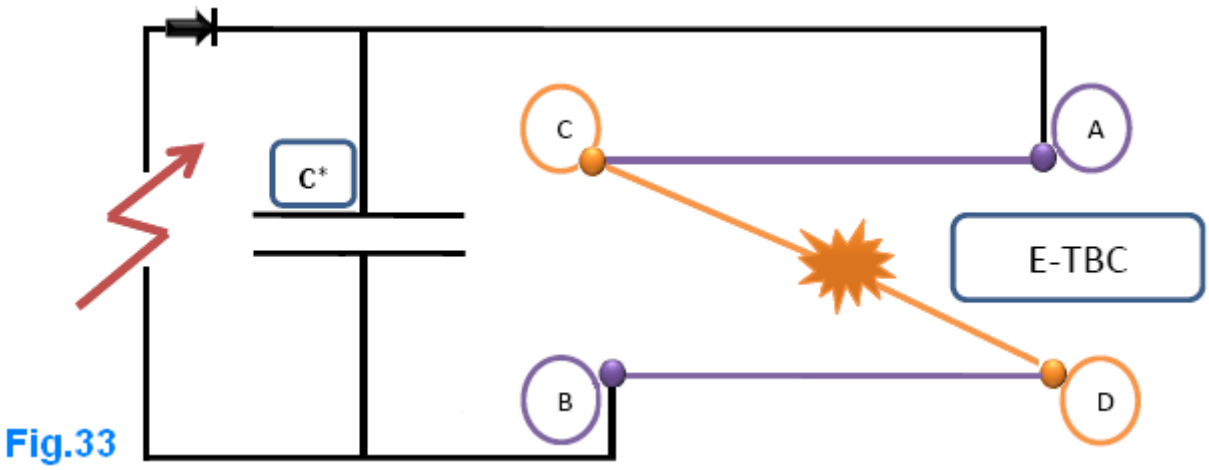

Fig.33

The first thing which happens is the charging of capacitor C*, after that the capacitor "C" of the extended TBC will be charged until it reaches the voltage needed to make the spark-gap fire. When that happens, the spark-gap has a very low resistance value, making the E-TBC fully formed. At this point, the incoming electric energy from the high-voltage power supply will find a load whose impedance matches it's resonant frequency. This, in turn, produces the maximum possible voltage across inductance L of the E-TBC. Further, the resulting electromagnetic field will increase cycle by cycle causing the device to resonate fully after a very short time.

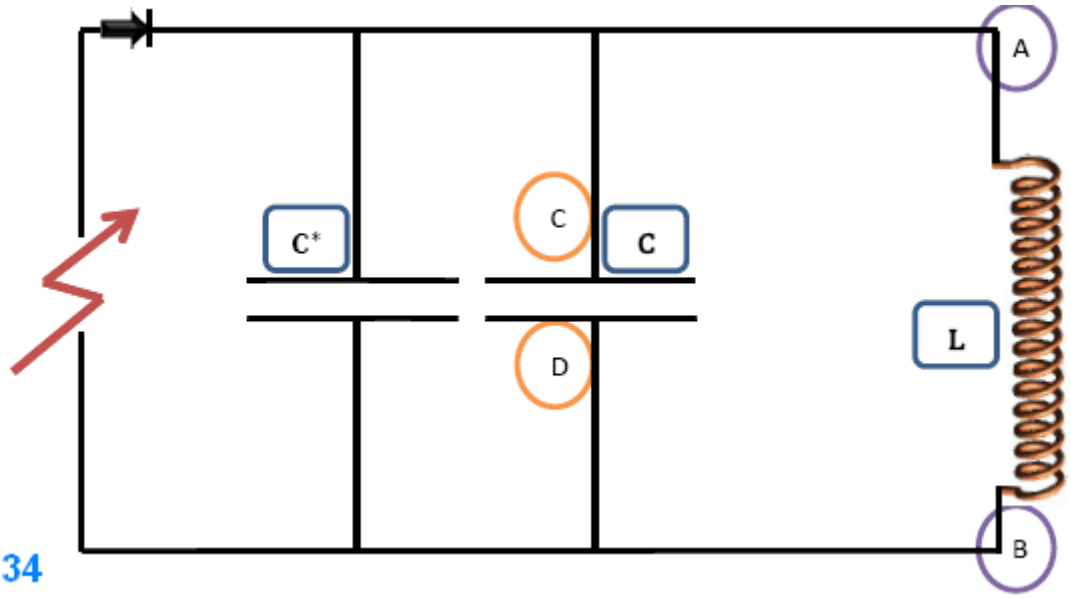

Fig.34

This is the equivalent circuit when the spark-gap fires

Constructing the extended TBC

The extended Tesla Bi-filar Coil is just a high-voltage capacitor which has a magnetic behaviour. So, it is both a capacitor and coil at the same time. Constructing this device is relatively simple. You need two lengths of aluminium foil, each 1.2 meters long (later I will explain the possibilities of modifying the characteristics of an extended TBC). Because it is a capacitor, you need 3 pieces of polyethylene sheet, each 1.3 meters long.

To construct a high voltage capacitor usually you need 2 pieces of polyethylene sheet but it's better to use 3 pieces since we are working with a high voltage (Fig.35), this will depend on your skills in constructing a high voltage capacitor.

You need welding rods to insure the electrical conductivity of the aluminium foils, Fig.36 indicates how to do that. Actually the best length and width of aluminium foil need some experimentation; you have to establish the positions of the magnetic and electrical points (Fig.37). **A** and **B** are the magnetic points (coil) while **C** and **D** are the electric points (capacitor).

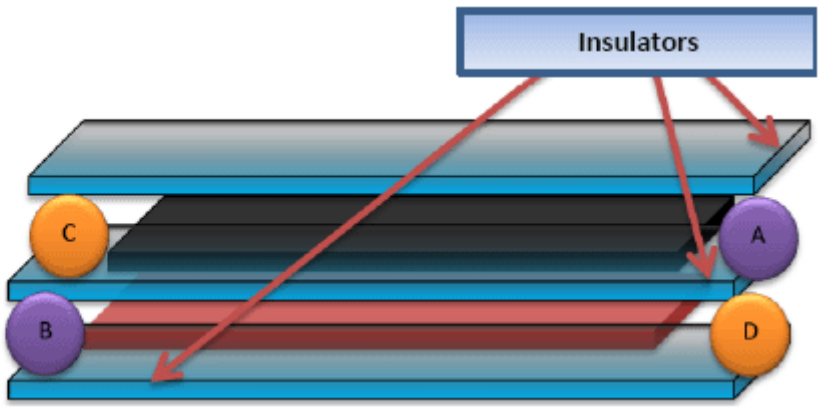

Fig.35

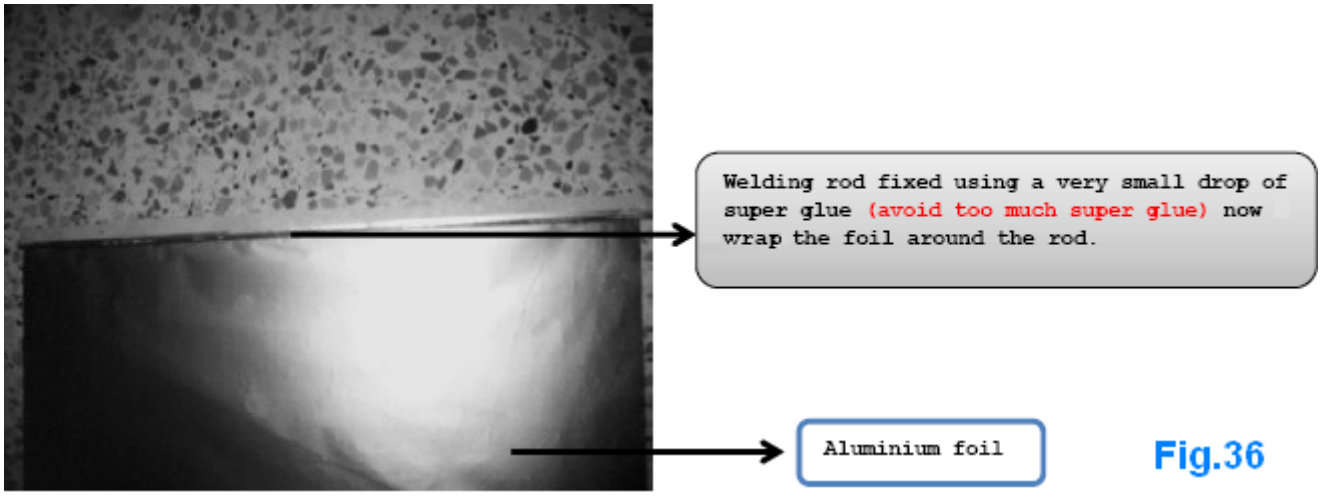

Fig.36

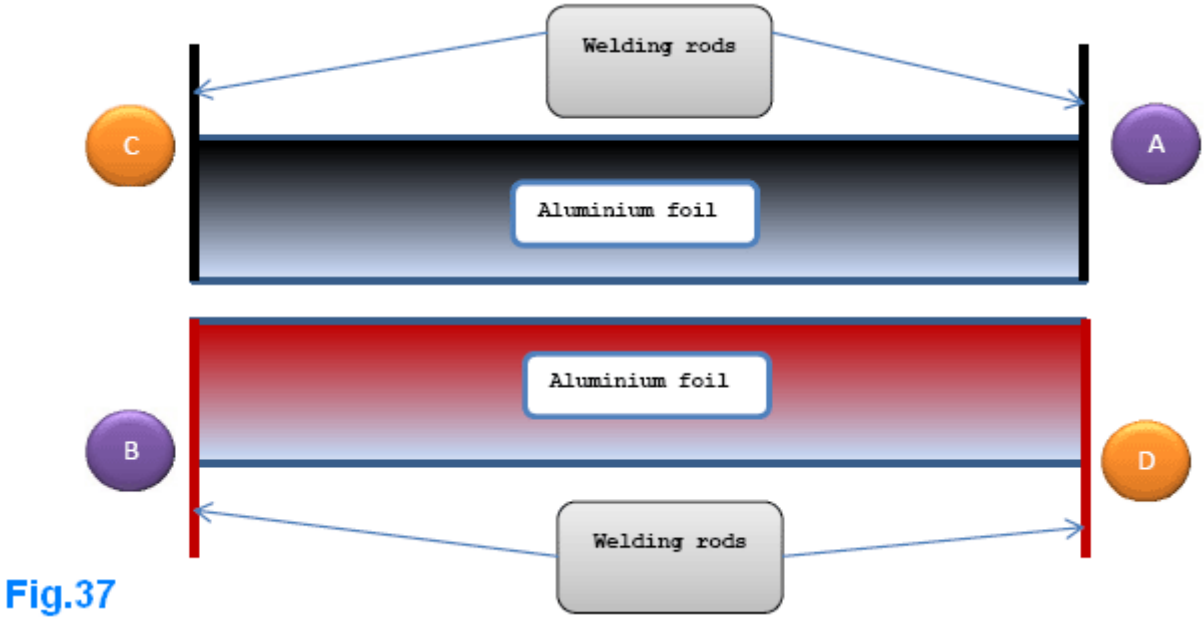

Fig.37

The E-TBC need a coil former for it to be wound on it (Figure 38)

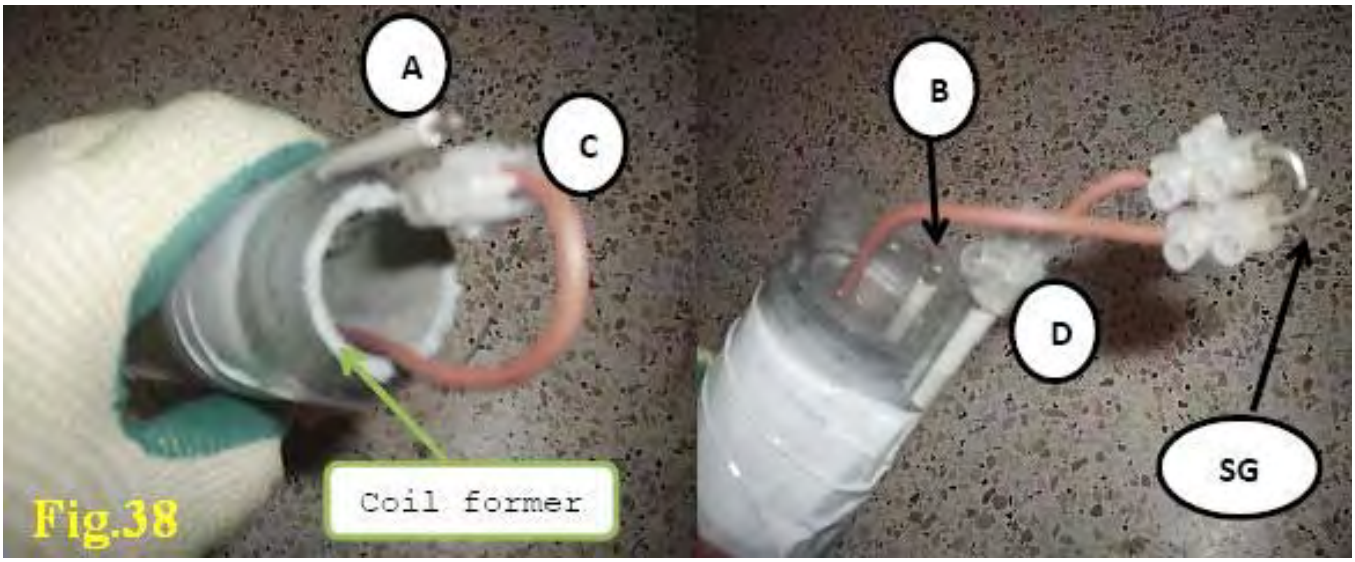

Fig.38

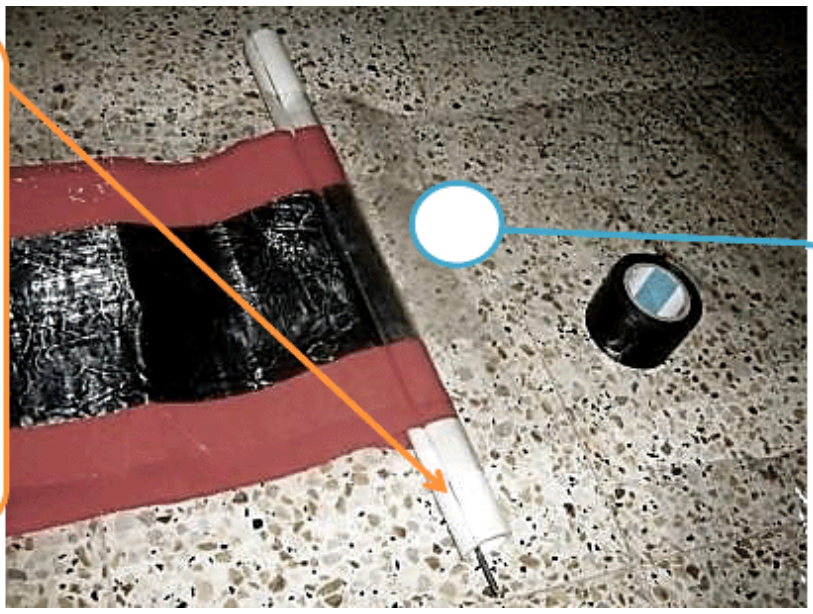
The following photo shows the dimensions used in the prototype (Fig.39)

The width of aluminum foil is 10 cm; the length of each capacitor plate is 120 cm

Fig.39

Internal arcing is a common problem with high-voltage capacitors (Fig.40)

*Notice the cutoff along the plastic tube; this will help in penetration the aluminum foils, the points **C** and **B** will be inside the tube but **A** and **D** will be outside, now firmly turn the plastic tube to form your **E-TBC.***



An internal arcing is a common problem in a high voltage capacitor; a good isolation is needed as well as a good insulator.

Fig.40

The best combination between the length and the width of an extended TBC has a major influence on the electric energy obtained at the L2 coil (the reactant coil). For example, the electric arcing experienced at the L2 coil using the E-TBC shown in Fig.41, was very weak, the length shown by the black arrow is very much greater than the width (orange arrow), this give a weak magnetic flux due to the small coil inductance, the coil inductance is very important because it will transform the replicated power into electromagnetic flux.

Fig.41

The reactant coil (L2):

The coil length is about 25cm as shown in Figure 42, the diameter is 6 cm, and the thickness of the wire is 1.18 mm (AWG #17 or swg 18) and the number of turns is about 200. Fig.43 shows some nice sparks from L2 coil:

The spark shown above is very strong but it can't burn through thin paper! This proves that the electric energy obtained is reactive, and so it can't do work as it is. Converting a high-voltage reactive electric power into Direct Current isn't easy to achieve. Working with a voltage over 10KV is really dangerous, in my device I had about 40KV of reactive power which to be converted.

Ideas:
To solve this problem let's think again about the energy equation of our extended TBC. The idea is to work with a step-down method rather than using the step-up technique.

The energy equation can be written like this: **Power in one second = CVF** x **VF**

CVF is the available current in one second since C is the capacitance value of the E-TBC, V is the voltage used, and F is the resonance frequency.

VF is the limit value when stepping up the voltage across the L2 coil, the gained electric power goes up proportional to the voltage value across L2, when achieving VF the total obtained power will be exactly: **$C V^2 F^2$** which is a very high power level. I know that this can be confusing, but this system has equal voltage and current. When stepping up the voltage, the current remains constant because it depends on the product **CVF**. We could increase the voltage by adding more turns to the L2 coil, when doing this the current is the same but the available electric energy will be given by: **Power in one second = CVF x V***

Where **V*** is the voltage across L2.

Using this new equation will help us a great deal in determining the voltage needed across the L2 coil in order to achieve the required electric power.

Example:
Imagine you have the following working conditions:

C = 10 nF
V = 30 KV
F = 100 KHz
You need a power of 30 KW, what L2 voltage is needed to achieve this power level?

Using the previous relation will give us:

$30{,}000 = CVF \times V^*$
$30{,}000 = 10 \times 10^{-9} \times 30 \times 10^3 \times 100 \times 10^3 \times V^*$
$30{,}000 = 30 \times V^* \Rightarrow V^* = 1{,}000$ volts

to obtain 30 KW you only need 1000 volts across the L2 coil. To achieve this power level you need direct resonance, feeding the E-TBC with a high-voltage only, without direct resonance, will not give this result since the voltage across the coil of the E-TBC will be limited by the electrode separation of the spark gap.

The voltage **V** across the E-TBC is very important here because the product CVF is the current obtained using the reactant coil (L2). The working frequency **F** is important too. Similar to an ordinary transformer, if we want to use the step-down method effectively, we have to think about using too many turns when winding the E-TBC. When designing an E-TBC, it is important to think about the length of the capacitor plates because the length between **B** and **D** will give the total value of the induced voltage between the capacitor plates which increase the electromagnetic flux (Figure 44).

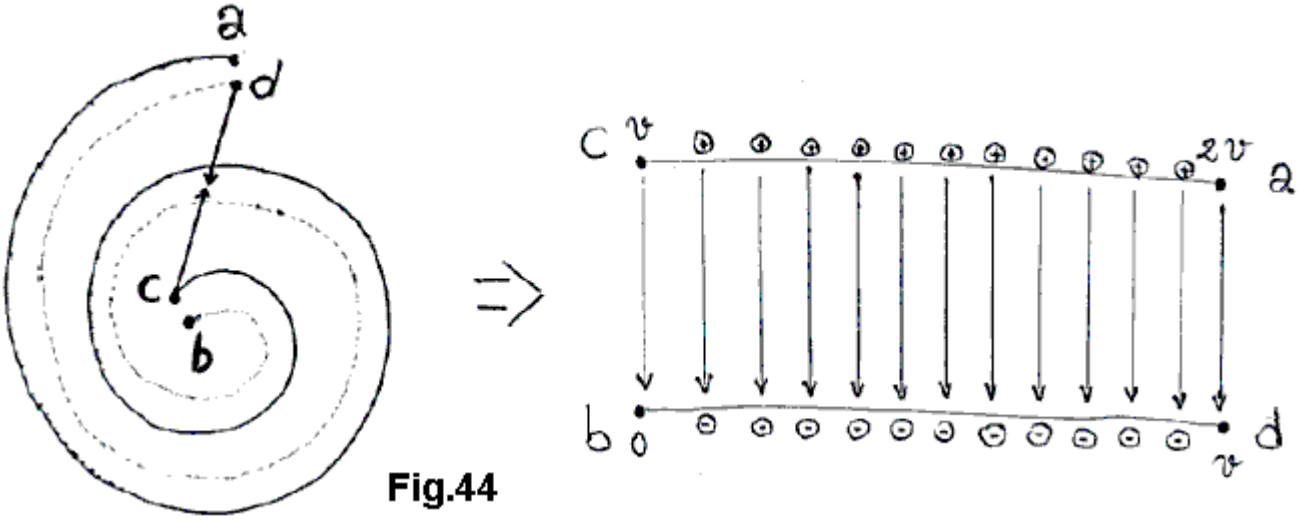


Fig.44

A simple diagram of the resonance energy device can be like the following drawing (Fig.45):

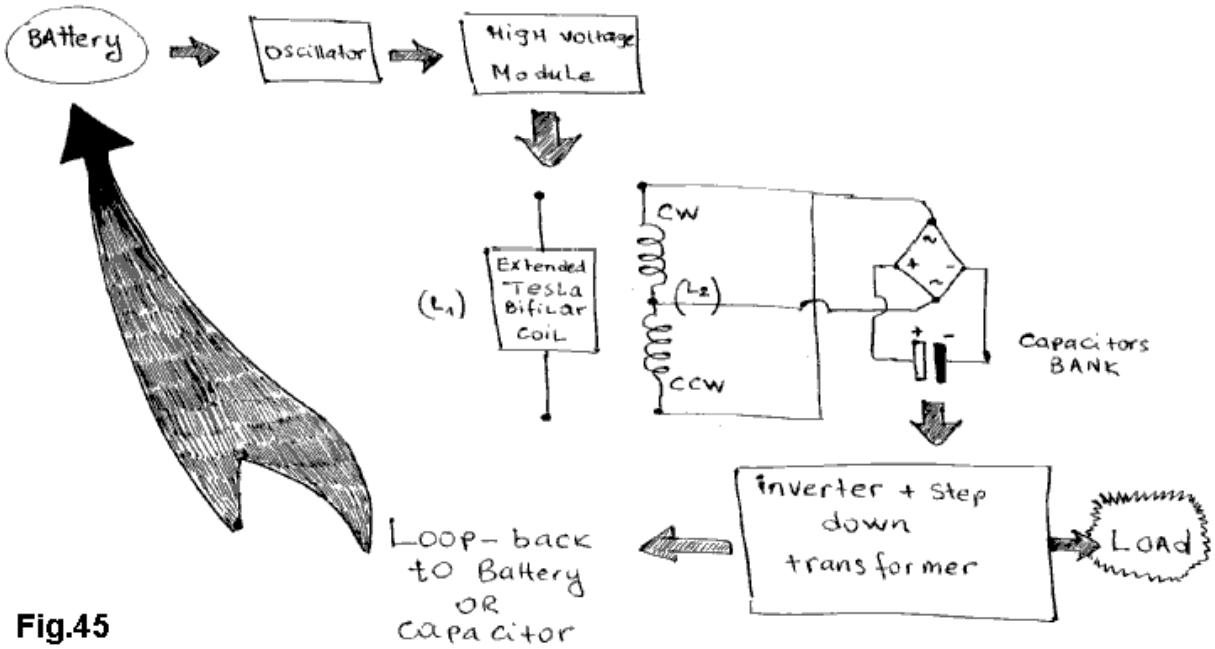

Fig.45

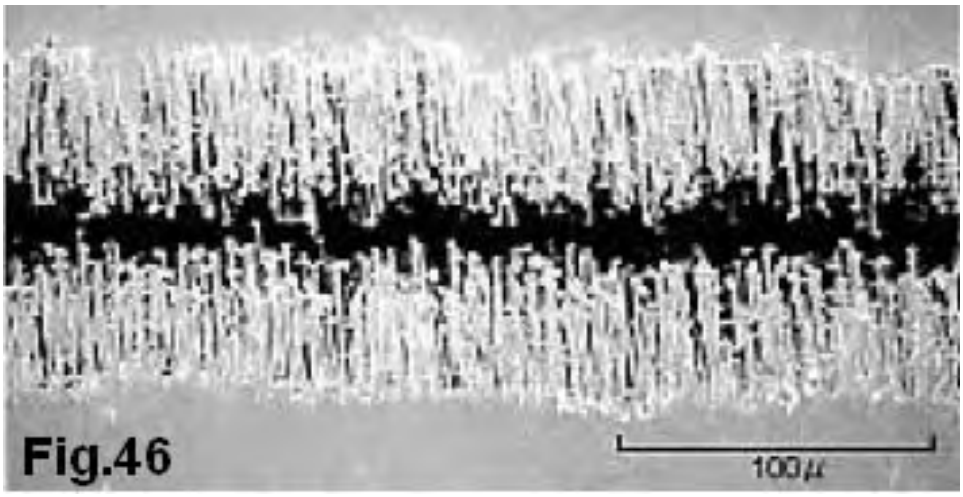
When converting the reactive electric power from the L2 coil to Direct Current and stepping down the energy obtained to the mains voltage and frequency (for example, 220V, 50Hz), the current will be boosted yet again.

Some applications may not need an inverter. An electric heater can be fed directly from the capacitors banks but we have to prevent the Alternating Current coming from L2 to enter the heater by using another high inductance coil.

Another idea about increasing the capacitive side of the extended TBC is to use etched aluminium foil to increase the surface area. The foil can be treated chemically using high-voltage. The result is shown in Fig.46:



Maybe this is the technique used by Donald Smith to avoid the need for an earth connection. I have already mentioned about using negative energy to avoid the earth connection requirement in the Resonance Energy device but I can't guarantee that this is the method used by Donald Smith.

Any questions, or suggestions are welcome via my e-mail: hopehope3012 (at) gmail (dot) com

Chinese Developer Ming Cao.
a free-energy developer in mainland China, comments on the designs of Don Smith, and Tariel Kapanadze. He says:

None of these things originate from me, they come from Tesla and God.

1. The most important issue, is resonance. Don Smith said that we should make the wire length of the primary coil to be one quarter of the wire length of the secondary coil in order that they will resonate together. My experiments show that this is not true. In a Tesla Coil, the primary coil and it's capacitor form a tank circuit which is an L/C circuit, which oscillate at it's own resonant frequency, and when it does that, it generates a longitudinal wave at that exact frequency. The frequency of this longitudinal wave is determined by the inductance of the primary coil combined with the capacitance of it's tank circuit capacitor, and not the wire length of the primary coil alone. The secondary coil with it's sphere at the top, together form an antenna, which transmits this longitudinal wave. The secondary coil and it's top sphere together form a quarter-wave resonant antenna for this longitudinal wave. They do not form an L/C circuit and that is why very few people have managed to replicate Don Smith's devices.

2. In the devices of Don Smith and Tariel Kapanadze, there is no sphere. We see a single coil as the secondary. This is no longer a quarter-wave antenna, but a half-wave antenna. The highest voltage shows up at the very centre of this coil, and zero voltage shows up at the two ends of the coil winding. These are where the energising coil and the pick up coil should be positioned.

3. The longitudinal wave which passes through the secondary coil is not a current at all, it is a signal running through it, so if we let the secondary to charge a capacitor, we will get nowhere. All we will get is hot electricity caused by the loose induction coupling. The arc at the top of a typical Tesla coil is lightning voltage, and no capacitor on earth can handle that voltage, so even a very high voltage capacitor will be over stressed and the arc will shock through it.

4. The speed of this wave is well defined. It depends on the total capacitance of the coil, and the sphere if there is one. In a typical Tesla coil, the bigger the sphere, the bigger the capacitance, and the lower the resonant frequency of the secondary coil. People are trying to explain it by L/C circuit theory, but this is not necessarily true. Increased capacitance will slow the wave down. If there is no sphere, as in the devices of Don Smith and Tariel Kapanadze, the total capacitance is quite small, and so, the speed of the wave should approach the value (π/2) x C, where C is the speed of light. This speed of the longitudinal wave is claimed by Tesla himself. I kind of verified this by experiment. I said "kind of", because in my experiment, I got a speed of (π/2) x C x (8/9). The wave is slowed down by the copper losses and the capacitance of the coil, mostly the capacitance, but it's definitely faster than the speed of light.

5. So, to tune the secondary, we should not use the speed of light at all, Don was playing a game with us here. Take Don's device as an example. If we position the primary coil at the centre of the secondary coil, then that middle point of the secondary should either be grounded or connected to a large metal sphere, and each half of the secondary coil should act as a half-wave antenna. Also, the pick-up coils should be located at the two far end terminals. The speed of the longitudinal wave along the secondary coil is unpredictable and so we can only predict a general speed range, we cannot tell whether it is already resonating by performing calculations. Like Nick Giannopoulo's arrangement (see below) and Tesla's patent diagram, there are two quarter wave coils, whose inner terminals are connected together and open to the air. Here 'open to the air' means that it is different from the other turns of the coil. The longitudinal wave is climbing the turns rather than passing along the wire. But at the end of each quarter wave coil, there is no other turn to climb any more, only a long wire for it to travel along. This straight long wire is open to the air and provides a capacitance for the whole device, and this additional capacitance will slow down the longitudinal wave which is passing through it, so that the resonant frequency for the combination of these two secondary coils will be lower. But if we eliminate the straight wire, and make it a single half-wave secondary coil, the longitudinal wave can keep climbing the turns, and there's no additional capacitance, so that the speed of the longitudinal wave will be very close to (π/2) x C, and the resonant frequency will be higher. We can use the same wire length and same diameter coil former to build different devices, which will work at completely different frequencies. So the resonant frequency is unpredictable and we need to find the exact frequency by equipment measurement, or it won't work. The only correct way of tuning the secondary is shown by Eric Dollard in his video of the 1980s, entitled "Eric Dollard Transverse and Longitudinal Wave" which at the present time can be found on YouTube at http://www.youtube.com/watch?v=6BnCUBKgnnc.

6. A pick-up coil is always necessary, and it should be positioned near the zero node of a standing wave. This is one of the only two ways of harness the longitudinal wave. This method is the dynamic way, the other way is the static method, which I believe was used by Ed Gray.

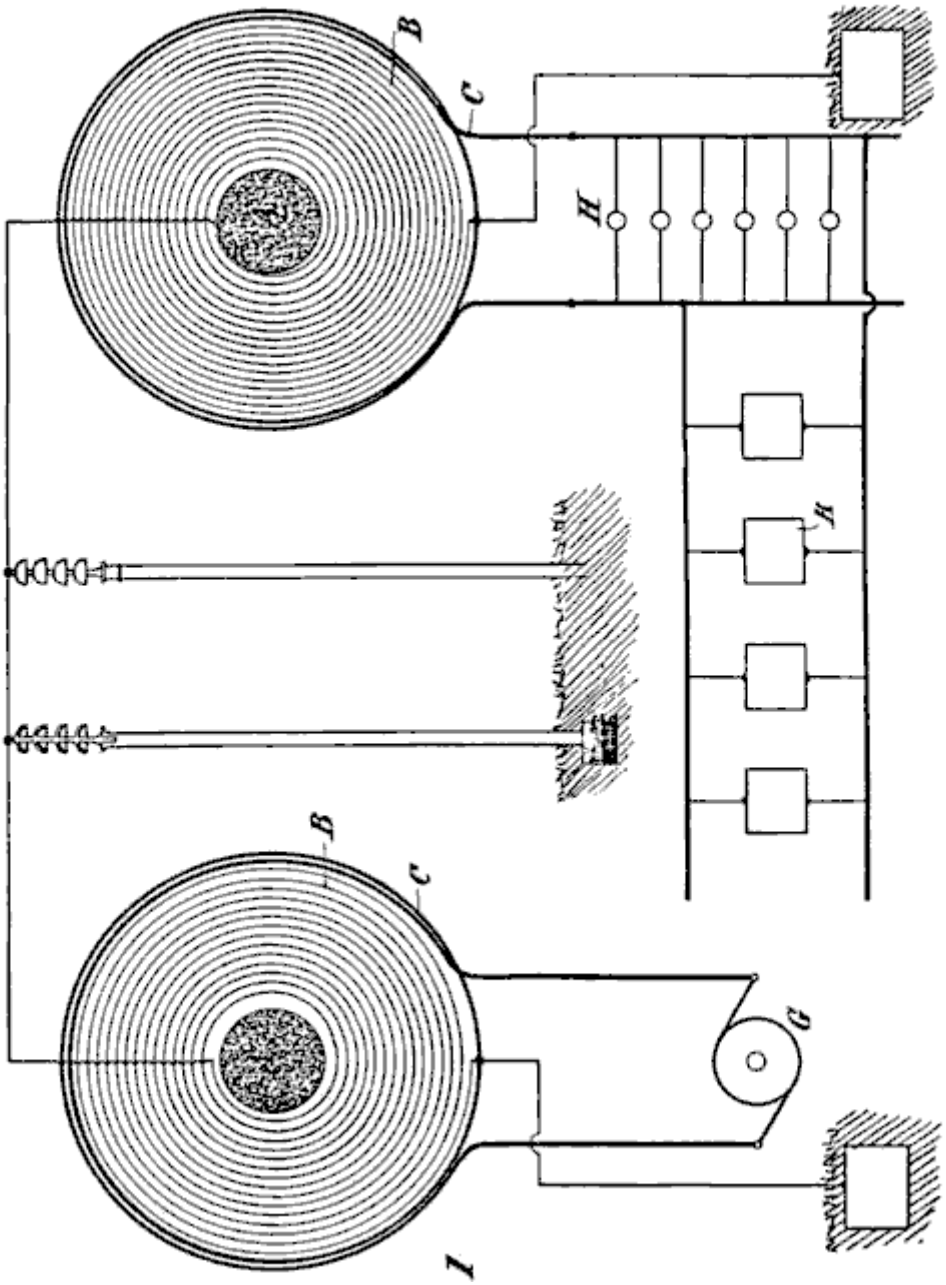
7. In Dr. Peter Lindemann's book and video, he says that Tesla is using unidirectional current. I have to disagree with this. When we charge a capacitor and discharge it through a spark gap, the discharge current "bounces" between the two plates of the capacitor, until the energy is all lost at the spark gap. This process repeats itself endlessly in a typical Tesla Coil. We can see this primary waveform with an oscilloscope and it is alternating current. Thousands of Tesla Coils work in this way and generate lightning. I am confident that this is how it operates.

8. It is not like Don Smith said, that doubling the voltage quadruples the output. It does look like that, but it is actually the current flowing through the primary doing the job. Of course we increase the current by increasing the breakdown voltage of the spark gap by widening the gap. But fundamentally, it is the current which is doing the job. Ed Gray's tube uses a short straight copper bar as the energising 'coil', but it's not a coil, it has little inductance to generate voltage, it only has high current passing through it to energise the longitudinal wave. Of course I haven't actually seen this process, it is a conclusion which is not fully based on experiment.

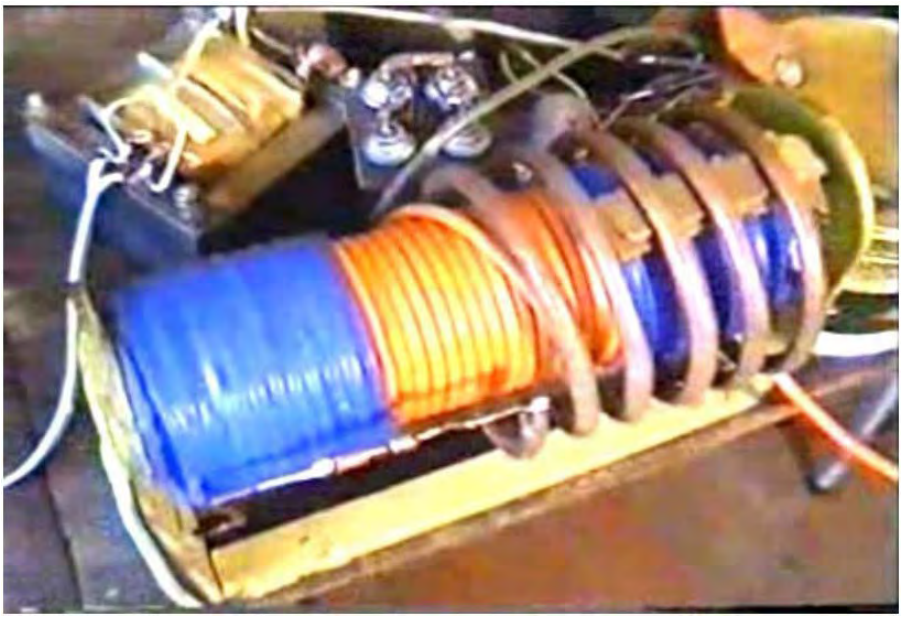
9. The larger the number of turns in the pick-up coil, the higher the output voltage will be. I still cannot understand how the pick-up process works, but it does pick up more energy.

I get all these by low voltage from a signal generator, as I haven't finished building a high voltage device yet, although I'm already working on it. But I think it's safe for me to believe that these results are solid and good enough to share.

Here is a image from Tesla's patent 593,138 Electrical Transformer.



We can see it's exactly the same as Nick Giannopoulos' setup, except that Tesla is using a generator in this diagram, I believe for simplicity. As long as the generator is generating the exact frequency of current, it will work fine. The secondary at the energising side is a quarter-wave coil, and at the pick-up side is another quarter-wave coil. The highest voltage is at the far end of these two secondary coils and their connecting wire, and zero voltage is at the very outside turn of each of the coils. Now if we change the spiral form coil to helical, it becomes Nick's set-up. And let's take this further, we can shorten the connecting wire until the two solenoid secondary coils actually become one big coil, then, when combined it is a half-wave coil, and the highest voltage is at the middle point of it. Now it becomes Don Smith's and Tariel Kapanadze's device, like this:



Because the energy is also coming back from the energising side, Kapanadze adds another pick-up coil right underneath the primary energising coil. This arrangement, I think, is very hard to replicate, because it is so very hard to tune, for several reasons:

1. The Secondary wire length is rather short, and the wave speed is very very close to (π/2) x C, so the frequency should be very high, at least 5-7MHz I would guess, or perhaps even higher.

2. The pick-up coil and the energising primary coil is too close to the centre point of the half wave secondary coil. Because the centre point is the point of highest voltage, if the input is a little high, there would be arc shock between the secondary to the energising coil and the pick-up coil, at lightning voltage levels, and so even the best isolation is useless. Also, the centre point is very very sensitive, any conductor close to it will add to the total capacitance of the coil and of course that will alter the half-wave resonant frequency. This adds more difficulty to the tuning adjustment. Besides, after all, people don't even know it's a half-wave coil if he doesn't tell us.

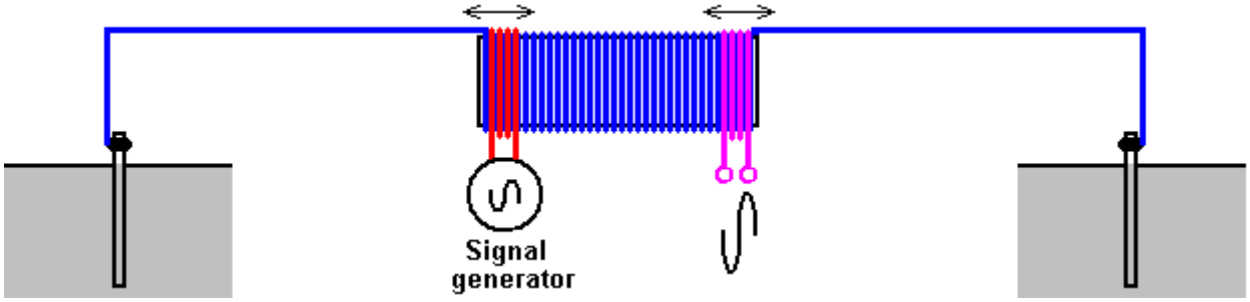
3. The coupling coefficient **K** is a little high, this will increase the hot transformer effect by inductive coupling, and that will not help at all.

Don Smith did indeed say something useful. He said that we can make the secondary coil a fixed size, and then slide the primary coil inside it. Well based on experimental results, this sliding process is altering the actual effective length of the secondary coil. In general, we should assess coil size by counting the turns from the turn right underneath the primary energising coil, to the turn right underneath the pick-up coil, this section is the actual secondary, and this section should be a half-wave resonate coil, the rest of the coil just sits there doing nothing.

But it's not that simple, the terminals of the secondary coil should connect to the earth or to a large sphere, or a typical Tesla Coil secondary with the same quarter-wave resonant frequency. Otherwise the signal will bounce backwards and forwards in the coil producing a mess, or generating an arc, and this is bad for performance, and this is why a solid ground connection is desirable. And this is the true meaning when Don says "slide the primary coil to do the fine tuning".

So, returning to the Kapanadze device, the energising coil covers a large area of the secondary coil, making the effective length of the secondary coil very much shorter, again, boosting the working frequency of the device even higher. For such a device, it is impossible to tune it without a 20Mhz signal generator, an oscilloscope and complete understanding of how a longitudinal wave behaves. For a start, I don't even know where to connect the oscilloscope probe or which terminal should connect to the ground, I'm so lucky to be able to watch Eric Dollard's old video, and I recommend everybody to watch that video, watch it over and over again, also many other educational videos from Eric. A lot of fundamental stuff about how a longitudinal wave behaves are explained there, it's like a treasure map covered in dust in a quiet corner of an open library.

Ming's video http://www.youtube.com/watch?v=1p41KLfOM2E&feature=youtu.be demonstrates what he is saying here. For the video he uses an input coil, a monitoring coil and a secondary coil, each end of which is earthed using separate earth connections:



Ming also remarks:

For the set-up in the video, the secondary coil is wound using 1mm diameter enamelled copper wire, 365 turns around a 160mm diameter PVC pipe. The total coil length is 39.5cm. The total wire length of the secondary is approximately 182m. The white material is several layers of insulating glue to prevent arcing between adjacent turns when working with high voltage. The primary coil and the pick-up coil are wound with audio cable which is more than 4 square millimetres in cross section. The primary coil has 2 strands, 2 turns. The pick-up coil has 4 strands and only one turn. I use this thick wire, because I am going to use these coils for my high voltage project.

For a low voltage experiment like shown in the video, it would be quite adequate to use ordinary copper wire of 1 square millimetre cross section (swg 18 or AWG 17). If the secondary wire length is reduced, then the resonant frequency will be higher, but the principle is the same.

If only low voltage is going to be used - perhaps just to study the nature of longitudinal waves, then the secondary coil can be made using very thin wire of 0.3 to 0.4mm diameter (swg 30 to swg 27) enamelled copper wire, which will cost much less. I made my coils with thick wire because I intend to continue using high voltages.

It's been a long time, but I've got some more understanding about harnessing radiant energy. I have made two additional videos: http://www.youtube.com/watch?v=WJUfj53geBo and http://www.youtube.com/watch?v=BdBjKVyKBZA In these two videos, I explain the method of converting Tesla's 'cold' electricity to normal 'hot' electricity by storing it in a capacitor. I strongly believe that, the method shown in the second video is exactly what Don is doing with his famous device, which has no pick-up coil, just a two-part secondary.

In the first video, I replace the pick-up coil with an uncoated sheet of copper, to show people that, this is not a transformer, and so, is not based on electromagnetic induction. The pick-up coil is fundamentally, a piece of metal which can be electrified by a longitudinal wave. I can remove the diode and the capacitor, and just let the copper sheet discharge to ground through a spark gap and two ordinary 200-watt incandescent light bulbs connected in series, the light bulbs are pretty bright although not fully lit, but pretty bright in spite of this being a non-resonant situation. They look like this:

The copper sheet is electrified, and it's charge is flowing to ground, and it is this very process which forms the current. So if we consider it as a transformer, and consider the pick-up coil as a inductor, and add a load to this "inductor" to form a closed loop, then we are going in the wrong direction.

Then I re-read about Nick Giannopoulos' device, and I noticed that he said that the light coming from his bulb is blue and white. Following his circuit diagram, I believe that it is like this:

I get this kind of light when I attach the light bulb directly to the sheet copper without an earth connection or any other additional wire. Here at this stage, we have no 'hot' electricity. The blue-white light is caused by the high voltage of the metal, to which the bulb is attached. The high voltage is not caused by induction, it is purely static charge on the metal surface, caused by longitudinal wave electrification. If we use Tesla's specially made bulbs as shown in his lectures, we have his single-wire lighting system, and we will have a very bright light suitable for general-purpose lighting instead of this kind of blue-white light. Generally speaking, my bare copper sheet is the equivalent of Nick's pick-up coil plus his step-down transformer, which, of course, is not a transformer at all.

Note: As will be seen in the videos, Ming uses two separate earth connections. One is the earthing wire of his mains electricity and the other is a connection to his cold water pipes.

Subsequently, a forum post by a Mexican man says:

Hello ‘Salty Citrus’,

I love your video!!!! I can really appreciate the amount of work you and your group have spent to develop and perfect the Don Smith / Tesla free-energy device. Thank you for pursuing such a noble cause.

I am intrigued by your switching network using the CREE CMF20120. How did you wire the MOSFET's?
You used a UCC3825A Pulse-Width Modulator to clock the signal --> MOSFETS --> Gate Drive Transformers (x3) --> push-pull transistors --> CMF20120? Did you run the CMF20120 in series? Sorry about so many questions, but I am totally impressed by your ingenuity, and completely agree that your solid-state solution has undoubted benefits over Tesla's conventional spark gap.

I would be honoured if you could take the time to answer my questions. I would love to replicate your circuits.

I wish you the best of luck with your endeavours.

Sincerely,

‘Lost_bro’ (half a world away)

Re: ‘Lost_bro’

Thanks for the compliment. The success does credit to my team. Thanks to my team. Yes, the CMF20120 run in series in this solution. The voltage balancing between each MOSFET is critical as is the balancing between RC and DC voltage created by R.

Welcome to our forum for the exchange of information. China is an hospitable country. If you have any information or ideas, please don’t hesitate to share them with us. ‘Half a world away’ is not a great distance.

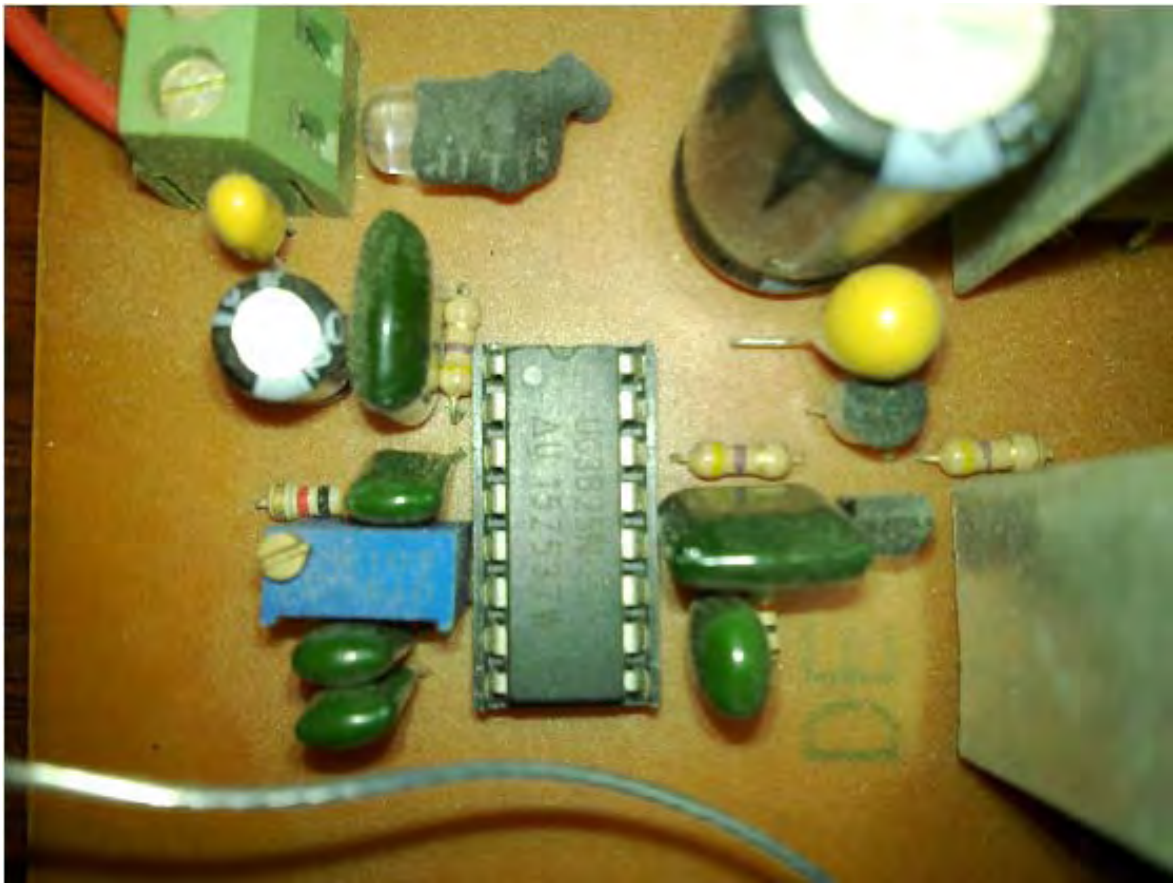
All the best,

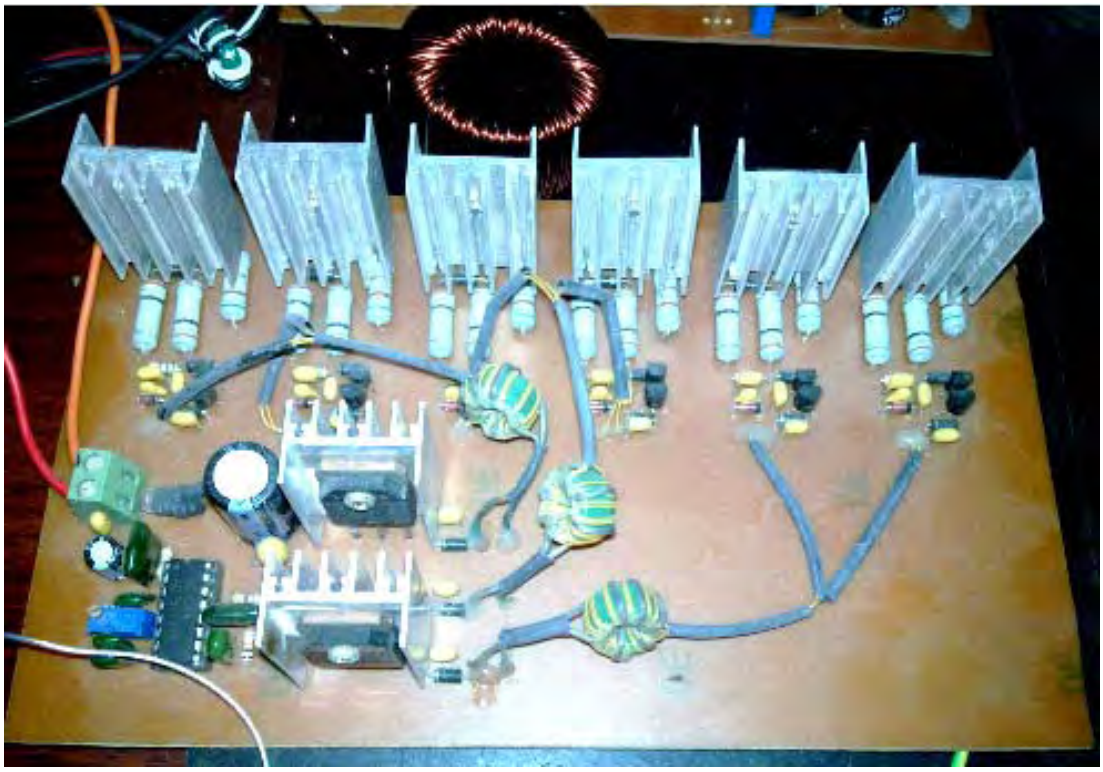
Sincerely

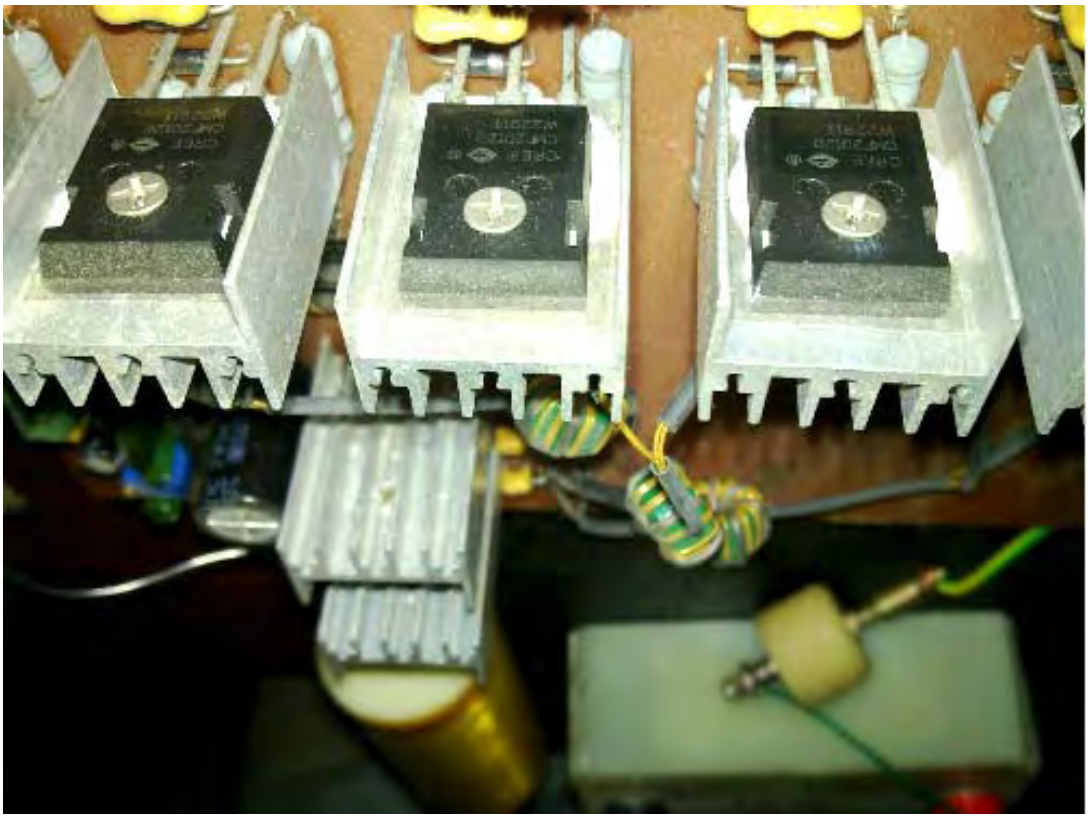
‘Salty Citrus’

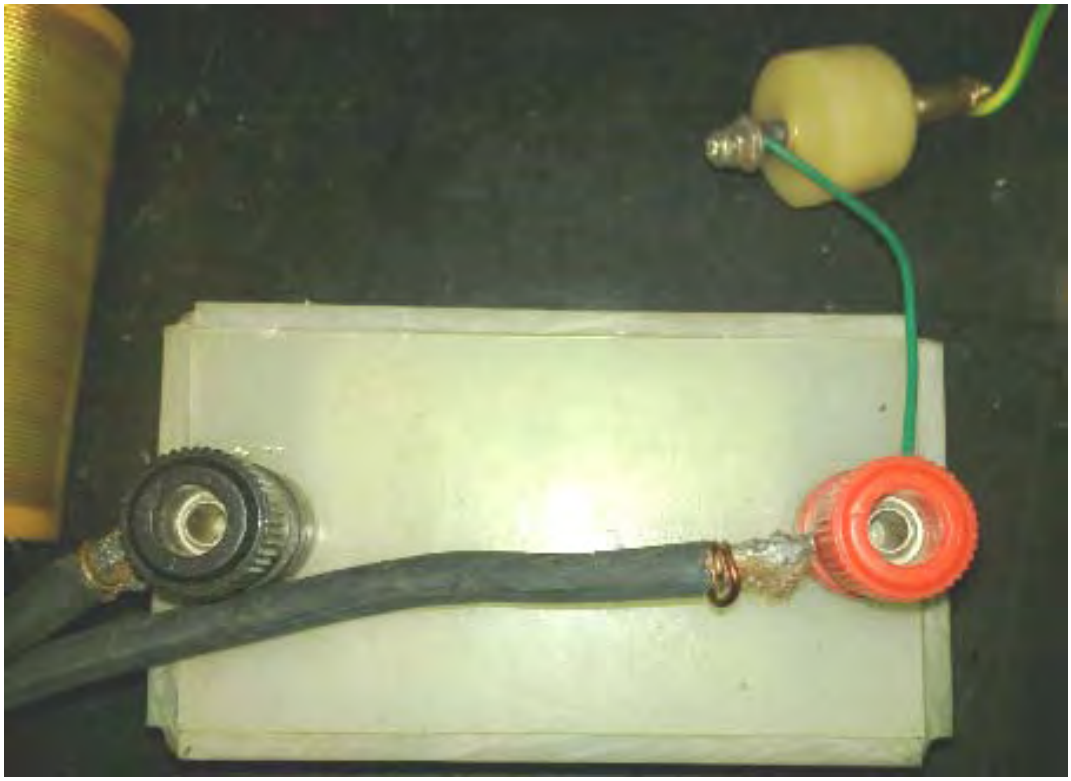
An earlier entry on the Chinese forum translates as:

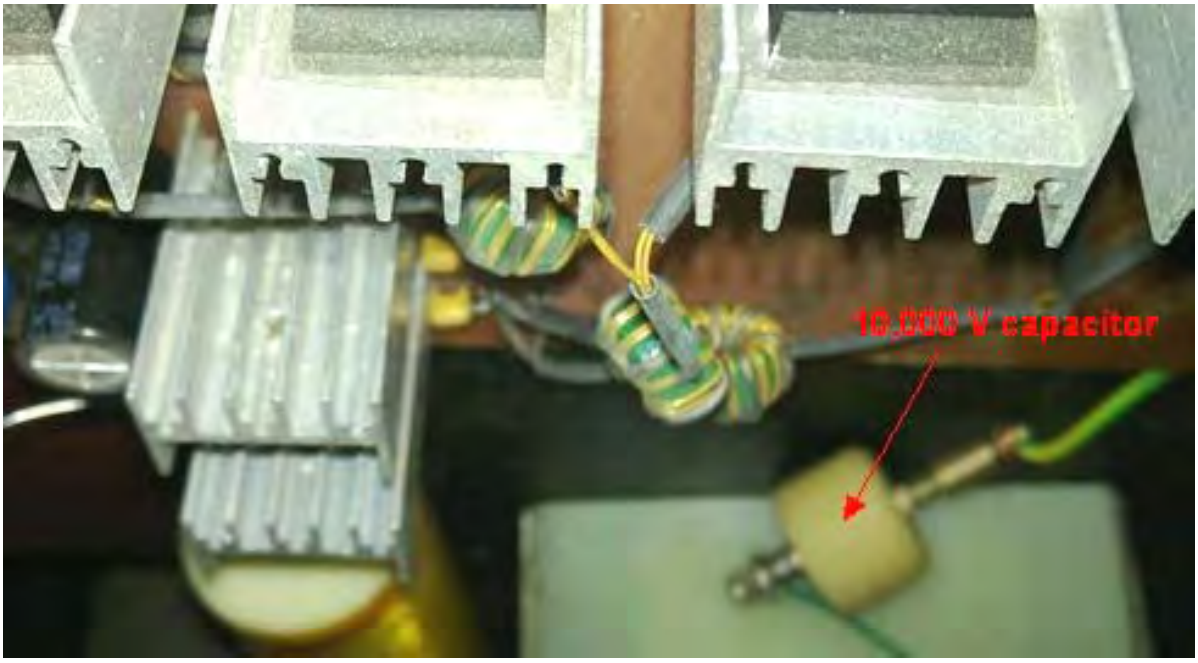
Here is an earlier build. It is simple and has no step-down section and so cannot be self-powered:











10,000 V capacitor

Each bulb is 100 watts. The first board has a 12-volt input and an adjustable output which can be varied from 500V to 1600V (any higher voltage would damage the four 450V 20 microfarad capacitors). In the video, the variable resistor is used to set the voltage level of the FBT after boost as the voltage step-up circuit can go up as high as 3,000 volts.

The L2 coil is wound in a single direction and has just one tap at the centre. The idea is from Tesla's Colorado Springs Notes, in which Tesla disclosed the best method for a resonant driver. The frequency used in this circuit is about 230 kHz.

Question: There is nothing to do with quarter-wavelength, but is there anything with the length of the L1 and L2 coils on quarter-wavelength?
Answer: I think that the phase is more important.

Question: Do you need a Phase-Locked Loop circuit with a certain phase difference?
Answer: Basically, I use a fixed frequency, I have tried a Phase-Locked Loop and the effect is the same.

Question: Do you use direct drive with the spark gap only being used to limit voltage?
Answer: You can use a vacuum tube to drive it.

Question: If you drive it directly, then the loading will be very big and the current will increase, whereas if you use a spark gap, then the spark will become smaller and the current will be steady.
Answer: If the load affects the input, then you cannot drive it even with a spark gap. If you trigger with a spark gap, then the load will not increase the input. The spark gap is just a switch.

Question: Is there any direct Lenz relationship between the load and the primary?
Answer: Once the phase has been adjusted, the primary has no adverse effect on the secondary.

Commenting on his circuitry, 'Salty Citrus' states:

The diode symbols with a tick indicate a Zener diode (or bidirectional TVS-Transient Voltage Suppressor or "varistor"). For example, in this circuit, they are used to suppress the Grid voltage of the MOSFET, to maintain the gate voltage within the range of +20V to -20V. The above circuit is just a description of the structure of the MOS series method. Specific components will be needed for your own requirements considering the MOSFETs being used in your construction.

The voltage E0 can be adjusted. The source can be made using a TL494 IC operating at 12V, or alternatively, an adjustable, voltage-stabilised inverter can be used. The voltage setting depends on the numbers of MOSFETs which are being used in series and the parameters of Grid voltage and the turns ratio of the isolation transformer. The circuit is arranged so that each MOSFET has its own separate isolation transformer, and all of the primary windings of those transformers are connected in series to form a single current path. The number of turns in the primary of each isolation transformer is exactly the same. To drive an IGBT(or MOSFET), VT6 provides a high-frequency pulse current to drive the Gates of the MOSFETs, so as to achieve consistent switching.

In my circuit, the frequency used is 220 kHz, for this frequency, I use six MOSFETs type CMF2012 (1200V, 37A, Resistance Drain-to-Source of just 80 milliohms). This MOSFET from CREE has excellent performance, but you have to design the drive circuit carefully, 2V to 22V for the Gate voltage will be best. I particularly stress that it is very important that MOSFETs operated in series, require voltage balancing and an accurate drive. Especially important is having synchronized drive signals and the rise and fall time of the drive signal should be as short as possible, so that the switching time difference between the MOSFETs will be short, and that improves the high frequency operation.

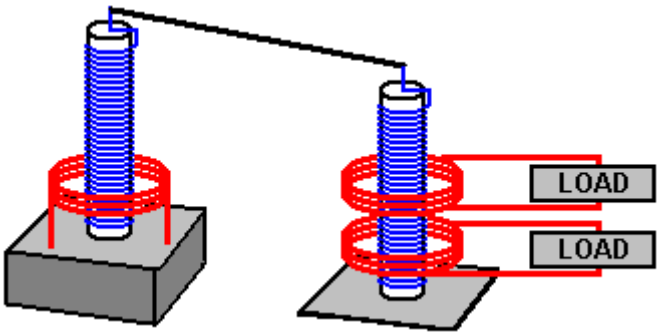
Another Russian Development

At http://www.youtube.com/watch?v=sRLFfs9I18Q there is a video which shows a self-powered motionless generator with an output of 105 watts:

Thanks are due to Wesley for his translation of the Russian soundtrack. No circuit details are available that this time, but the video has “Part 1” in the title and so further details may be provided at a later time.

Tesla Coils Back-to-Back

I have been told of one man who used his common sense and produced an impressive result. He used a Tesla Coil as the driving force, and then used a second Tesla Coil back-to-back with the first one, to step the high voltage back down again. Doing that, he was able to light a series of powerful light bulbs from the “L1” output coils. He also confirmed that doubling the voltage, quadrupled the power output, verifying what Don said. He also found that adding additional coils with bulbs to the output Tesla Coil, did not increase the input power at all, did not cause any of the existing light bulbs to shine any less brightly, and yet lit the additional bulbs. That would appear to be confirmation of Don’s statement that any number of magnetic copies of the original oscillating magnetic field of the first Tesla Coil, can provide a full-power electrical output without requiring any additional input power. I’m no expert, but my understanding of the arrangement is:



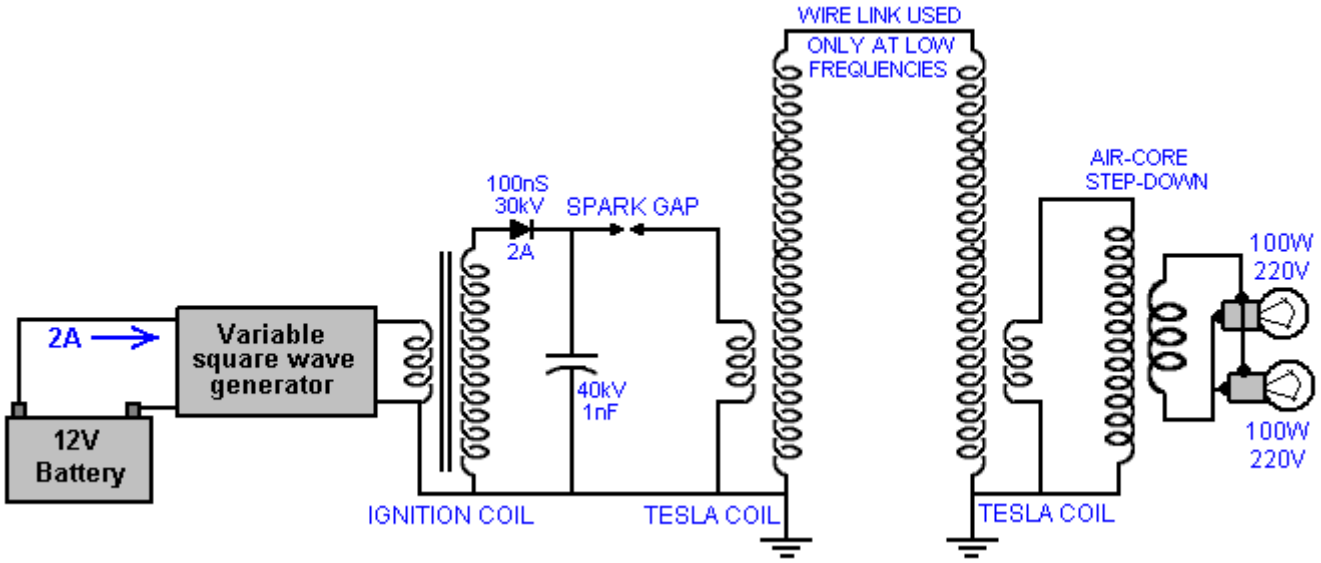
As the large diameter coil is exactly one quarter the length of the smaller diameter coil, there is an automatic resonance of both when the applied frequency is just right. As the first narrow coil is identical to the second narrow coil, they are also automatically resonant together. Again, as the large coils which feed the loads are exactly one quarter the wire length of the narrow coils, they also resonate at the common frequency and at that frequency, the input power is at its minimum while the output power is at its maximum. The spike at the top of each of the narrow coils is connected with a wire to channel the generated power from the first Tesla Coil to the second one.

This arrangement may seem too simple to be effective, but with Tesla technology "too simple" just does not apply. This can be seen clearly from the work of **Nikanor "Nick" Giannopoulos**. Before he ever learned anything about electronics, Nick read and understood Nikola Tesla's "Colorado Spring Notes" (http://www.free-energy-info.tuks.nl/TeslaCSN.pdf 60Mb) and this helped with his present level of understanding. Interestingly, and perhaps not surprisingly, Nick had difficulty with conventional electronics after becoming familiar with Tesla's technology.

Nick used a square wave signal generator adjustable from 50 kHz downwards and with a fully adjustable Mark/Space ratio. This was used to drive an oil-filled car ignition coil, which, as he points out is not a Tesla Coil in spite of the frequently held view that it is. Ignition coils only operate at low frequency due to the limitations of their core material. However, John Stone points out that certain coil designs, such as those for the Fiat 'Punto' car, are built in such a way that replacing the core with ferrite should be possible, and that would allow high frequency operation.

Anyway, Nick uses a standard car ignition coil at lower frequency and uses it to feed a spark gap like this which is constructed from two chipboard screws:

His circuit is:



Nick has had very impressive results from his circuit, although it is still very much a work in progress with more development and testing still to be done. The 24 watt input of 12V at 2A is producing two very brightly lit 220V light bulbs. This does not tell us very much about the actual output power as bulbs are notorious for lighting brightly at low power levels, especially if the frequency is high. But, a very important point is the quality of the light which is an unusual, blue-white colour, quite unlike the colour produced when connected to the 220V mains supply. This is generally a sign of the power being 'cold' electricity. While he has not yet had the opportunity to test it, Nick believes that the circuit as it stands now is quite capable of powering much higher loads, and considering the colour of the light, I would be inclined to agree with him, although anything like that has to be tested and proven before any solid conclusions can be drawn from what is already known about the performance. The circuit performance is much improved if two separate physical earth ground connections are made.

Please don't fall into the trap of thinking that because the sparks are occurring at less than 5 kHz, that the Tesla coils also operate at that frequency. If you strike a bell which vibrates at 400 Hz, does that mean that you have to hit it 400 times every second in order to hear it? Actually, no, you don't, and the same thing applies here where the resonant frequency of the Tesla coils is approximately 650 kHz. The primaries are wound on 100 mm diameter PVC pipe sections and 19 turns of 1.02 mm diameter enamelled copper wire is used for them (19 swg or #18 AWG). The secondary coils are wound on 70 mm diameter PVC pipe using 0.41 mm diameter enamelled copper wire (27 swg or #26 AWG) with a total length of four time the primary winding wire length. As you will see later on in this chapter, resonance in a coil involves a standing wave inside the wire. That standing wave is

created by the signal bouncing off the end of the wire and being reflected back. At frequencies other than the resonant frequency, this results in a constantly changing set of many different waves travelling in both directions and at different intensities (what could reasonably be described as a total mess). When the resonant frequency is fed to the coil, then all of that mess disappears and just one waveform remains, and at any point along the wire, that waveform appears to be stationary although, of course, it is not actually stationary, just the effect of the peaks always occurring at exactly the same spot and the troughs occurring at exactly the same spot, making successive waves look exactly the same as the previous one.

This feature has one very practical aspect, namely that if you run the same wire away from the coil turns to connect to whatever the next circuit component happens to be, then the wave inside the wire will not bounce back at the end of the coil turns but will continue on to the end of the wire before bouncing back. So, the connecting wire length has to be included when reckoning the wire length in the turns of the coil. On the other hand, if the wire in the coil turns is terminated at the ends of the coil and wire of a very different diameter is used for connecting to the next component in the circuit, then the signal inside the wire will bounce back from the sudden change in wire diameter and so the connecting wire length will not be part of the wire length in the turns of the coil. This is an important feature if you are aiming for an exact 4:1 wire length ratio (and 4:1 wire weight) between the Tesla Coil windings in order to impose an automatic resonance between the two windings.

It should be noted that PVC (especially non-white PVC) has a very restrictive effect on high frequency coils. At low frequencies, PVC is ok, but it drags down the coil performance as the frequency rises, lowering the "Q" (for "Quality") factor of the coil. Using acrylic instead of PVC overcomes this. Alternatively, coating the PVC with a high-voltage insulating material such as shellac or one of the proprietary coating agents, will improve matters considerably. The ideal, of course, is to have no former at all and have the coil standing unaided because of it's own strength.

The Screened Transformer of Joseph Boyd.

It is not at all clear if the Boyd power system should be located here or in chapter 7 which deals with aerials. Joseph talks about the way that radio circuits operate and why only very limited power appears to be the limit of radio receivers. He explains a method of extracting serious levels of power from a transmitting coil and a receiving coil, but the higher power levels require an input oscillator, and so, while an aerial and earth can be used for lower power levels, input power is needed for optimum performance. Here is part of Joseph's patent application:

US Patent Application 2008/0129397 5th June 2008 Joseph Boyd

ELECTROMAGNETIC ELECTRIC GENERATOR

Abstract:
An electrical generator that uses a high frequency oscillator in a tuned circuit, set to resonate with the transmitter coil of a full-length high frequency transformer unit, to generate electromagnetic energy, to transform this energy to electrical energy and to collect this energy.

1. Field of the Invention

The present invention is an electrical generator that uses a high frequency oscillator in a tuned circuit, set to resonate with the transmitter coil of a full-length high frequency transformer unit, to generate electromagnetic energy, to transform this energy to electrical energy and to collect this energy.

2. Description of the Related Art

If an oscillator circuit is properly connected to a tuned antenna so that it resonates, a current will flow between the aerial and the ground, and this produces the high frequency electromagnetic air waves and ground waves of our radios and other electronic equipment.

An oscillator of the same type used in electromagnetic wave transmission equipment is used to generate the electromagnetic energy used in this patent. These electromagnetic transmitters are well developed and are used world wide, and broadcast at frequencies that extend from the longest radio waves to the very short ones. Certain radios send their signals great distances, some even travelling around the world.

Although these high frequency electromagnetic energy waves are all around us, this energy has long been considered impossible to collect on a large scale due to the induction characteristics of the electromagnetic wave

as it passes a metallic object. As the wave goes by a wire tuned to resonate at the frequency of the wave, it induces an electrical charge in the wire, but to use this charge, we need another wire to close the circuit and let the charge flow. If we use another wire alongside the first wire and connected to it, the wave induces a charge in it exactly like in the first wire and no current will circulate in the two wires.

This problem of collecting the energy of the wave was solved by the invention of the half-length electromagnetic transformer, but the half-length electromagnetic transformer applies only to the means of collecting the atmospheric energy. The invention of the full-length electromagnetic transformer of this invention, however, allows us to combine the generation of the electromagnetic wave and the electrical converter into one compact unit.

BRIEF SUMMARY OF THE INVENTION

Basically, this unit uses an oscillating electric current to generate an electromagnetic wave, which releases a much greater electric current, and the total electrical energy derived in this manner, is over and above the amount of energy needed to operate the equipment.

It has long been assumed that the only energy involved in high frequency electromagnetic transmission is that supplied by the operator to drive his equipment. The actual energy of the electromagnetic wave is often over a hundred times greater than this since the amount of electromagnetic energy in the earth is practically unlimited, there appears to be no limit to the size of the electromagnetic generators, or to the size of the power plants based on this energy source. This energy is available, world wide, free for the taking.

This energy is related to the light waves and is probably a variation of the light waves, however, the radio type waves are longer than light waves and are vibrating at a lower frequency. Light waves are a source of high energy just for the taking, also. Anything that is brought up to a high heat, will give off light energy. A very small wire in a light bulb, when brought to a high heat will release a light ray of such power that it will go all the way to the moon. This is natural energy, produced by the speed of the earth through space. Using the math of Dynetics, the speed of the earth necessary to give any pound of earth the atomic energy of one pound of uranium, came out exactly the same as the speed of light (186,300 miles per second). The fact that the math came out exactly at this speed leaves little doubt that the speed of the earth through space is the speed of light, and that every pound of material on earth has the energy of one pound of uranium, due to this speed.

The electromagnetic energy in the low frequency range differs from other types of energy, in many ways, but of interest to us is that it is propagated by electrical currents, travels through the air like the light waves, and is detected and may be collected, when it induces an electric charge in a wire.

This is an ideal source of energy. The generators may be hand-held or large enough to replace the biggest power plants. They may be used to drive motor cycles, sleds, autos, trucks, trains, ships and planes. The fact that the output is in the form of electrical energy is, in itself, a great benefit, but the fact that the generating equipment is light and compact is a real plus for all types of mobile equipment.

It is possible that this invention will supply all of the electrical energy needed in the homes making the distribution lines unnecessary, and if used to drive automobiles, our dependence on oil will be a thing of the past.
This invention makes possible an abundance of energy, available to mankind any where in the world. Even the poorest nations will have an abundance of energy.

The oscillating equipment that generates the electromagnetic wave used in this invention includes an oscillator, of some type driving a tuned transmitter coil that resonates with a tuned collector coil in a full-length electromagnetic transformer. The induced current is collected in the collector coil and may be rectified and stored in a battery or used to do work. The oscillator circuit is an ordinary oscillator circuit, driven by a tube, crystal or even an electoral arc, and the tuning means and rectification set-up are standard.

The basic element that is novel to this invention is the full-length electromagnetic transformer unit that is made up of two or more metallic pipe like sheaths side by side. The sheaths are not connected together, electrically. Two or more coils are wound in the sheaths.

The transmitter coil uses an insulated wire, which is threaded up through one sheath, and down through another sheath a number of times forming a long flat continuous circuit of wire inside of the pipe like sheaths. And then the collector coil is threaded up through the sheaths, and wound the same way. The two coils may have a different number of turns. The coils are tuned to resonate at the oscillator frequency and an electromagnetic wave is generated in the transmission coil. The wave induces a charge in that part of the collector coil that is in the same sheath, and next to it, and if the wave is moving up in the sheath, the charges of all of the collector wires in that sheath are moving up, and if the wave is moving down, the charges of all of the collector wires are moving down. But the transmitter wave in one sheath does not induce a current in the wires of another sheath, nor does it

induce a current in a wire outside of that sheath. This allows a current induced in one sheath to freely circulate in the other sheaths or on an outside wire.

When the transmitter coil is brought up to resonance and broadcasts its electromagnetic wave inside of the sheaths, it benefits us in two ways. It keeps the wave inside of the sheaths and prevents it from spreading far and wide, and it concentrates the wave on that part of the collector coil in the same sheath.
Since each of the collector wires are of the same length, say ½ wave length of the electromagnetic wave, and since they are parallel and side by side, a resonant electromagnetic wave induces equal charges in all of the collector wires within the sheath. These induced currents are exactly in phase and are connected in series, so that the voltages add up to an amount proportional to the number of turns.

More than two sheaths may be used with the coils wound inside, or the ff11 length-transformer may be combined with the half-length transformer where the winding is part inside the sheath and part outside of the sheaths. The oscillator may be replaced by an aerial in cases where low power is needed. The inductance coil may be left entirely outside of the transformer, and the coupling made to the transmission coil by magnetic induction.
These and other objects, features and advantages of the present invention will become more apparent upon reading the following specification in conjunction with the accompanying drawing figure.

BRIEF DESCRIPTION OF THE FIGURES

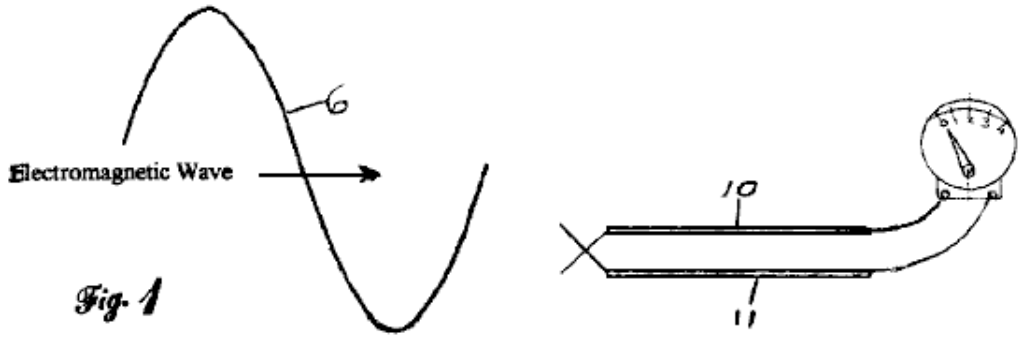


Fig.1 is a view of an electromagnetic wave, due to resonance, passing two side by side wires tuned to the same frequency. The wave generates equal alternating charges in each wire, and no current flows when the wires are connected.

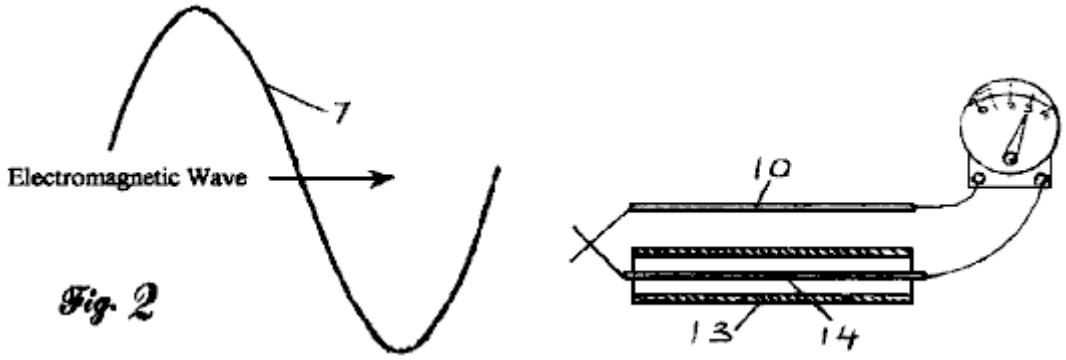

Fig.2 is a view of a resonating electromagnetic wave passing two wires, tuned to resonate, where one wire is surrounded by a metal sheath. The outer metal sheath stops the wave and prevents it from inducing a charge in the shielded wire. The Charge induced in the outside wire now flows freely through the shielded wire.

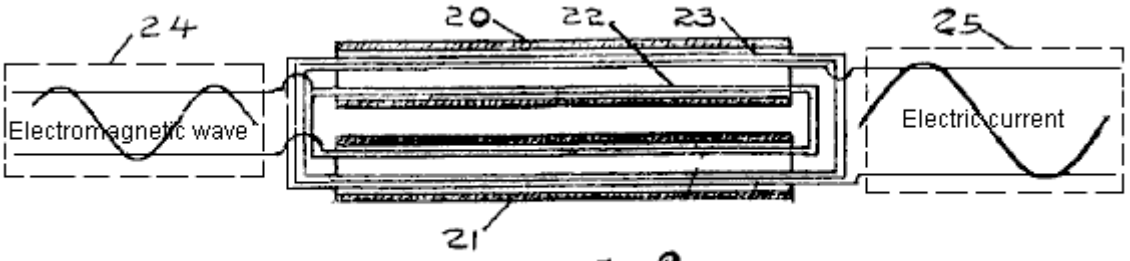

Fig. 3

Fig.3 is a view of a full length electromagnetic transformer made of two metallic pipe like sheaths, having two wires threaded up through the inner opening of one sheath and down through the inner opening of the other sheath, a number of times to form two continuous coils. When an electromagnetic wave is fed into the tuned transmitter coil, an alternating current is induced in the tuned collector coil.

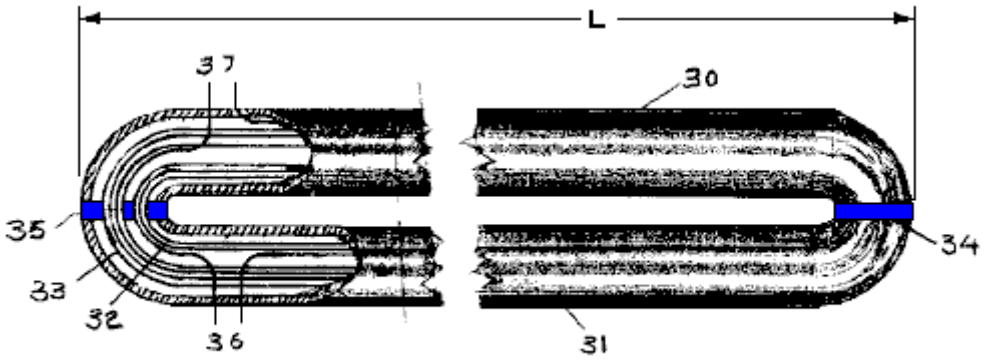

Fig. 4

Fig.4 is a view of a full-length electromagnetic transformer, having two sheaths, insulated from each other, and a cutaway portion shows the coils inside.

Fig. 5

Fig.5 is a view of a full-length electromagnetic transformer, having four sections insulated from each other.

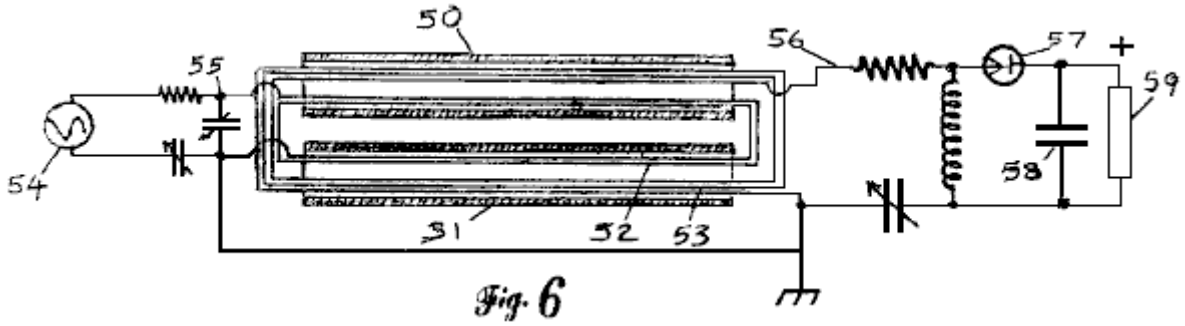

Fig. 6

Fig.6 is a section view of a full length electromagnetic transformer made of two metallic pipe like sheaths, where an oscillator circuit is fastened to a tuned transmitter coil, which induces a current in the tuned collector coil; and a half-wave rectifier circuit converts the high frequency current to DC current.

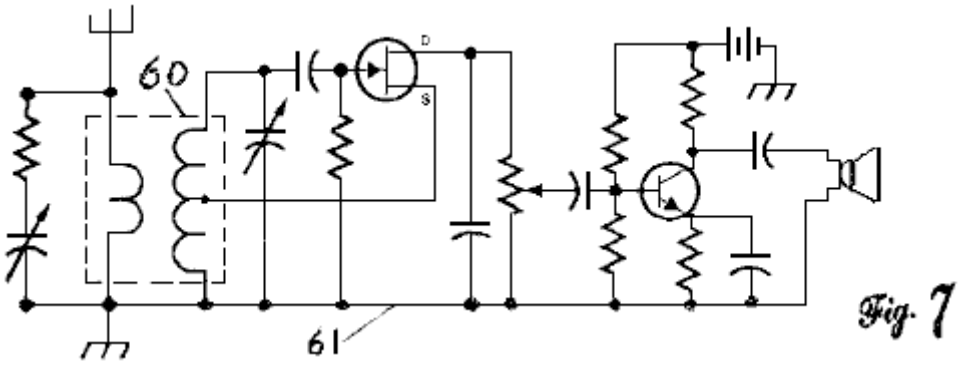

Fig. 7

Fig.7 shows a view of a full-length transformer, used as an inductance in a radio receiver or other similar electronic circuit **61**. In this case the transmitter coil is between the aerial and ground, and the collector coil acts as the radio frequency inductance.

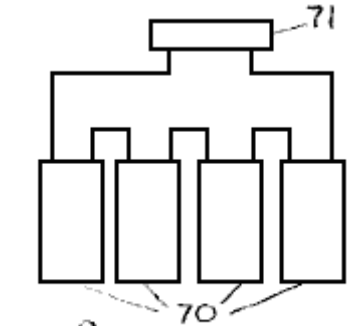

Fig. 8

Fig.8 shows a number of full-length transformers, connected in series. They all have rectifiers to convert the high frequency AC current to DC current and the voltages at the load add up.

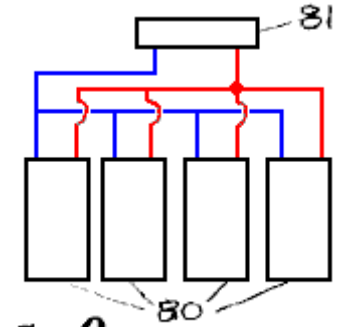

Fig. 9

Fig.9 shows a view of a full-length transformer, connected in parallel. In this case the currents at the load add up.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

When a circuit is made to resonate at some frequency, it generates an electromagnetic wave. These waves move at the speed of light and travel great distances, and this makes possible our radios, televisions and cell phones. These waves, in passing a wire suspended in the air, set up alternating charges in the wire, varying at the frequency of the wave. If we put an inductance, that is tuned to the frequency of the wave, between the wire and the ground the circuit will resonate and charges will flow back and forth on the wire. This allows us to pick out the wave we are interested in, amplify it and read its message. We have long known that the voltage of the wave we choose to receive is greatly amplified when we make our circuit resonate at that wave's frequency, but we have been unable to accumulate this additional energy from the wave because we are limited to what energy we can pick up by the equipment that we use.

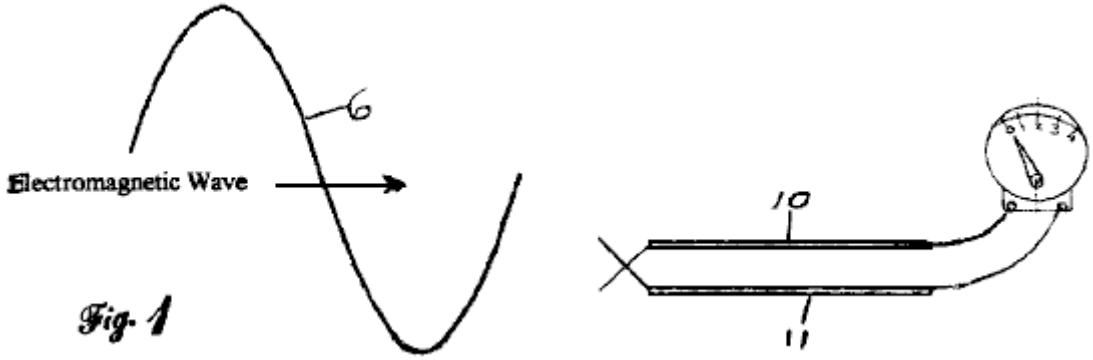

Fig. 1

Fig.1 shows why this is so. The passing electromagnetic wave **6** generates an alternating electric charge in the wire **10**, tuned to the wave frequency to close the circuit so that the induced charge can circulate, we have added a second wire **11**, but if we connect the ends of the wires together, the electromagnetic wave **6** induces a charge in the second wire exactly like the one in the first wire, and no current will flow. Any effort to circulate the charge induced in wire **10** is blocked by an equal opposing charge in **11**.

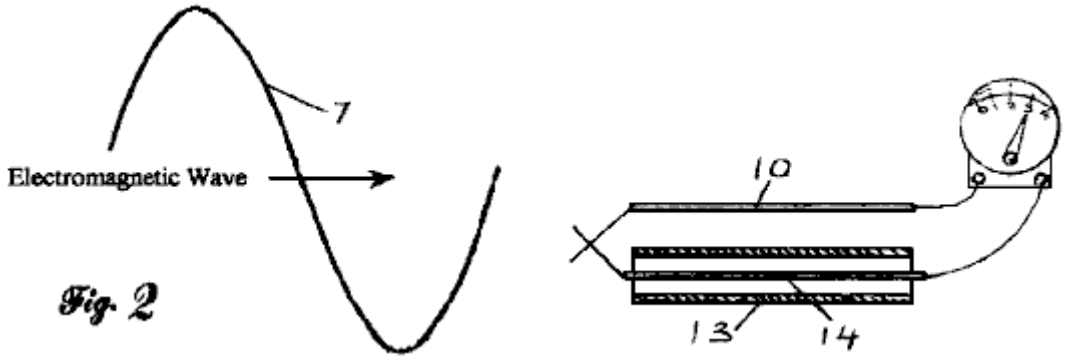

Fig. 2

In **Fig.2** we have replaced the wire **11** with a metallic, pipe like sheath **13** having an insulated wire **14** inside when an electromagnetic wave **7** passes, the wave is stopped at the sheath **14** and does not induce any charges in the inner wire **14**. This allows the inside wire **14** to conduct the charge induced in the wire **12**.

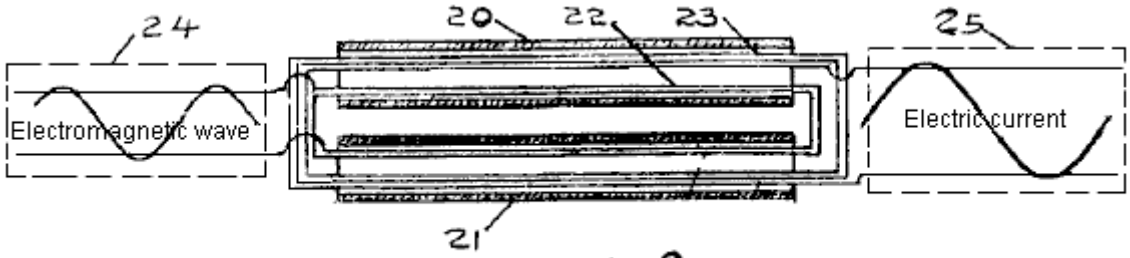

Fig. 3

In **Fig.3** we see two sheaths **20** and **21**, parallel and insulated from each other. Two separate coils **22** and **23** are wound inside the sheaths. The coil **22** is the transmitter coil and it is tuned to resonate at the frequency of the oscillator circuit **24**, and this generates an electromagnetic wave that induces a current in the collector coil **23**, which is adapted and used in the tuned collector circuit **25**.

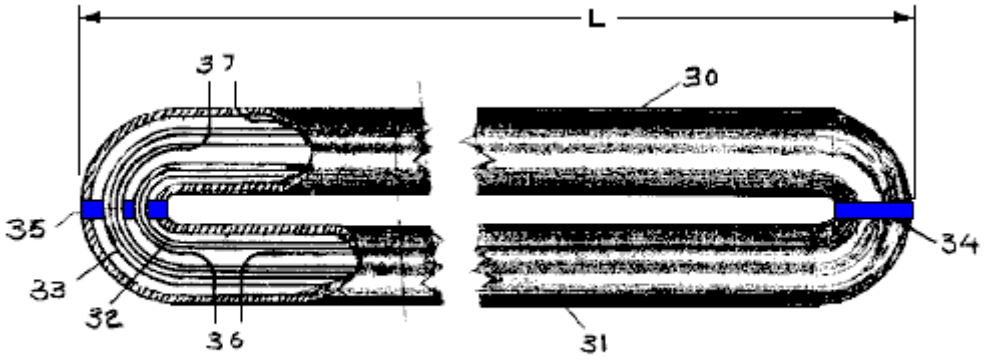

Fig. 4

Fig.4 is a view of a full-length electromagnetic electric generator using two separate sheaths **30** and **31**, where the electromagnetic wave is almost completely contained within the sheaths. The sheaths are parallel and insulated from each other by insulators **34** and **35**. The transmitter coil **32** and the collector coil **33** are shown in the cut-away, and are wound completely inside the sheaths. Additional coils may be added as needed. The transmitter coil **32** is tuned to resonate at the frequency of the oscillator circuit, which connects in at **36**. And this generates an electromagnetic wave that is contained within the sheaths and induces a current in the collector coil **33**, which is tuned to resonate at the wave frequency and is coupled to the collector circuit at the terminal **37**. The insulating separators **34** and **35** are necessary to prevent induced current from flowing in the sheaths **30** and **31**.

Fig. 5

A number of sheaths may be combined, as is shown in **Fig.5**. In this case four sheaths **40**, **41**, **42** and **43** are combined, so that the coils wound inside the sheaths are in series, and the sheaths are electrically separated by the insulators **44**, **45**, **46** and **47**. The tuned circuit for the transmitter coil is hooked up at connectors **48**, and the collector circuit connects to the collector coil at **49**.

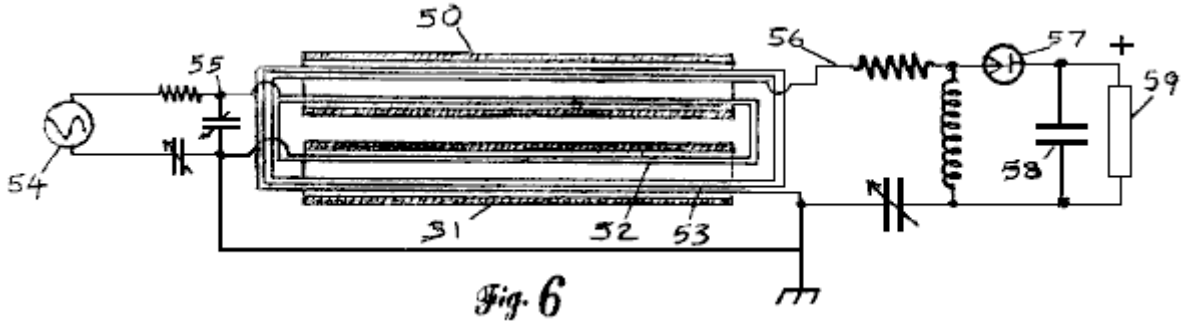

Fig. 6

A simple circuit for operating the full-length electromagnetic transformer is shown in **Fig.6**. The two sheaths **50** and **51** are shown with the transmitter coil **52** and collector coil **53**. The transmitter coil is connected to the tuned circuit **55**, which is driven by the oscillator **54**. The oscillator **54** is tuned to oscillate at some frequency and the transformer circuit **55** and collector circuit **56** are tuned to resonate with it. At resonance the transmitter coil **52** emits an electromagnetic wave which induces a current in the collector coil **53**. Shown here is a half-wave rectifier **57** and capacitor **58** connected to the load **59**. The rectifier is necessary on each collector unit, because we can add the direct currents of the separate units, but the alternating currents of the units might be out of phase and without the rectifier they would cancel out.

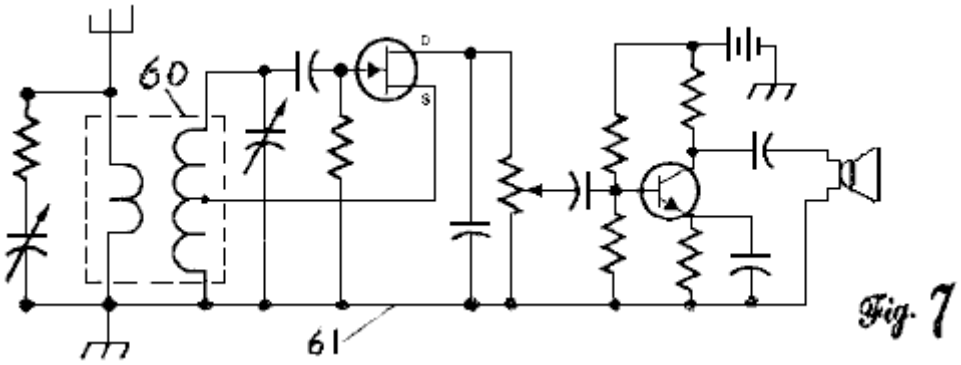

Fig. 7

Fig.7 shows the transmitter coil connected between an aerial and the ground, where the aerial circuit and collector circuit are tuned to resonate at a desired frequency to greatly boost the sensitivity and to amplify the signal. This type application will work equally well with transmitters.

Also, using the half-length transformer as an aerial and the full-length transformer as the radio frequency transformer works the same with both receivers and transmitters. The oscillator circuit can use a high frequency magnetic inductance and the full-length transformer unit to resonate with a half-length transformer which acts as an aerial. A unit such as this would greatly add to the power of a radar system.

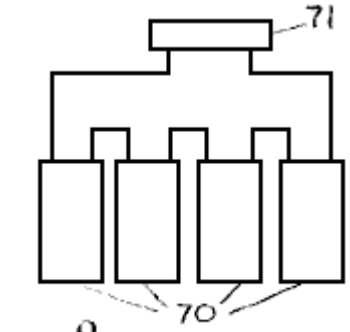

Fig. 8

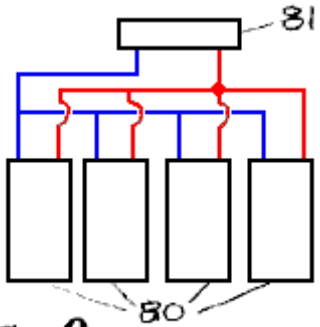

Fig. 9

The full-length units, when combined with rectifiers, may be connected in series as in **Fig.8**, or in parallel as in **Fig.9**

While the invention has been disclosed in it's preferred forms, it will be apparent to those skilled in the art that many modifications, additions, and deletions can be made therein without departing from the spirit and scope of the invention and its equivalents as set forth in the following claims.

Claims:

1. An electric generator that uses an oscillating circuit to resonate with inductances enclosed in a full-length electromagnetic transformer unit, comprising: two or more parallel, metallic, pipe-like sheaths, insulated from each other; an electromagnetic transmitter coil, which is wound inside the sheaths, using an insulated wire, threaded up through the inside opening of one of the sheaths and down on the inside of a second sheath, one or more times, to form a continuous coil; a means of tuning the transmitter coil to the frequency of the oscillating circuit, so that the transmitter coil resonates and generates an electromagnetic wave that is contained within the sheaths; a collector coil composed of an insulated wire, threaded up through the inside opening of one of the sheaths and down on the inside of a second sheath, one or more times, to form a continuous coil, wherein the electromagnetic wave of the transmitter coil induces an electric charge in the collector coil; and a means of tuning the collector coil to resonate at the frequency of the oscillating circuit; so that the electromagnetic wave induces a current in the collector coil, and since the coil is contained within the sheaths, the current is free to flow, and the high frequency alternating current, so generated, can be used elsewhere in an electronic circuit, or altered and used as a power source.

2. The full-length electromagnetic transformer unit of claim 1, where the collected current is rectified, and the DC current is stored in capacitors and used to do work.

3. The full-length electromagnetic transformer unit of claim 1, where the transmitter coil acts as a tuned

inductance, in a receiver, between the aerial and the ground, and a tuned collector coil resonates to increase the sensitivity and the amplitude of the signal.

4. The full-length electromagnetic transformer unit of claim 3, where the tuned transmitter coil resonates with an oscillator and an aerial to act as a transmitter for radios, televisions, cell phones, radars and computers.

5. The full-length electromagnetic transformer unit of claim 1, where the lengths of the sheaths are some multiple of the wave length of a particular electromagnetic frequency.

6. The full-length electromagnetic transformer unit of claim 5, where a number of the units are connected in parallel to increase the current.

7. The full-length electromagnetic transformer unit of claim 5, where a number of the units are connected in series to increase the voltage.

8. The full-length electromagnetic transformer unit of claim 5, where the parts are reduced to a size small enough to fit in, and supply power to, a cell phone, a lap-top computer, or other electrical appliance.

9. The full-length electromagnetic transformer unit of claim 1 further comprising three or more, metallic, parallel, side by side, pipe like sheaths, where the sheaths are not electrically connected, and have two or more coils wound inside the sheaths.

****

Up to the present time (June 2013), I have not heard of anyone attempting to replicate the design shown in this patent, and so it is just being put forward here in case somebody wants to try it. It appears to be a clever technique. The power gain is maximised by tuning the transmitting and receiving coils to the frequency of the oscillator, although in practice, it is highly likely that the oscillator frequency would be adjusted to the transmitter coil as it is so easy to adjust the frequency of an oscillator.

Boyd does not go into great detail about attaining resonance, and that is generally a major difficulty in any design which does not have automatic tuning. It needs to be borne in mind that the length of wire in each coil (and possibly its weight) is a key factor. Boyd talks about the coils possibly having the same number of turns, and that is fine **provided** that the coils are identical in size, that is, having the same shape when viewed from the top and the same depth of turns when viewed from the side, and exactly the same number of turns with each coil having exactly the same wire length. Resonance in a length of wire, whether it is laid out straight or wound into a coil, tends to confuse many people. Richard Quick's very clear explanation of resonance in any length of wire, in his US patent 7,973,296 of 5th July 2011 is very helpful. He says:

"Quarter-Wave" Resonance; Standing Electromagnetic Waves"

One of the two main types is electrical resonance is referred to here as quarter-wave resonance. This type of resonance depends almost entirely on the length of a wire element For reasons described below, if a segment or length of wire is one quarter as long as the "voltage waves" which are travelling through the wire, then a set of "reflected" waves will be added to the emitted waves, in a synchronised alignment which creates stronger "superimposed waves".

Accordingly, an understanding of the "quarter-wave" phenomenon will help a reader understand how a straightforward and easily-controlled factor (i.e., the length of a wire ribbon which will be used to form a spiral coil) can help create a "quarter-wave" resonant response, which will create the types of electromagnetic pulses and fields referred to as "standing waves".

The speed at which a voltage impulse is transmitted through a metal wire is extremely fast. It is essentially the same as the speed of light, which travels 300 million meters (186,000 miles) in a single second (that distance would circle the earth more than 7 times).

If wavelength (in meters) is multiplied by frequency (cycles per second), the result will be the speed of light, 300 million meters/second. Therefore, the wavelength of an "alternating current" (AC) voltage, at some particular frequency, will be the speed of light, divided by which frequency.

Therefore, using simple division, if an alternating voltage operates at a frequency of 1 megahertz (MHz), which is a million cycles per second, then the "wavelength" at that frequency will be 300 meters. If the frequency halves become 500 kilohertz, the wavelength becomes twice as long (600 meters); and, if the frequency were to increase to 2 megahertz, the wavelength drops to 150 meters.

It should be noted which the term "cycles" is what scientists call "a dimensionless unit", which drops out and becomes silent when other physical terms are multiplied or divided.

At AC frequencies of 10 kilohertz or greater, the common references to “alternating current” (AC) voltage begin using a different term, which is “radio-frequency” (RF) voltage. Accordingly, RF voltage is a form (or subset) of AC voltage, which operates at frequencies higher than 10 kilohertz. RF power generators are readily available, and are sold by numerous companies which can be easily located by an Internet search, using the term “RF power generator”. For example, Hotek Technologies Inc. (hotektech.com) sells two RF power generators, called the AG 1024 and AG 1012 models, which can provide output power at frequencies ranging from 20 kHz to 1 MHz; the 1012 model has a power output of 1000 watts, while the 1024 model has a power output of 2000 watts. The output frequency of any such RF power supply can be adjusted and “tuned” across the entire range of operating frequencies, merely by turning knobs or manipulating other controls in a power supply of this type.

In a wire having a fixed and unchanging length, the easiest way to create a “standing wave” is to adjust the RF frequency emitted by a power supply with an adjustable frequency, until the “tuned” frequency creates a wavelength which is 4 times as long as the wire. This principle is well-known to physicists, and it is commonly referred to as “quarter-wave” behaviour, since the length of the wire segment must be one quarter as long as the wavelength. Since it is important to this invention, the principles behind it are illustrated in a series of drawings provided in **Fig.1** to **Fig.4**, all of which are well-known prior art.

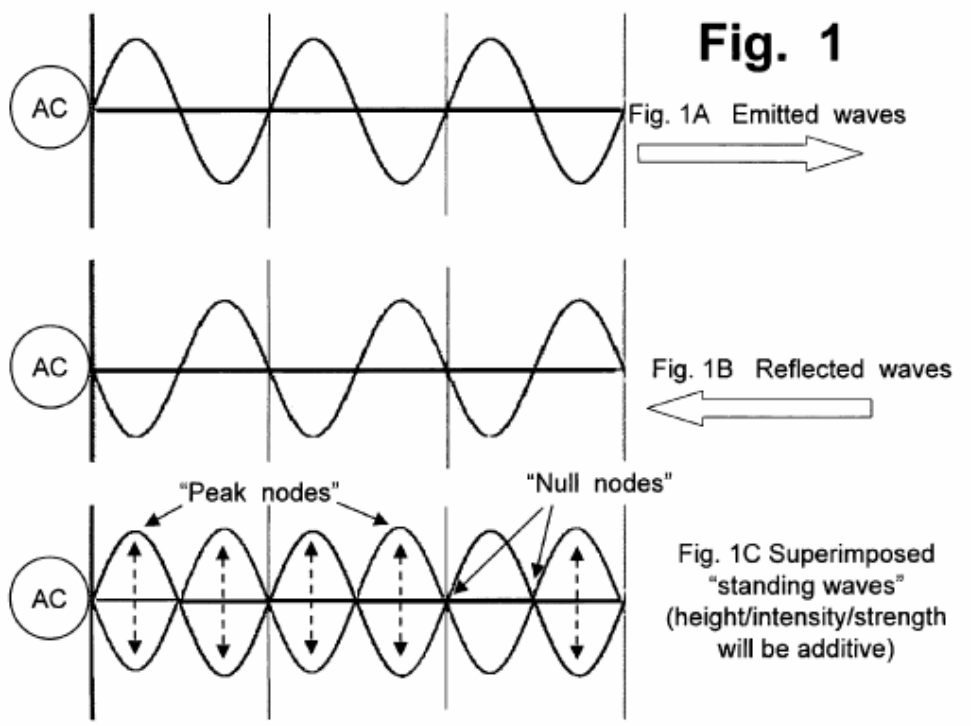

Fig.1A indicates an idealized wavelength of an alternating voltage, depicted by a sine wave which is being sent from an AC power supply (shown by a circle at the left end of a horizontal straight wire) into the “input” end of the wire. The voltage waves travel through the wire towards the right, as indicated by the block arrow in **Fig.1A**. When the waves reach the end of the wire, they cannot leave the wire (at least, not in a simplified and “ideal” system, which is being assumed and used here to explain the principle of how a simple straight wire can create a standing wave). Therefore, the voltage wave will effectively “bounce” or “reflect” back from the tip of the wire, and the “reflected wave” will begin travelling back through the wire, going in the opposite direction, as indicated by the left-pointing block arrow in **Fig.1B**.

Because of the laws of conservation of energy, the reflection and “return travel” of these types of waves, when they bounce off the tip of a wire, is actually quite good, and rather efficient, as discussed below, provided which the wire tip does not emit sparks, arc discharges, or other forms of “escaping” electrical energy.

Accordingly, **Fig.1A** depicts a set of “emitted waves” travelling towards the right, while **Fig.1B** depicts an idealised set of “reflected waves” travelling toward the left along the same wire.

Fig.1C illustrates what happens when both sets of waves (emitted and reflected) are superimposed on each other. Since the two sets of waves are travelling at exactly the same speed, and since they have exactly the same wavelength, they will create a “standing wave” pattern when they are added together. As can be visualised from **Fig.1C**, there will be a set of locations, along the length of the wire, which can be referred to as “peak nodes”, where the AC voltage reaches it’s maximum.

At a location halfway between a pair of adjacent “peak nodes”, there will be a spot which can be called a “null node”, a “zero node”, a trough or valley node, or similar terms. At each “null node” location, the AC voltage will

appear to be not fluctuating at all. Those are the sites, along the length of the wire, where each “positive” hump (created by a sine wave travelling toward the right) will be counter-balanced and offset by a “negative hump” with exactly the same height, travelling at an identical speed toward the left.

As a result, this type of response within a wire creates a “standing wave”. If the instantaneous voltage is measured at a “null node”, it would appear that nothing is happening, in terms of fluctuating voltage. Furthermore, the “null node” will not be moving, along the length of the wire; instead, it will appear to be standing still.

This can be demonstrated, in a coil, by using a “grounded lead” to test for voltages along the length of a coil. If a “grounded lead” coupled to a volt meter is used to touch the surfaces of a series of strands in a non-insulated coil (such as a coil made of thin copper tubing, wrapped around a plastic cylindrical shape, as used in the types of large transformers used by hobbyists to create “Tesla coils” which will emit large and visually impressive electrical arcs), the “test lead” will detect no apparent voltage at a null node, which will occur at some particular strand in the coil. At a different strand of the coil, the “test lead” will detect an alternating voltage which has twice the strength and intensity of the voltage being emitted by the power supply.

If voltage is measured at a “peak node”, the voltage will be doing something which can be called, using vernacular or laymen's terms, “the full-tilt boogie”. The AC voltage levels will be moving back and forth, between: (i) a very high and intense positive voltage, to (ii) an equally intense negative voltage. This is indicated by the “bubble” shapes shown along the wire in **Fig.1C**.

The “bubbles” which are shown in **Fig.1C** can help someone understand how standing waves are created, and how they act in a synchronised manner. However, which drawing fails to show another result which is very important in what actually happens in a standing wave. For purposes of description and analysis at this introductory level, the system can be assumed to be “ideal”, which implies a perfect “mirror-image” reflection of each wave from the right end of the wire. An “ideal” system also implies that no reflections occur at the left hand end of the wire where the power supply is located, and all “reflected” wave activity simply ceases. In real circuits and wires of this type, second and third order reflections do in fact occur, and they are used to further increase the strength and power output of these types of systems; however, those additional factors and “harmonics” should be ignored until after the basic principles of this type of system have been grasped and understood.

In an ideal system, when the reflected waves (which are travelling toward the left, in the wire segments illustrated in **Fig.1**) are “superimposed” on the emitted waves (travelling toward the right), the “peak” positive voltage which will be instantaneously reached, at the highest point of each “bubble” shown in **Fig.1C**, will occur when the positive peak of an emitted wave crosses a mirror-image positive peak of a reflected wave, travelling in the opposite direction. Accordingly, when those two “positive peak” values are added to each other, the instantaneous positive peak voltage which will occur, in the wire, will actually be twice as intense as the “positive peak” voltage being emitted by the AC power supply.

An instant later, at that exact point on that segment of wire, a negative peak voltage will be created, which will be the sum of (i) the negative peak voltage emitted by the power supply, and (ii) the negative peak voltage of a reflected wave also will pass through, travelling toward the left. At which instant, when those two negative peak voltages are added to each other, the instantaneous negative voltage which will occur, in the wire, will be twice as intense as the “negative peak” voltage being generated by the AC power supply.

A more accurate and representative visual depiction of a “standing wave” in a wire would actually show the heights of the peaks as being twice as tall as the peaks of the emitted voltage waves, and the reflected voltage waves. However, which depiction might confuse people, so it usually is not shown in drawings of “standing waves”.

Accordingly, the instantaneous response in the wire, at a location halfway between two “null nodes”, is doing something which can fairly and properly be called “the full-tilt double double boogie”. The “double double” phrase (note which it contains not just one but two “doubles”) was added to that phrase, for two reasons:

(i) To emphasise the fact that each and every voltage peak (maximum positive, and maximum negative) will be twice as strong, and twice as intense, as the maximum positive and negative peak voltages emitted by the power supply; and,

(ii) to point out that the frequency of the superimposed “bubbles”, shown in **Fig.1C**, is actually twice as fast as the frequency of the AC cycle which is emitted by the power supply, as discussed below.

The “twice the intensity” result is directly comparable to what an observer will see, if a large mirror is placed behind a light bulb in an otherwise dark room. The mirror effectively keeps the room dark, everywhere behind the mirror, so there is no “magical doubling” of the light in the room; which would violate the basic law of conservation of energy. Instead, what the mirror does is to shift light away from the backside of the mirror, and keep that light energy on the reflective side of the mirror. Anyone standing in front of the mirror will see two apparent light bulbs. Both of those light bulbs (the original bulb, and the reflected image) will have the same brightness (if the mirror is perfect). Therefore, the mirror will double the intensity of the light energy reaching the observer.

That same effect, in a circuit, will happen if the end of a wire acts like a mirror. If a wire does not have any components which will cause it to become an active “emission source” (which is the behaviour of transmission

antennas and certain other components), in a way which efficiently releases voltage-created energy into the atmosphere, then the basic rules which require conservation of energy will prevent that energy from simply disappearing and ceasing to exist. As a result, even if the end of a wire is not designed to be a perfect reflector, a large portion of the voltage wave will indeed reflect off the wire tip, and travel back through the same wire, in a "second pass".

To understand adequately, the type and amount of "wave reflection" which occurs at a wire tip, consider what happens if a light bulb is shining in a room which has shiny, glossy white paint on all the walls and ceilings; then, consider how it would look if the same light bulb were located in a room with all of the walls and ceilings painted "matt black". The total amount of light which would be available, to carry out a task such as reading a newspaper, clearly would be much greater in the white room, because light reflects off white paint, even though white paint does not even begin to approach the type of "reflection quality or clarity" which a mirror creates. The difference in what happens, when light intensity in a room painted matt black is compared to a room painted a glossy white, does not arise from the presence or absence of "reflection quality or clarity"; instead, it is governed by the laws of conservation of energy. When light shines on to a surface which is painted matt black, the light energy is absorbed by the paint, and it literally warms the paint up. In contrast to that, glossy white paint will not absorb light energy, so it reflects the light back out, for a "second pass" through the air which fills a room.

Because of the laws of conservation of energy, and without depending on any "quality of reflectance" characteristic of wire tips, electrical energy cannot simply disappear, when it reaches the end of a wire. Instead, there are only two things which can happen to that energy:

(i) the electrical energy can be emitted into the surroundings, such as by emitting sparks, arcs, or radio-frequency signals which will carry energy; or

(ii) if the energy is not emitted by the tip of the wire, then, by simple necessity and because of the basic law of conservation of energy, it must be reflected back into the wire, and it will be forced to travel back through the wire again.

If a wire has a long and tapered tip, then the reflected wave might become somewhat diffused, and it might lose some portion of the "clarity" of the wave. However, since wavelengths in the frequencies of interest here are hundreds of meters long, the type of tip created by a conventional wire cutter will not create any significant diffusion, in a reflected wave. And, unlike the white-painted walls of a room, there is not a large area which is available, at the tip of a wire, which can create scatter, spread, or diffusion. As a result, the tip of a wire will be a relatively efficient mirror-type reflector, when an AC voltage is "pumped" into one end of the wire.

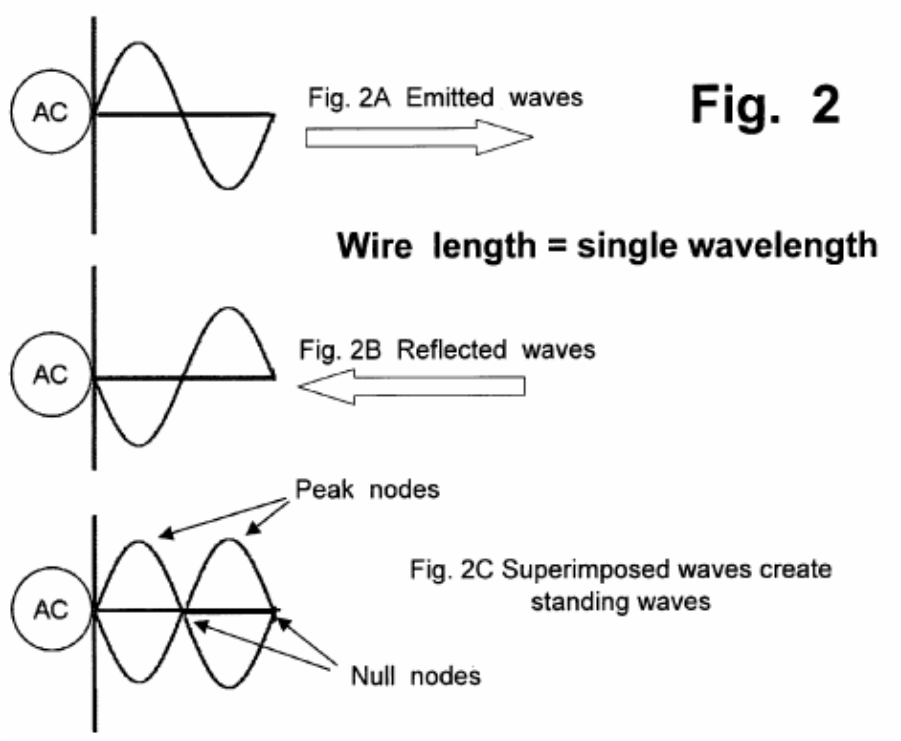
The second factor mentioned above, when the "double-double" boogie phrase was mentioned, relates to a doubling of the frequency of a standing wave. When a standing wave is created in a wire by reflection of an emitted AC voltage wave, the frequency of the standing wave is, quite literally, double the frequency of the emitted wave.

This can be seen, visually, by noting that in the emitted AC voltage, shown in **Fig.1A**, a single complete wavelength contains both a "positive hump" and a "negative hump". Accordingly, three complete sine waves, divided into three segments by the imaginary vertical lines, are shown in **Fig.1A**.

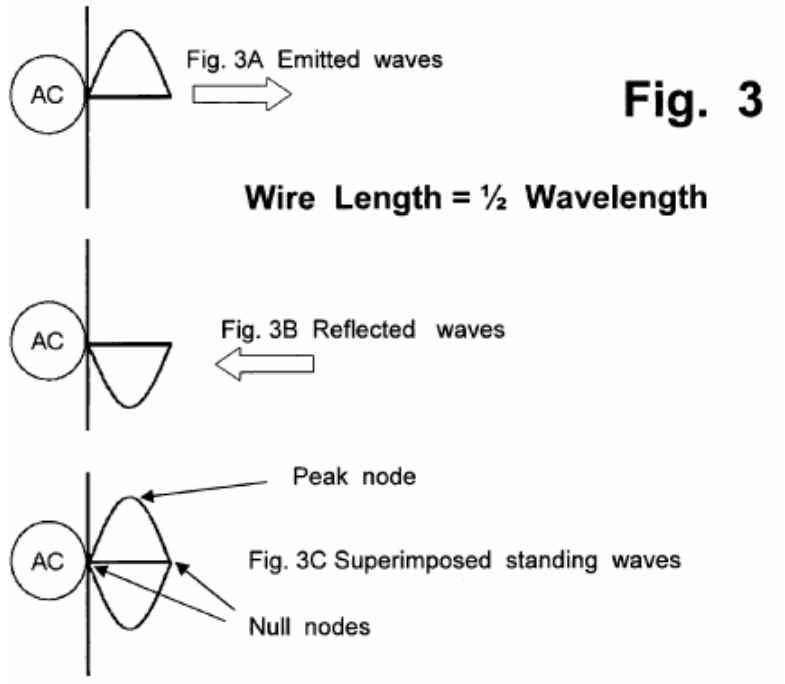
By contrast, each and every "bubble" shown in **Fig.1C** depicts a complete and total "wavelength", in a standing wave. Six of those standing wave "bubbles" fit into exactly the same length of wire which holds only 3 emitted wavelengths from the power supply.

The "frequency doubling" effect of standing waves is important, because AC systems can convey and release energy in a manner which increases, as the frequency of the AC voltage supply increases. To some extent, this is analogous to saying that, if a motor can be run at twice the speed (while still generating the same torque), then the work output of that motor can be twice as great, at the higher speed. That analogy is not entirely accurate, since work output from an electric device which uses AC power depends on "area of the curve" functions which occur when sine waves are involved. Nevertheless, as a general principle, if the frequency of the voltage peaks increases, then power output will also increase, in many types of electric circuit components.

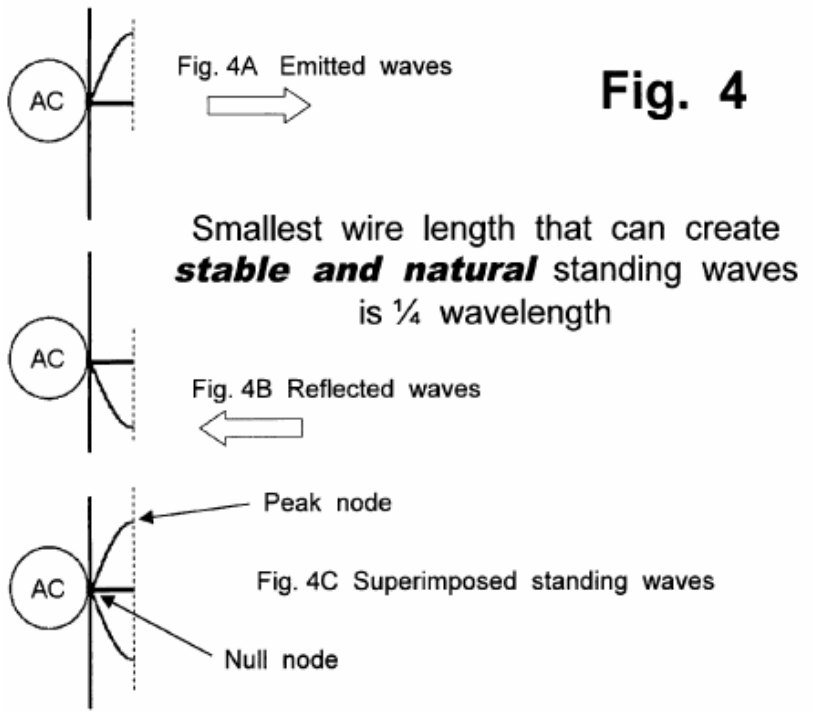
In the three panels of **Fig.1**, the wire length is three times as long as the wavelength of the voltage from the power supply. However, to create standing waves, a wire length does not need to be any particular multiple of the wavelength of an AC voltage. As can be seen by considering **Fig.1C**, the same types of "bubbles" would be created: (i) if the wire length were exactly twice as long as the wavelength; or, (ii) if the wire length were the same length as the wavelength.



Accordingly, **Fig.2** (which includes **Fig.2A** showing an emitted wave, **Fig.2B** showing a reflected wave, and **Fig.2C** showing the superimposed "bubbles") shows what happens in a wire segment which has a length which is equal to a single wavelength from an AC voltage at a fixed frequency. A resonant standing wave will be formed, with a frequency which is double the frequency of the input AC voltage. which same result will apply, in a wire having any length which is an exact (integer) multiple (such as 1x, 2x, 3x, etc.) of the wavelength of the AC voltage being pushed (or forced, driven, pumped, etc.) into the wire segment.



Moving to still shorter wires, the same principle also applies to any wire with a length equal to one half of an AC voltage wavelength. As shown in **Fig.3** (which includes **Fig. 3A** showing an emitted wave, **Fig. 3B** showing a reflected wave, and **Fig. 3C** showing the superimposed "bubbles"), if the wire length is one half of the wavelength, a natural and resonant standing wave will still form, with a frequency which is double the frequency of the input AC voltage.



Finally, moving to a still shorter wire, the same principle also applies to any wire which has a length equal to one quarter of an AC voltage wavelength, as shown in **Fig.4A**, **Fig.4B**, and **Fig.4C** Even though it does not stretch across or cover a complete "bubble", the standing wave shown in **Fig.4C** is nevertheless a stable, natural, and resonant "standing wave", with a frequency which is exactly twice the frequency of the input AC voltage.

It is possible to create partially stable and semi-resonant responses, using one eighth, one sixteenth, or shorter lengths of wire, by using additional devices which can remove electrical power from the system, or which can generate effects which are usually called "harmonics". However, those are not the types of natural and stable responses which can be created by a simple, basic system consisting of nothing more than: (i) a wire having a fixed length and a "reflective" tip; and (ii) an AC power source with a frequency which can be "tuned" until it creates a resonant response in any wire segment having a suitable length.

Therefore, since quarter-wave wire lengths are the shortest lengths which can create natural and stable standing waves, the conventional term which is commonly used, to describe what happens when a wire creates a resonant standing-wave response, is a "quarter-wave" response.

In some devices, telescoping components (or other elements which can alter the effective length of a wire-type element) can be used to alter the ability of the element to respond to a fixed wavelength. Many types of antennas use this approach, if they need to process signals which are being transmitted on fixed and known frequencies. However, those examples are not relevant to spiral coil reactors, which will use an approach which involves tuning and adjusting the frequency of the voltage which is being supplied to a reactor, until a resonant response is observed in coils with fixed and unchanging lengths.

It should also be noted that certain types of "tuning" elements (such as capacitors, which can have either fixed or adjustable capacitance levels) can also be coupled electrically to a wire, in a manner which "emulates" adding more length to that wire. This approach can be used to alter (or increase the range of) the frequencies to which a wire circuit will respond resonantly.

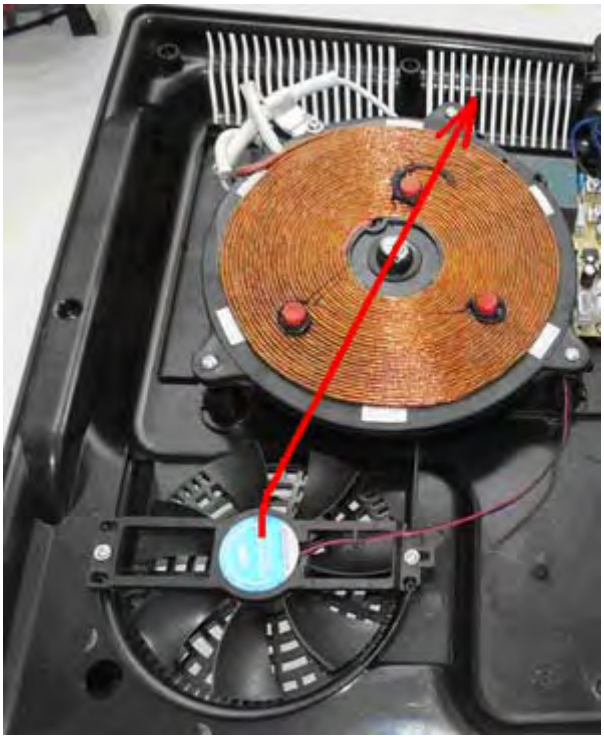
The 'Gegene' Magnetic Arrangement.

As we have seen from what Don Smith has said, a very effective method of gaining additional power is to make a high frequency magnetic transmitter as that allows several outputs to be taken from the transmitter without increasing the input power in any way. Recently, a clever idea for a simplified version of this has been shared on the web. As far as I am aware, this device was first presented by the Lithuanian 'FreeEnergyLT' whose website is at http://freeenergylt.narod2.ru/dynatron/

and the information then replicated and documented by J L Naudin on his website http://jnaudin.free.fr/gegene/indexen.htm and named ‘Gegene’ being short for ‘Great Efficiency Generator’. The clever idea is to use a commercial induction hot-plate as the transmitter. These have recently become available at low cost, this one:

Sold in the UK by Maplin, has power levels adjustable from 300 watts to 2000 watts, and costs only £30 delivered to your address. These devices operate by generating a powerful high frequency oscillating magnetic field which induces eddy currents in any magnetic material placed on the surface of the cooker. That is, cookware which is made of cast iron or steel (not stainless steel which is supposedly non-magnetic). The heating is very rapid and completely uniform across the item of cookware which is very helpful when cooking. The hot plate is controlled by sophisticated electronics which will not switch on unless there is an iron object on the plate and which varies the frequency and current in a way chosen by the designer.

The circuitry produces the magnetic field by pulsing current through a large, flat coil in the centre of the case as can be seen in this photograph of a typical induction plate with the case opened:



The brown coil gets hot, and so there are spacers on it to prevent the cool outer casing form picking up the heat of the coil. There is also a fan which draws air in from underneath the case and blows it across the coil in order to keep the heat down.

In order to use this magnetic transmitter, we need to place a suitable output coil on the plate, and power a load from the energy collected by that coil. This is a fairly recent idea and so there is still a good deal of experimentation going on, testing different coils, and various loads. It is generally agreed that the best load is a non-inductive load with halogen lamps and ordinary filament light bulbs being recommended. Halogen lamps are used in some low-cost commercial heaters, and they are very effective method of radiant heating. In his video at http://www.youtube.com/watch?v=LbAhUwHvJCE, Laurent powers seven separate 400-watt halogen lamps using a small 800-watt maximum plate which has a small 120 mm diameter transmitter coil:

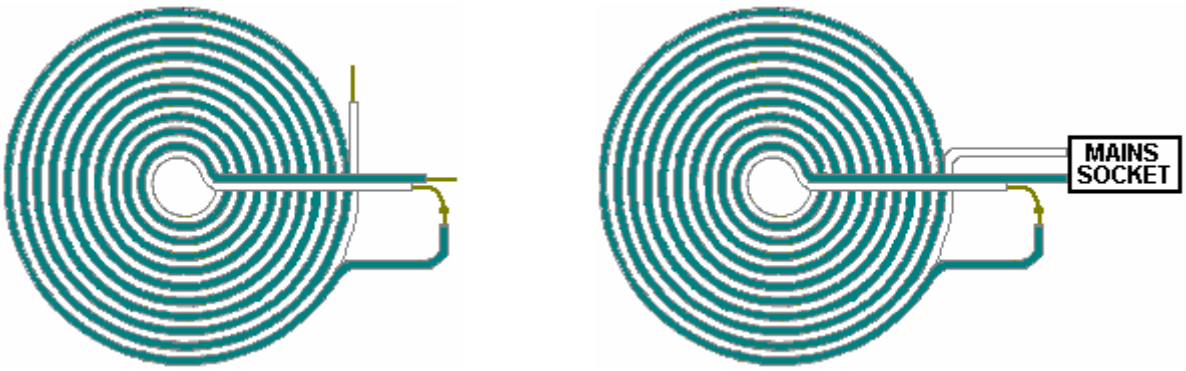
No particular power output is claimed by Laurent, but as you can see, the 2800 watts of halogen lamps are brightly lit while a wattmeter on the input to the plate reads just 758 watts. It seems to be fairly clear that there is a significant power gain with this arrangement. Then, Laurent places an additional coil on top of the first one and shows it lighting a 100-watt filament light bulb very brightly:

It is actually quite difficult to see the brightness of lamps shown in a video as the video camera automatically turns down the brightness of the recording. The important point here is that there is significant power output from a second coil, without there being any increase in the power input to the transmitter coil in the induction plate.

There are many different designs of electronics in commercial induction plates. Most will not start operating until a magnetic object is placed on top of the plate. If that is done, then the object needs to be removed very promptly as it heats up very rapidly. Fortunately, most plate designs keep operating as soon as the induction process is started and so there in no problem with removing the metal cookware (or whatever is used to start the process). Laurent's very small induction plate does not have that protection circuitry and so starts up as soon as it is switched on.

Jean-Louis Naudin uses a 2000-watt induction plate turned down to its 1000-watt setting. It has a 180 mm diameter pick-up coil. He says that for him, it is essential to have at least 1500-watts of load or else the induction plate will shut down with an error code indicating that no cookware is present.

The coils used are Tesla bi-filar pancake types, typically, attached to a thin sheet of MDF or plywood, say 2 mm thick, with superglue. Laurent's 120 mm coil has ten turns and Jean-Louis' 160 mm coil has sixteen turns, needing about 5 metres of twin-core wire, and Laurent's about 2.5 metres of wire. I suggest that the wire should be rated for mains voltage and have, perhaps 1 sq. mm cross-sectional area of copper wire in each conductor. A Tesla pancake coil is wound like this:



Please remember that this arrangement involves high voltages and so is not suitable for newcomers to electronics. This presentation is strictly for information purposes only and it is not a recommendation that you attempt to implement anything shown here, and if you choose to do so, then the responsibility is yours and yours alone.

Tariel Kapanadze's Self-Powered Generators

Tariel Kapanadze, like Don Smith, appears to have based his work on that of Nikola Tesla. There has been a video on the web, of one of his devices in operation, but it appears that the video has been removed. However, part of it can be seen here: http://www.youtube.com/watch?v=l3akywcvb9g The video commentary was not in English and so the information gathered from it is not as complete as it might be. However, in spite of that, a number of useful things can be learned from it. Unfortunately, Tariel refuses to share the details of his designs.

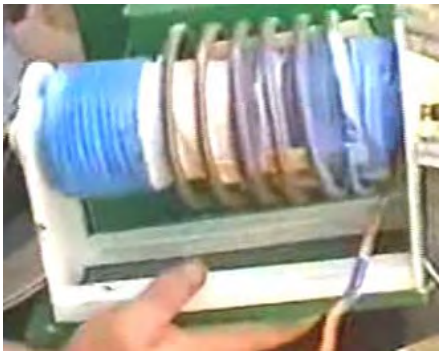
The video shows a demonstration being staged in a back garden, I believe, in Turkey. Strong sunshine was casting dense shadows which made video detail less than perfect. Essentially, Tariel demonstrated one of his builds of a Tesla-style free-energy device, powering both itself and a row of five light bulbs.

One of the most encouraging things about this video is that the construction and operation was of the most basic kind, with not the slightest suggestion of expensive laboratory work or anything high-precision. This is most definitely a backyard construction within the scope of any knowledgeable person.

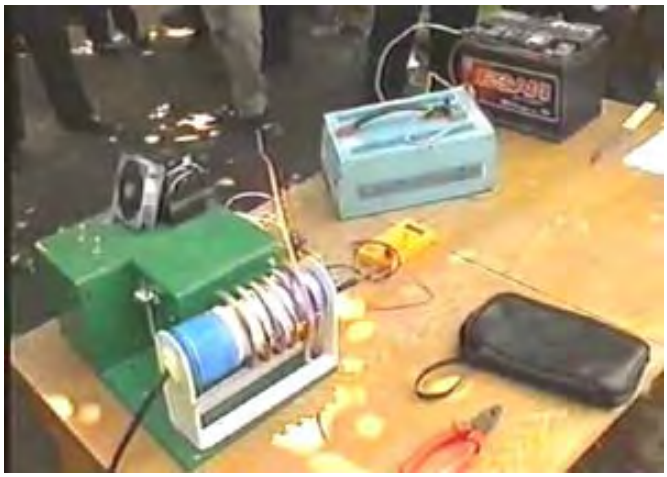
Electrical connections were made by twisting bare wires together:

and where necessary, tightening the twist with a pair of pliers:

This shows clearly that a high-power and very useful free-energy device can be made with the most simple of construction methods - no expensive connectors here, just a zero-cost twisted connection.



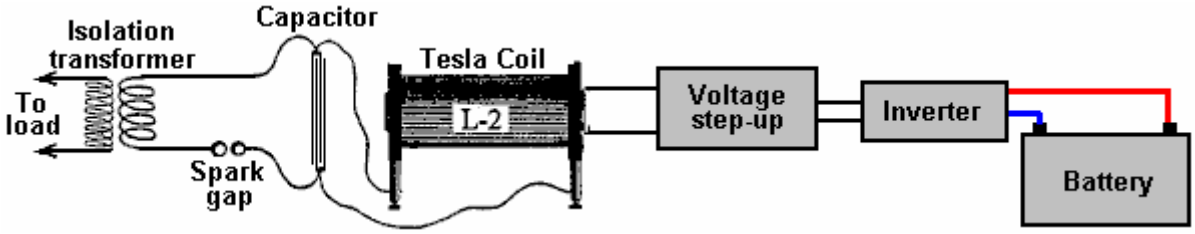
The device being displayed is a Tesla Coil powered, earth-connected system of the type already described. You will notice that the thick primary winding is not placed at one end of the central secondary winding but is much closer to the centre of the coil. Remember that Don Smith states that if the primary coil is placed centrally, then the amount of current which the coil can deliver is very large, in spite of the fact that most people think that a Tesla Coil can only produce trivial currents. Notice also that this Tesla Coil appears to be mounted on a cheap kitchen-roll holder. I have seen it said that Tariel makes a new device for each demonstration and takes it apart afterwards, so if that is correct, then it is likely that there is no great effort or expense involved in making one of these systems.



The main operational components are shown here, placed on one small table. There is a lead-acid battery (which is removed later in the demonstration), what appears to be an inverter to produce mains AC voltage from the battery, a high-voltage step-up system housed in a green box for safety reasons, a Tesla Coil, a spark gap mounted on the box and a fan-cooled component, probably a solid-state oscillator system driving the Tesla Coil. Not seen in this picture, is an item contained in a small box which might well be a high-voltage capacitor.

Two earth connections are organised. The first one is an old car radiator buried in the ground:

and the second is a bare wire wrapped around a garden tap's metal pipe and twisted tight as shown above. It is distinctly possible that the circuit is based on this circuit of Tesla's:



Perhaps, the battery powers the inverter which produces mains voltage, which is then stepped up to a high voltage level by the enclosed electronics. This then drives the Tesla Coil, producing both very high voltage and current with the capacitor storing the energy as a reservoir. The spark gap then pulses this energy, driving the primary winding of the isolation transformer which produces a lower voltage at substantial current (depending on the current-handling capacity of the transformer itself) powering the load, which in this case, is a row of light bulbs.

The load is a row of five light bulbs hung from a brush handle placed across the backs of two chairs:

As you can see, this is not exactly high-tech, high-cost construction here, with all of the materials being used for other things afterwards.

Initially, the battery is used to power the inverter and it is demonstrated that the current being drawn from the inverter is substantially less than the power entering the load. In conventional terms, this appears impossible, which is an indication that the conventional terms are out of date and need to be updated to include the observed facts from demonstrations such as this.

As the system is putting out a good deal more power than is required to drive it, might it not be possible to use part of the output power to provide the input power. This is often called "closing the loop" and it is demonstrated in this video as the next step.

First, the circuit is altered so that the input power connection to the inverter is taken from the output. Then the circuit is powered up using the battery as before. The battery is then disconnected and removed altogether, and the people helping with the demonstration pick up all of the active items and hold them up in the air so as to show that there are no hidden wires providing the extra power from some hidden source. The items on the table are not part of the circuit:

There is some additional information on Tariel including videos of some of his more powerful, newer designs at http://peswiki.com/index.php/Directory:Kapanadze_Free_Energy_Generator#Official_Website although it has to be said that there does not appear to be very much on him or his work available at this time.

In December 2009 an anonymous contributor e-mailed to say that Kapanadze returned to the ex-USSR republic of Georgia and that the video soundtrack is in the Georgian language and after the demonstration, the interview is in Russian. He has kindly translated the parts which relate to the device, as follows:

Question: What are you showing us today?
Answer: This is a device which draws energy from the environment. It draws 40 watts as it starts up, but then it can power itself and provide an output of 5 kilowatts. We don't know how much energy can be drawn from the environment, but in an earlier test, we drew 200 kilowatts of power.

Question: Is it possible to solve the energy problems of Georgia?
Answer: We consider that they have already been solved.

Question: Please tell us in simple terms, how your device works.
Answer: (1) Power is drawn from the battery to get the device running
(2) If we want, we can use part of the output power to drive a charger and charge the battery
(3) When the device is running, we can remove the battery and it then operates self-powered. This particular unit can deliver 5 kilowatts of power which is enough for a family. We can easily make a version which supplies 10 kilowatts. We don't know what the practical power limit is for a unit like this. With this particular device we have here, we do not draw more than 5 kilowatts as we don't want to burn out the components which we used in this build.

Question: Does your invention pick up current from mains wires?
Answer: The mains has nothing to do with this device. The energy produced comes directly from the environment.

Question: What do you call your device and do you dedicate it to anyone?
Answer: I would not dream of claiming this device to be my invention, I just found something which works. This is an invention of Nikola Tesla and all the credit is his. Tesla has done so much for mankind but today he is just forgotten. This device is his invention, his work.

Question: Why are you so sure that this is a design of Nikola Tesla's?
Answer: Because I worked from his invention - his design. I discovered how to get automatic resonance between the primary and secondary windings. The most important thing is to achieve resonance. Melnichenko came close to solving this problem. The government of Georgia refuses to take this invention seriously.

Question: You said that resonance must be maintained. Which parts resonate?

Answer: Here (pointing to the green box) and here (pointing to the Tesla Coil mounted on the top of the green box). The resonator is inside the green box and at present, it is secret until patented.

Question: How much would one of these units cost?
Answer: When mass produced, it would cost between 300 and 400 US dollars for a unit which has an output of 5 or 6 kilowatts.

Question: How much did it cost you to build this demonstration device?
Answer: About eight thousand (currency not specified). Parts had to be got in from twenty different places.

Question: Is this your house?
Answer: No, I rent this place because we have sold all that we have to make these devices. And, having done it, the government and many scientists say "We are not interested because a device like that is impossible and can't possibly exist!". I have not been allowed to make a presentation to them, but people who understand the Tesla Coil understand how this device works.

Kapanadze is an architect by profession and has not had any training in either physics or Electrical Engineering. The information on which this design was based was downloaded free from the internet.

One of the most important aspects of this video is the confirmation it gives for the work of Tesla and of Don Smith, in that it shows clearly, yet again, that large amounts of energy can be drawn from the local environment, without the need to burn a fuel. Another video: http://www.youtube.com/watch?v=gErefbcTz-U

People frequently ask for construction drawings or alternatively, outlets where they can buy one of his devices. Unfortunately, Tariel is not willing to share the details of his designs and so they will probably never be manufactured. Many people have tried to analyse and replicate his design.

Kapanadze Analysis by William McFreey

Shown below are two analysis papers on Tariel Kapanadze's designs. These papers by William McFreey are written primarily for physicist, and so they may not be easily understood by you if you are not familiar with scientific symbols and notation, so please feel free to move past this section..

While William McFreey's paper is highly technical, the designs disclosed in it have been prototyped and proved to be fully functional. However, it needs to be understood that there are several ways of extracting free-energy from our local environment. For example:

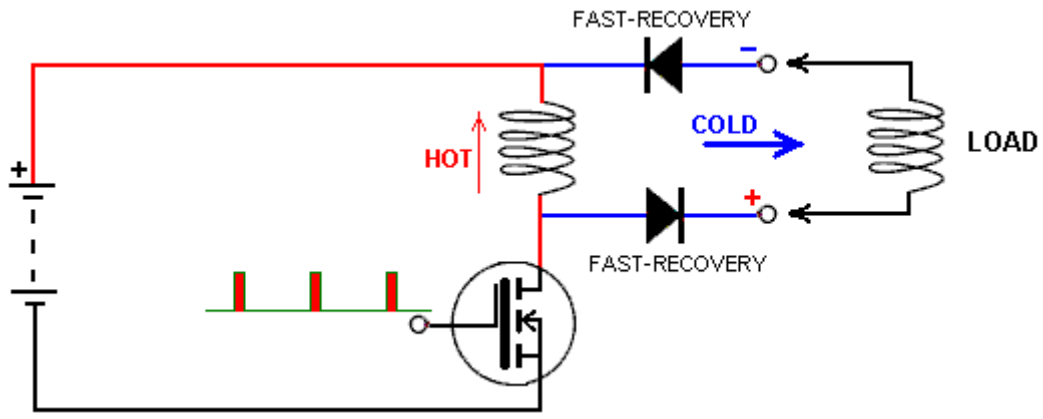
1. Thomas Henry Moray demonstrated that it is possible to draw kilowatts of energy directly from the local environment, using an aerial of relatively minor dimensions.
2. Stanley Meyer demonstrated that water can be separated into a hydrogen and oxygen gas mix using tiny power levels. This allows an ordinary petrol generator to be run self-powered on water alone.
3. Bob Boyce has produced a pulsed toroidal circuit which allows a battery to recharge itself.
4. Robert Adams produced a motor/generator design where permanent magnets generate an electrical output far in excess of the power needed to operate it.
5. Carlos Benitez designed a system which is self-powered and which provides kilowatts of excess power using just simple, standard electronic components.
6. Thane Heins has built and demonstrated simple asymmetrical transformers where the output power is more than thirty times greater than the input power.
7. Clemente Figuera produced a split-transformer design where the Lenz "Law" effect does not apply and so it produces far greater output power than input power.
8. John Bedini designed a pulsed flywheel motor/generator system which ran self-powered for years. Jim Watson built a large version which had many kilowatts of excess power.
9. Dr Oleg Gritskevitch built a self-powered motionless toroidal generator which produced 1.5 megawatts for two years.
10. James Hardy has demonstrated how the jet of water from a powerful water-pump can spin a generator fast enough to self-power the pump and supply additional electrical power for other equipment.
11. Mikhail Dmitriev has produced a gravity-powered generator which uses a small electrical motor to deflect weights on a rotor and that system produces kilowatts of excess power drawn from the gravitational field.

12. Lawrence Tseung has shown how a magnet embedded in an iron frame produces a greater output than the input power when it is powered with DC pulses.
13. Lawrence Tseung has also demonstrated that a heavy rotor powered by electromagnet pulses can have a substantially greater output power than the power needed to drive it.
14. Veljko Milkovic has demonstrated how combining a pendulum with a lever produces a system which has far greater mechanical output power than the mechanical power needed to operate it.
15. Richard Willis has shown how pulsing a magnetic material can produce kilowatts of excess power.
16. James Kwok has shown that introducing air into the bottom of a tank of water can generate tens of kilowatts of excess power through buoyancy.
17. Dietmar Hohl has published his design where permanent magnets cause permanent rotation of a cylinder without the need for any external source of power.
18. Mummar Yildiz has demonstrated a 300 watt permanent magnet only motor and then taken the motor completely apart to prove that there is no other source of power.
19. Lawrence Tseung has produced a variation on the Joule Thief circuit which has greater output power than the input power (something which I personally have built and can confirm).
20. Floyd Sweet produced a system where a tiny amount of power is used to wobble the magnetic poles of a specially conditioned magnet, producing thousands of times greater output power than the input power needed to power the system.

There are many other proven systems. The two papers from William McFreey can be freely downloaded from: http://www.free-energy-info.tuks.nl/McFreey.pdf.

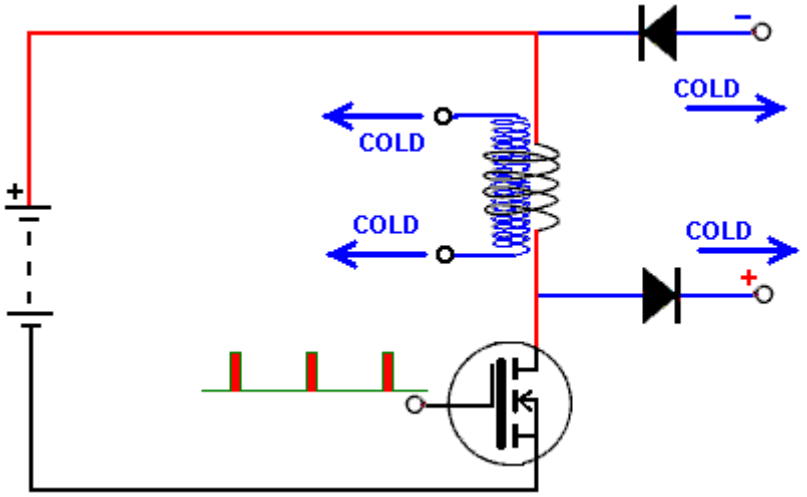
The Cold Electricity Coil of 'UFOpolitics'

A man who uses the forum ID of 'UFOpolitics' has been sharing his insights and experiences on various different forums, such as the one dealing directly with the production and use of cold electricity in solid-state circuits: http://www.energeticforum.com/renewable-energy/10529-my-motors-got-me-tap-into-radiant-energy-1.html His insights are unusual and very important. His basic statement is that if a coil is pulsed, using a circuit like this:



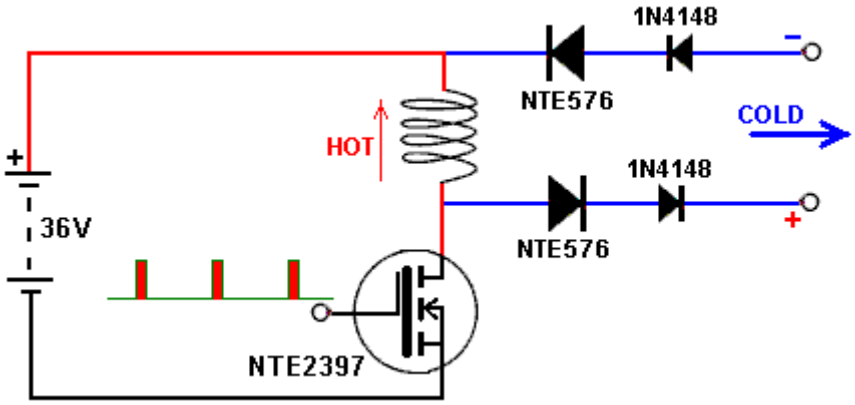
then conventional hot electricity pulses the coil when the transistor is switched ON, but if that current is switched OFF rapidly, then there is an inflow of cold electricity into the coil from the surrounding environment. That inflow of energy can be collected and diverted to power a load through the use of two high-speed diodes which can carry considerable current as the power inflow is substantial. The inflow of energy occurs when the transistor is switched OFF and so it is desirable to have the transistor switched off for most of the time, in other words, a low percentage Duty Cycle for the transistor. There **must** be a significant load on the cold electricity output. If there is not, then the cold electricity will flow back into the hot electricity section of the circuit and it may damage the transistors. Tom Bearden states that resistors boost cold electricity rather than hindering it's flow, so the load should be a coil, a DC motor with brushes or a fluorescent light bulb.

It has been observed that the incoming energy tends to flow inwards towards the centre of the coil, so an additional method of collecting this extra energy is to place a second coil inside the main coil, and wound in the same direction as it, like this:



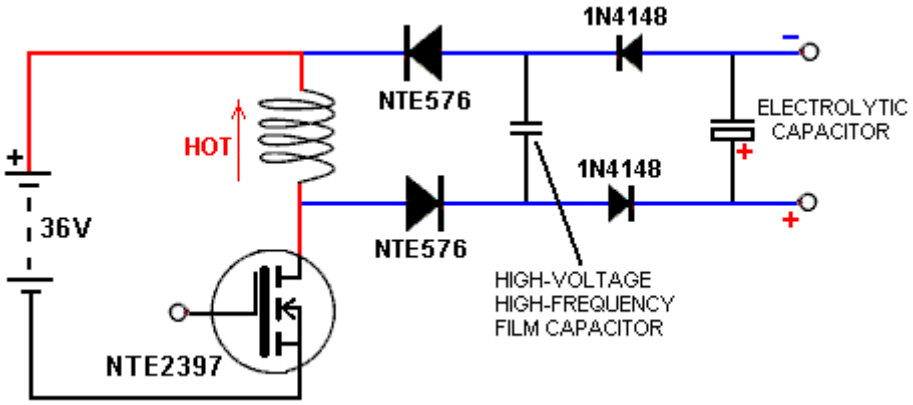
This provides two separate, independent cold electricity power outputs. Diodes are not needed for the inner 'secondary' coil. This inner coil is a pick-up coil and is not related in any way to the number of turns in the hot electricity pulsing coil. Instead, this coil collects inflowing cold electricity during the period when the pulsing coil is switched OFF. The hot electricity pulsing coil can be wound directly on top of the extra pick-up coil or the extra coil can be wound separately and placed inside the main coil spool.

Very surprisingly, it is recommended that the powerful high-speed diode used to channel the cold electricity out of the circuit, be followed by a small 1N4148 silicon epitaxial planar high-speed diode (75V 0.45A) as this is said to clean up the cold electricity output even more. It is important that the cold electricity has to encounter the more powerful silicon diodes before reaching the 1N4148 diodes, so the order of the diodes is very important, and should be as shown here:

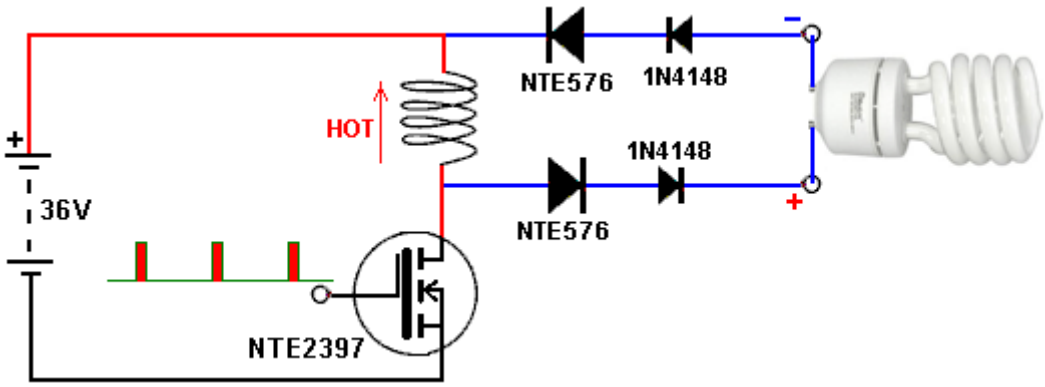


Alternative diodes for the NTE576 (6A, 35nS, 400V) are the NTE577 (5A, 70nS, 1000V) and the HFA16PB (16A, 19nS, 600V). The main requirement is high-speed operation, voltage rating of at least 400V and current rating of at least 5 amps..

There is one additional thing to be done with this circuit when a DC output is required and that is to apply filtering to the output. First, when the energy has passed through the NTE576 (or equivalent) power diodes, it encounters a high-frequency (low capacity) high quality film capacitor placed across the output in order to siphon off any high-frequency voltage ripple before it is passed through the small 1N4148 diodes and into a smoothing and storage electrolytic capacitor. Storing the cold electricity in the electrolytic capacitor converts it into conventional hot electricity.



While this circuit looks like something which you just switch on and it works, that is not the case as there is an essential start-up procedure where the signal applied to the transistor is started at just a few cycles per second and 50% duty cycle and that input is then adjusted carefully and slowly while monitoring the voltages and currents produced by the circuit. This is a seriously powerful system with the capability of producing a major power output.



It is very important that the circuit is not powered up without a suitable load on the cold electricity output. A suitable load is a self-ballasted 230-volt fluorescent light. It must be understood that just flipping the power switch to it's ON position is not sufficient to get an inflow of cold electricity. Instead, it is necessary to progress the start-up sequence carefully, and a fluorescent light is particularly helpful for doing this although a neon bulb is also a popular choice of temporary load, because these devices allow the current flow in the load to be assessed visually.

Before switch-on, the input oscillator is set to 50% duty cycle and minimum frequency. Then the frequency is raised very slowly, causing the lamp to start flashing. As the frequency is raised, the current drawn from the battery needs to be monitored as it is the current flowing through the transistor, and the current is kept down by lowering the duty cycle progressively. This process is continued carefully and if successful, the colour of the light produced will initially be purple or green before reaching continuous bright white light. Videos showing the light produced and the fact that it is not dangerous to life or affected by water can be seen at http://www.youtube.com/watch?v=W1KALMgFscg&list=UUdmFG5BeS0YnD2b5zasXXng&index=1&feature=plcp .

The driving force is a series of powerful magnetic pulses, and implementing the physical circuit to achieve that requires careful construction. The battery driving the circuit is a 36 volt combination of cells. The coil is wound as an air-core construction on a 2-inch (50 mm) diameter spool and the DC resistance is arranged to be about 1.4 or 1.5 ohms. This, in turn, requires a substantial drive from the transistor and so it is normal to connect six powerful output transistors in parallel in order to spread the current flow between them as well as dissipating the heat generated across several transistors bolted to a common heat-sink of generous area.

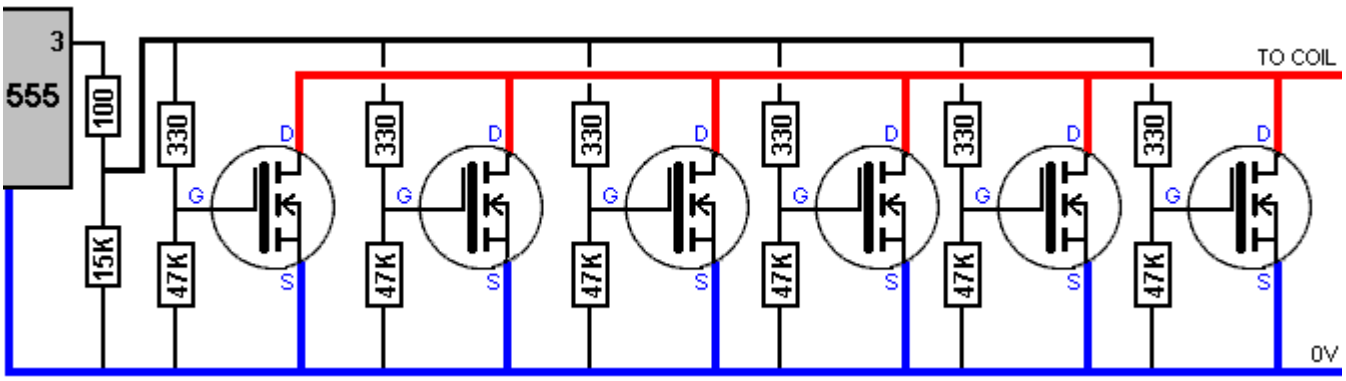
How the coil is wound is something to consider. The objective is to have a coil of about 1.5 ohm resistance and which has the maximum magnetic effect for the current passed through it. Copper wire has become very expensive and so it would be very costly to wind the coil with vast lengths of thick wire, not to mention the very large size and great weight which would be produced by doing that. The copper wire options in Europe are typically to work with half-kilogram reels of wire. The details of some of these are as follows:

Gauge (swg)	Wire length	Total ohms	Amps/strand	Strands	Total amps
14	17.5 m	0.09	9.3	None	-
16	27 m	0.22	5.9	None	-
18	48 m	0.71	3.7	None	-
20	85 m	2.23	1.8	2	3.6
22	140 m	6.07	1.2	4	4.8
24	225 m	15.81	0.73	11	8.0
26	340 m	35.70	0.45	24	11.0
28	500 m	77.50	0.29	52	15.0

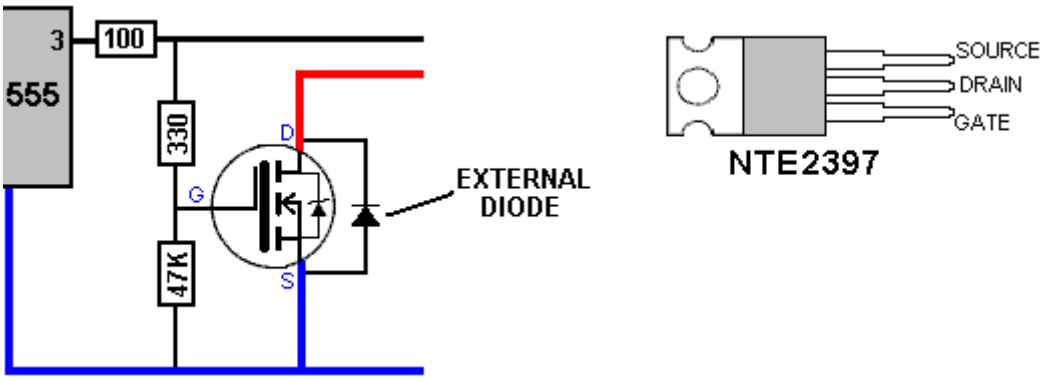
We can see from this that a 500 gram reel of 14 swg wire has a total resistance of just 0.09 ohms and so it would take sixteen reels (weighing 8 kilograms and costing a lot of money) to wind just a one-strand coil using that wire, producing a coil which could carry a current of 9.3 amps. As opposed to that, a single reel of 28 swg could provide 52 separate windings, which when connected in parallel, could carry 15 amps as well as costing and weighing far less. It would be tedious, but not impossible, to wind a 52-strand coil, so a more reasonable number of strands connected in parallel might be used. We are aiming at a DC resistance of about 1.45 ohms in any coil arrangement which we select.

The magnetic field produced by a single strand is generally less than the magnetic field produced by two strands carrying the same total current. So, if we were to pick 22 swg wire, then we could measure out four 133.5 metre lengths, join them at the start, and wind the four strands simultaneously, side-by-side to form a coil with a DC resistance of 1.45 ohms. It is important that the strands are exactly the same length so that they carry exactly the same current and no one strand gets overloaded with current due to it having a lower resistance than the other strands. It should be realised that as the maximum current which the wire can carry is 4.8 amps and the resistance is only 1.45 ohms, the maximum continuous DC voltage which can be sustained by the coil is only 7 volts, and so as a 36-volt battery is being used, we **must** adjust the frequency and duty cycle very carefully, especially since we are starting at very low frequencies. If the full battery voltage is applied continuously to the coil, then the coil will be destroyed.

Various members of the forum have suggested, built and tested different circuits for feeding a variable-frequency variable-duty-cycle drive signal to the output transistor. However, 'UFOpolitics' recommends a simple 555 timer circuit. If you are not familiar with electronic circuits, then read chapter 12 which explains them in some detail, including the 555 timer family of circuits. The point stressed by 'UFOpolitics' is that the output taken from pin 3 of the 555 chip passes first through a 100 ohm resistor and then, every transistor gets a separate feed via a two resistor voltage divider pair. The 47K Gate-to-Ground resistor is to ensure that the FET turns off properly. It may be possible to increase the value of these resistors but they should never be less than 47K.

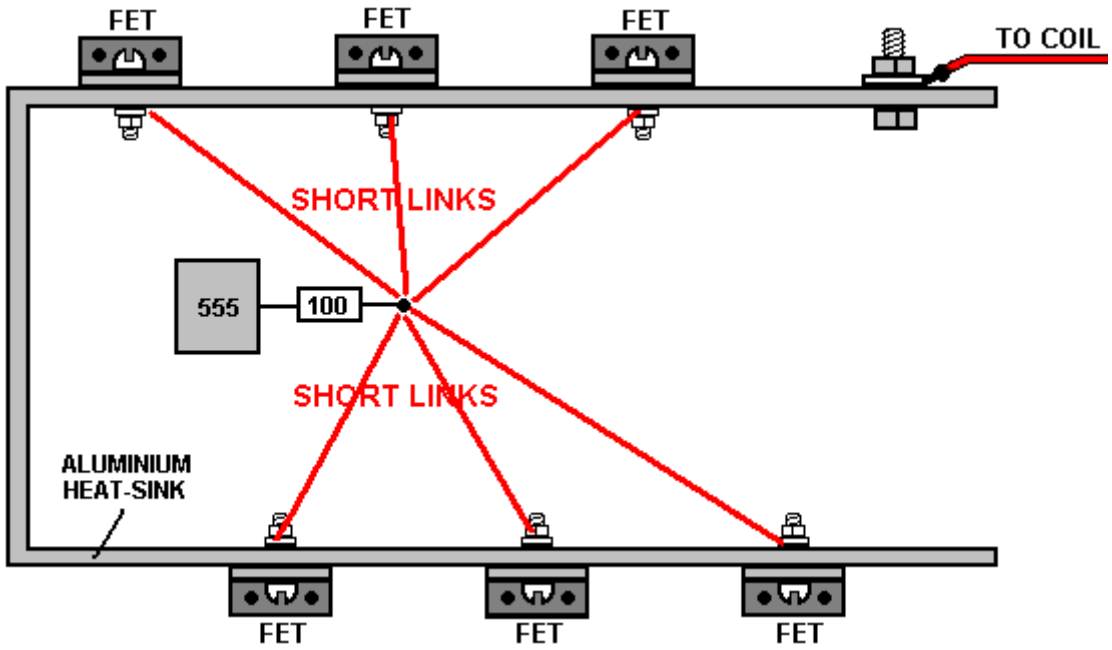


The thick lines in this diagram indicate heavy-duty wiring which can carry high currents without generating any real heat when doing so. It is also recommended that although the FET has an internal diode, an extra external high-speed diode (NTE576 or similar), be connected across each FET in order to boost the switching speed:



A FET has a gate capacitance of about 1 nF. The faster it can be charged / discharged the faster the FET will switch (and stay cool). What determines the speed of charge / discharge for the gate capacitance is the length of wire from driver to gate or gates is inductance (where one metre of wire produces 0.05µH). In addition to that, different lengths of Gate connection wire will create different switching delays and the different inductances can then initiate High Frequency oscillations with repetitive ON/OFF/ON/OFF switching actions. The result might be burned FETS and lack of cold electricity activities.

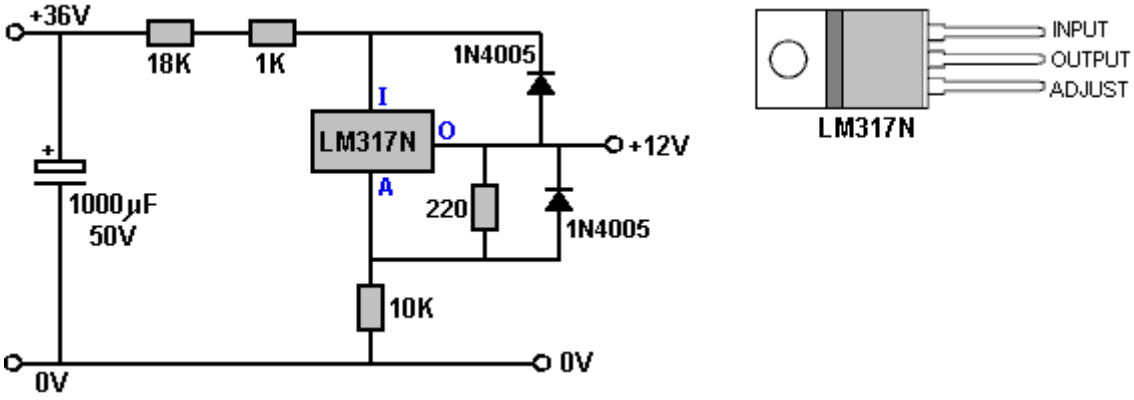
Another point made by 'UFOpolitics' is that the physical layout should have the connecting wires or tracks kept as short as possible and he suggests this layout:



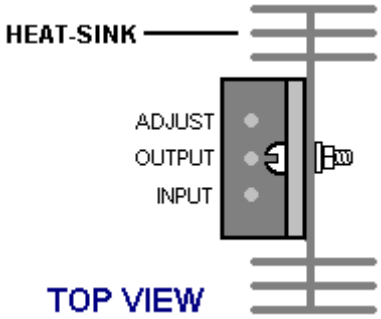
There are two things to note here. Firstly, the 100 ohm resistor coming from pin 3 of the 555 timer IC is positioned centrally between the six FET transistors mounted on the aluminium heat-sink, and that point is carried closer to each FET with a low-resistance conductor to give a good-quality link for the resistors feeding the Gate of each FET. Secondly, the heat-sink itself is also used to provide a low-resistance electrical connection to the coil which the FETs are driving. The connection to the heat-sink is via a nut and bolt clamping a solder tag firmly to a cleaned area of the heat-sink. Each FET is electrically connected to the heat sink through it's mounting tag which forms it's heat-sink connection as well as connecting to the Drain of the Transistor. However, if the aluminium heat sink is a black anodised type, then, apart from cleaning between each FET and the heat-sink contact area, it is worth running a thick wire also linking the central FET pins to the output wire connection point.

The transistors used in the prototype, and recommended for replications are the NTE2397. This is not a very common transistor in Europe at this time and so the popular IRF740 might perhaps be used as it appears to have all of the main characteristics of the NTE2397 transistor. 'UFOpolitics' suggests the 2SK2837 (500V, 20A, 80A pulsed), or the IRFP460 (500V, 0.27 Ohm, 20A and 80A pulsed).

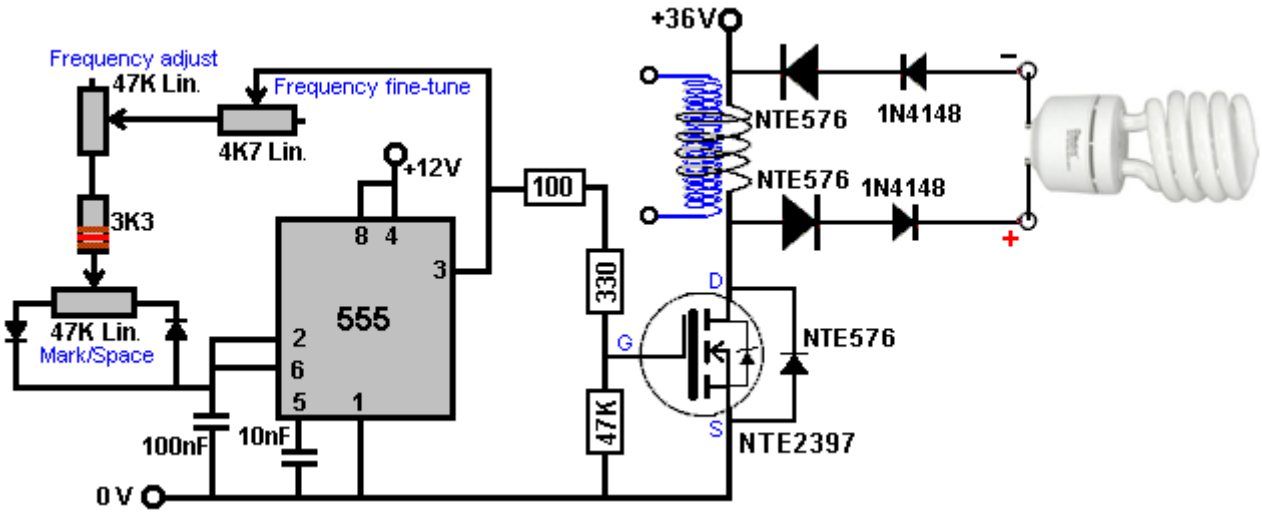
As the 555 timer has a maximum supply voltage of 15 volts, an LM317N voltage-stabiliser chip is used to create a 12-volt supply from the 36-volt battery (a 24V battery could be used):



The LM317N integrated circuit should be attached to a good heat sink as it is dropping off 24 of the 36 volts powering the circuit, and so, has to dissipate twice the power that the NE555 chip uses:



There are various pulsing circuits which have been used successfully with this system. 'UFOpolitics' considers the NE555 chip to be the most straightforward, so perhaps my suggestion for this arrangement might be a suitable choice:

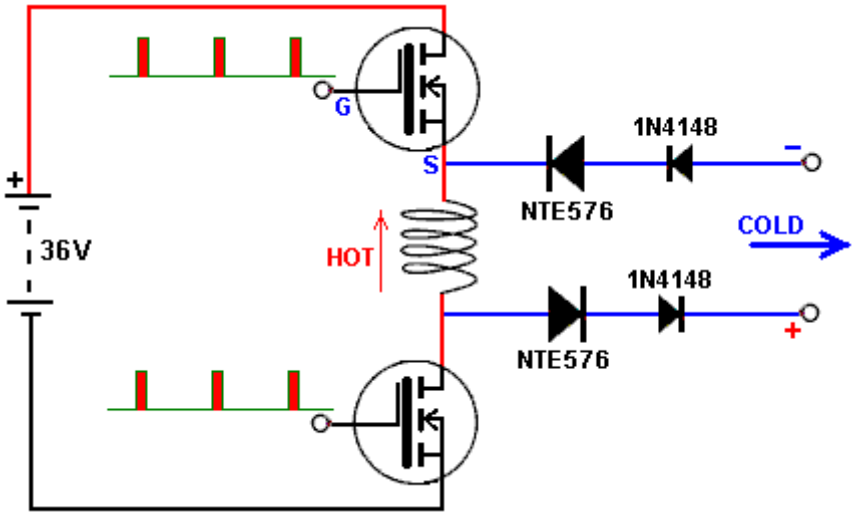


This gives fine control of the frequency and independent adjustment of the Mark/Space ratio or 'Duty Cycle' and it needs only three very cheap components other than the controls. If the expensive multi-turn high quality variable resistors are available, then the 4.7K 'fine-tune' variable resistor can be omitted as those variable resistors make the adjustments easier to control. The 'Lin.' In the diagram stands for 'Linear' which means that the resistance varies steadily at a constant rate as the shaft of the variable resistor is rotated.

In the ‘UFOpolitics’ circuit, it is important to turn the frequency down to it’s minimum value and set the Mark/Space ratio to 50%, before powering the circuit down. Otherwise it would be easy to power the circuit up with a much higher frequency than is advisable and so, causing damage to some of the circuit components.

There are ways to boost the performance over what has already been described. One way is to insert a stainless steel core inside the coil. Stainless steel is supposed to be non-magnetic but in practice, that is not always the case. However, ideally, this steel core is improved by altering it’s crystalline structure by heating it up and then quenching it by submerging it in cold water.

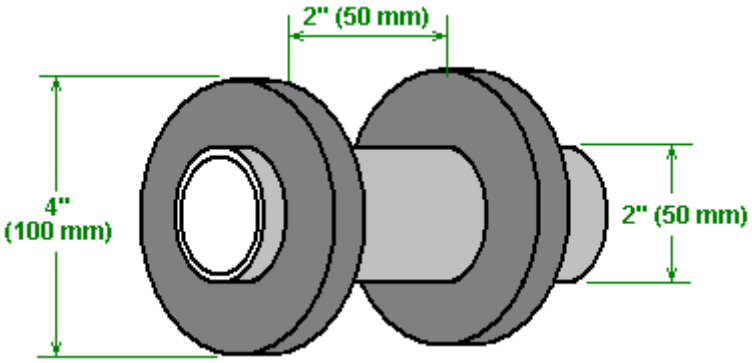
Another improvement is to isolate the coil better at switch-off through the use of a second transistor. Having a ‘switched-off’ transistor at each end of the coil certainly blocks the flow of hot electricity, but if Tom Bearden is correct, the resistance of the transistors in their OFF state will actually boost the flow of cold electricity as it reacts in the reverse way to how hot electricity reacts. The arrangement is like this:



While this looks like a very simple circuit to implement, that is not the case. The upper transistor is switched ON by the voltage difference between it’s Gate “G” and it‘s Source “S”. But, the voltage at it’s Source is not fixed but varies rapidly due to the changing current in the coil, and that does not help when solid and reliable switching of the upper transistor is needed. A P-channel FET could be used instead and that would have it’s Source connected to the fixed voltage of the Plus of the 36V battery. That would help the switching enormously, but there would still be timing issues between the two transistors switching ON and OFF at exactly the same time. Other circuits have been suggested for doing that type of switching, but in the early stages, ‘UFOpolitics’ recommends that things be kept as simple as possible, so using just one transistor is the best option.

Switching speed is an item of major importance, even to the extent that the reduction in the speed of switching caused by using more than one transistor in parallel has caused the suggestion to be made that it might actually be a better option to use just one FET since these high-performance FETs are capable of carrying the whole of the switching current, and it is mainly to lower the FET operating temperature that multiple FET use is suggested. Every extra FET used in parallel, slows the switching down. However, it should be realised that there is a somewhat greater risk of burning the FET out if just one is used.

The coil dimensions recommended are two-inch (50 mm) diameter and 2-inch length. The wound coil is likely to be about three-inches (75 mm) so making the flange diameter 4-inches (100 mm) is realistic:



The recommended material is fibreglass which has high heat-resisting properties as well as being easy to work, the personal choice of 'UFOpolitics' is Polyester Resin with Methyl Ethyl Kethol (MEK) Hardener. A suggested alternative is acrylic, which is not as heat resistant. Acrylic is excellent for high-frequency applications but this circuitry does not operate at high frequencies. Whatever spool material is chosen, it needs to be non-magnetic. When connected in the circuit, the start of the coil winding wire goes to the battery positive.

Here is another coil wound on acrylic tube and with all four diodes connected to the ends of the coil:

It should be understood that cold electricity provides almost unlimited power and it has uses which are not readily understood by many people.

'UFOpolitics' suggests that the hot electricity drive circuitry be tested initially using just a resistive load. If everything checks out correctly, then test with a lesser value resistor in series with the coil, and if that checks out satisfactorily, then testing cautiously with the coil on it's own.

Cold electricity can charge batteries rapidly and after a series of charge and discharge cycles, batteries become 'conditioned' to cold electricity and the experiences of Electrodyne Corp. staff show that large conditioned batteries which are fully discharged, can be recharged in under one minute. A member of the present forum has tried this with the 'UFOpolitics' circuit and he reports:

Yesterday a friend and I took 6 identical, old, 12V, 115Ah batteries and made two 36V banks. We set up bank "A" (the better three) to power the device to charge bank "B". Bank A was 37.00v at rest and Bank B was 34.94V.

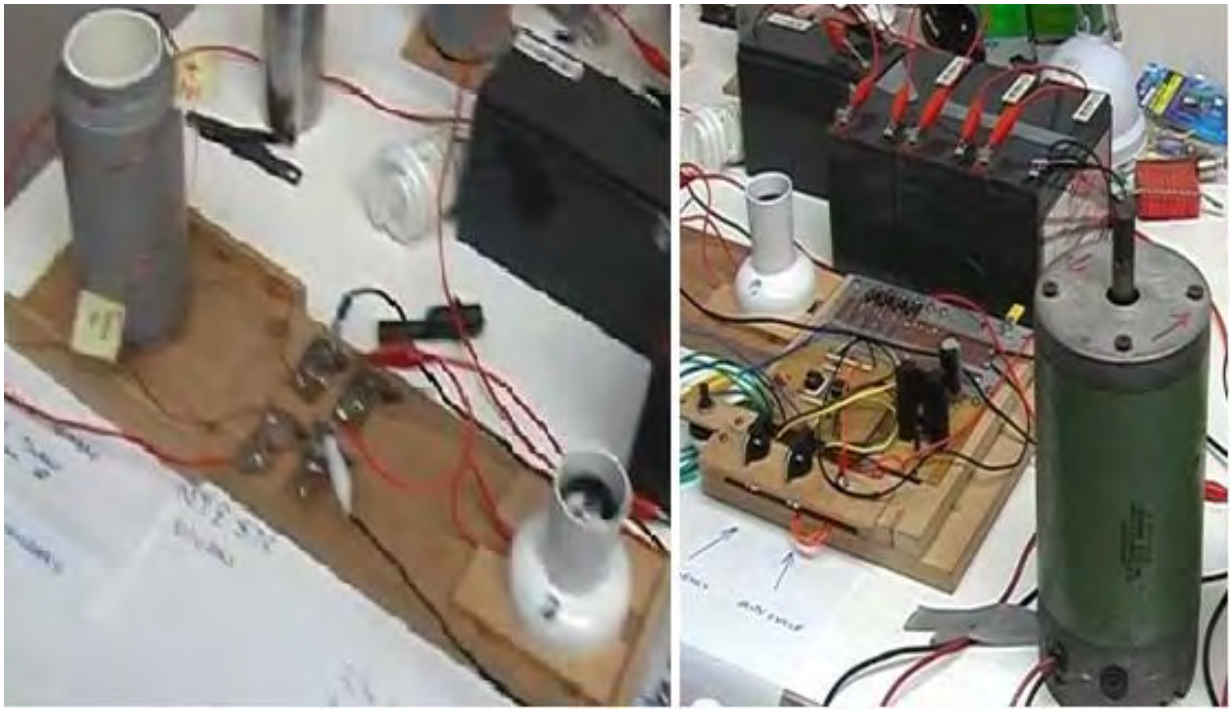
My lowest frequency was 133Hz (I need to change my cap and add another 100k pot with the one which is controlling the frequency) and the duty cycle was at 13%. We started at 2A draw on the Primary circuit.

As I raised the frequency, the batteries on charge jumped up to 38.4V then dropped evenly to 36.27V and started up again (at about 0.01V every 2 seconds). After two and a half hours, they were up to 39.94V. At this point we stopped the charging and let everything rest for 10 minutes. So far everything seems very normal for this kind of charging, except that the device appears to be very stable and powerful...pushing the batteries right on up continuously. The Primary battery voltage dropped initially to 36.20V and stayed there the whole time, then recovered to 36.98V during the 10 minute rest.

Then we switched battery banks A and B and charged the opposite way for about 20 minutes. We stopped and rested things again, swapped the banks back and started charging bank B again for another 20 minutes and stopped. After letting the batteries rest for a few hours in order to get truer readings, bank A was at 37.07V and bank B was at 38.32V. Both battery banks had gained power. These were not very good batteries, either. One of the bank B batteries was at 10.69V at the start. Another interesting note: The amp draw on the Primary dropped from 2A to 1.5A as the frequency was raised from 133Hz to about 550Hz.

This was with the very first use of cold electricity with these low-grade batteries and a major improvement can be expected after many additional charge/discharge cycles. This completely overcomes the factors which make a battery bank unsuitable for household power. If an entire battery bank can be recharged in just minutes, then it opens the way for serious household power using a battery bank.

Cold electricity can also run motors very powerfully. Forum member 'Netica' found that putting a capacitor across the motor terminals improved the running very substantially, giving impressive performance. His video of this is at http://www.youtube.com/watch?feature=player_detailpage&v=7uAYKhrPDPc and the motor, running off an air-core coil with no steel insert. His set-up looks like this:



It is also possible to submerge cold electricity circuits in water without causing any harm:

A video of this is located here: http://www.youtube.com/watch?v=W1KALMgFscg&feature=channel&list=UL including demonstrating the use of very powerful light bulbs. A general running demonstration is here: http://www.youtube.com/watch?v=yVzhKpEqUgc&feature=player_embedded .

Stanley Meyer's Electrical Particle Generator.
Stan, who is famous for his water-splitting and related automotive achievements, actually held about forty patents on a wide range of inventions. Here is one of his patents which circulates magnetic particles in a fluid, and while the fluid does move, none of the other components in the device move and a high level of constructional skills is not called for. This is a highly efficient generator of electricity.

This is a slightly re-worded excerpt from this Stan Meyer patent. Although it does not state it in the patent, Stan appears to make it understood that this system produces a significant power gain – something with Patent Offices find very difficult to accept.

Patent CA 1,213,671 4th February 1983 Inventor: Stanley A. Meyer

ELECTRICAL PARTICLE GENERATOR

ABSTRACT
An electrical particle generator comprising a non-magnetic pipe in a closed loop having a substantial amount of magnetised particles encapsulated inside it. A magnetic accelerator assembly is positioned on the pipe, which has an inductive primary winding and a low-voltage input to the winding. A secondary winding is positioned on the pipe opposite to the primary winding. Upon voltage being applied to the primary winding, the magnetised particles are passed through the magnetic accelerator assembly with increased velocity. These accelerated particles passing through the pipe, induce an electrical voltage/current potential as they pass through the secondary winding. The increased secondary voltage is utilised in an amplifier arrangement.

BACKGROUND AND PRIOR ART
The prior art teachings expound the fundamental principle tat a magnetic field passing through inductive windings will generate a voltage/current or enhance the voltage across it if the winding is a secondary winding.

It is also taught by the prior art, that a magnetic element in a primary inductive field will be attracted at one end of the coil and repelled at the other end. That is, a moving magnetic element will be accelerated in motion by the attraction and repulsion of the magnetic field of the primary inductive winding.

In the conventional step-up transfer, the voltage across the secondary is a function of the number of turns in the secondary relative to the number of turns in the primary winding. Other factors are the diameter of the wire and whether the core is air or a magnetic material.

SUMMARY OF THE INVENTION

The present invention utilises the basic principle of the particle accelerator and the principle of inducing a voltage in a secondary winding by passing a magnetic element through it.

The structure comprises a primary voltage inductive winding having a magnetic core, plus a low-voltage input. There is a secondary winding with a greater number of turns than the turns in the primary winding, plus an output for using the voltage induced in that winding.

The primary winding and core are positioned on one side of an endless, closed-loop, non-magnetic pipe. The secondary windings are positioned on the opposite side of the endless pipe. The pipe is filled with discrete magnetic particles, preferably of a gas, and each particle has a magnetic polarised charge placed on it.

Due to their magnetic polarisation charges, the particles will sustain some motion. As the particles approach the accelerator assembly, which is the primary coil, the magnetic field generated by the coil attracts the particles and accelerates them through the coil. As each particles passes through the coil, the repulsion end of the coil boosts the particle on it's way. This causes each particle to exit from the coil with an increased velocity.

As the magnetic particles pass through the secondary coil winding, they induce a voltage across the ends of that coil. Due to the larger number of turns, this induced voltage is much higher than the voltage across the primary coil.

The main objective of this invention is to provide an electrical generator which is capable of producing a voltage/current of much greater magnitude than has been possible previously. Another objective is to provide a generator which uses magnetic particles and a magnetic accelerator. Another object is to provide a generator which can control the amplitude of the output. Another objective is to provide a generator which can be used with DC, AC, pulsed or other configurations of waveforms. Another objective is to provide a generator which can be used in either a single-phase or a 3-phase electrical system. Another objective is to provide a generator for developing magnetised particles for use in an electrical particle generator. Another objective is to provide an electrical generator which uses readily available components to construct a simple embodiment of this invention.

BRIEF DESCRIPTION OF THE DRAWINGS

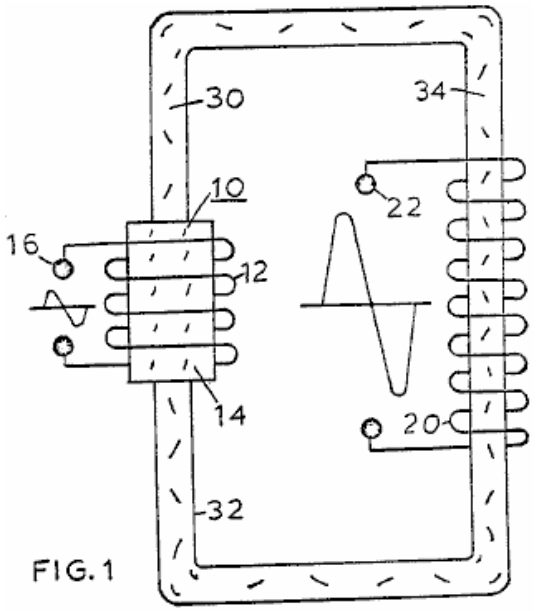


FIG. 1

Fig.1 is a simplified illustration of the principles of the invention, shown partially in cross-section and partially pictorially.

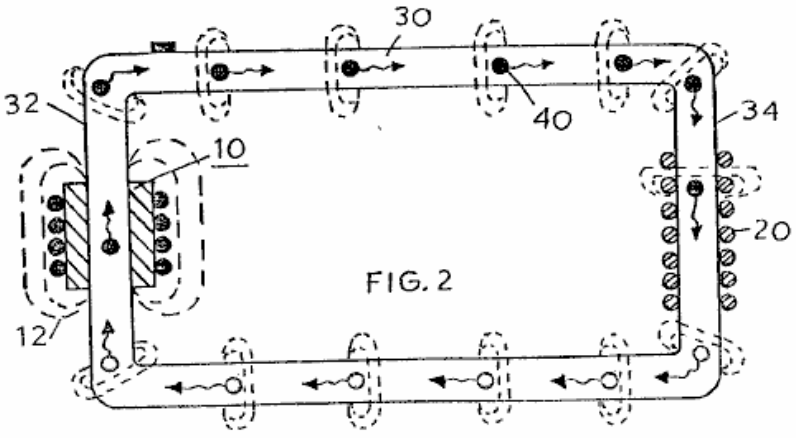

Fig.2 is an electrical schematic illustration of the embodiment shown in **Fig.1**.

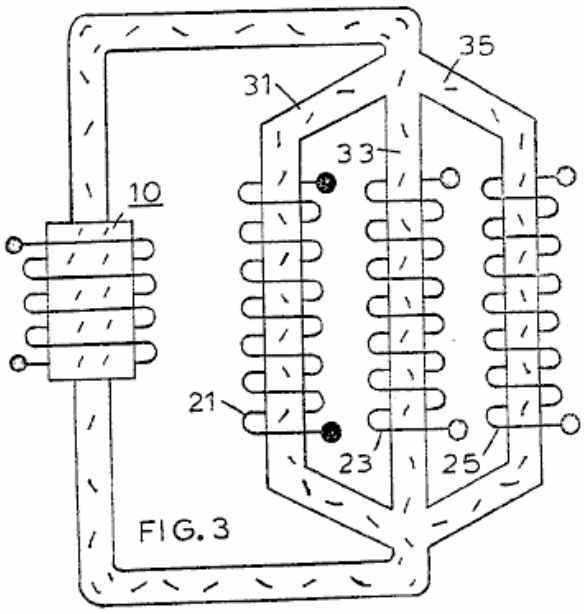

Fig.3 is an illustration similar to **Fig.2** but which is adaptable to 3-phase use.

DETAILED DESCRIPTION

Fig.1 and **Fig.2** show the invention in it's most simplified schematic form:

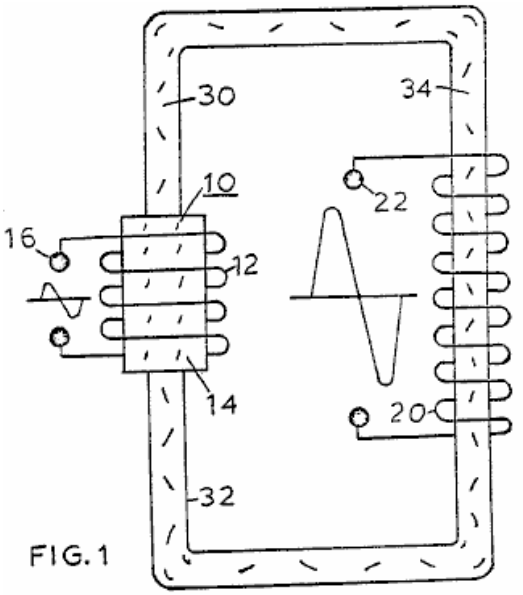

FIG.1

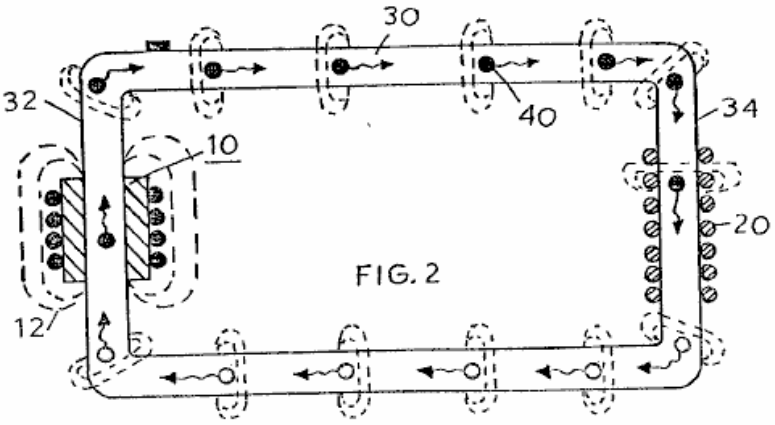

FIG. 2

It comprises a primary coil magnetic accelerator assembly **10**, a closed-loop non-magnetic pipe **30**, and a secondary winding **20**. The magnetic accelerator assembly is comprised of primary windings **12**, a magnetic core **14**, and voltage taps **16**. The primary windings are positioned around end **32** of the closed-loop pipe **30** which is made from non-magnetic tubing.

At the opposite end **34** of the closed-loop pipe **30**, are the secondary windings **20**. The end terminals **22** of the secondary winding **20**, allow the voltage generated in the winding to be used. Contained inside pipe **30**, there is a substantial number of magnetic particles **40** as shown in **Fig.2**. The particles **40** must be light enough to be freely mobile and so may be particles suspended in a fluid medium such as gas, liquid or light-weight movable solid particles. Of these options, the use of a gas is preferred. If solid particles are used as the transporting medium, then it may be desirable to remove all air from inside the pipe in order to reduce the resistance to the flowing particles. Each of the particles **40** is magnetised and the following description refers to one individual particle and not to the mass of particles as a whole.

The voltage applied to terminals **16** of primary winding **12**, is a low voltage, and it's magnitude may be used as an input signal control. By varying the input voltage, the accelerator will vary the speed of the circulating particles, which will, in turn, vary the magnitude of the voltage/current output of the secondary winding **20**. The output **22** of the secondary transformer winding **20**, is a high voltage/current output.

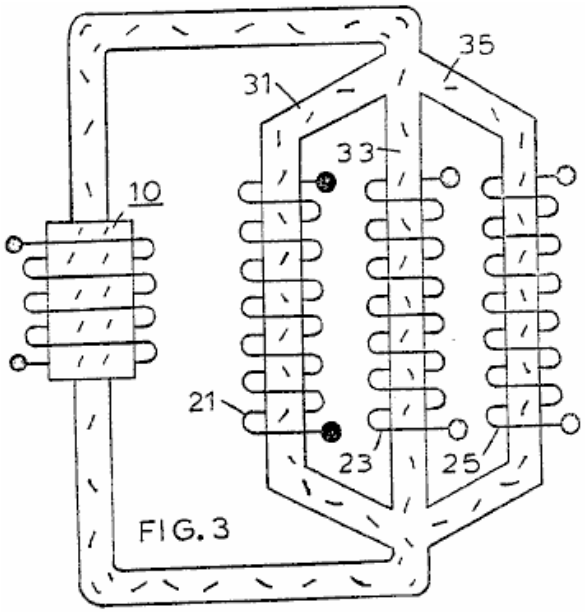

FIG. 3

It can be appreciated that the system shown in **Fig.1** and **Fig.2** where there is just one closed loop, provides a single-phase output in the secondary winding **20**. **Fig.3** shows a closed-loop arrangement with three parallel non-magnetic tubes **31**, **33** and **35**, each with it's own output winding **21**, **23** and **25**. Each of these three windings are a single-phase output, and as their three pipes share a common input junction and a common output junction, these three output windings provide a balanced 3-phase electrical system.

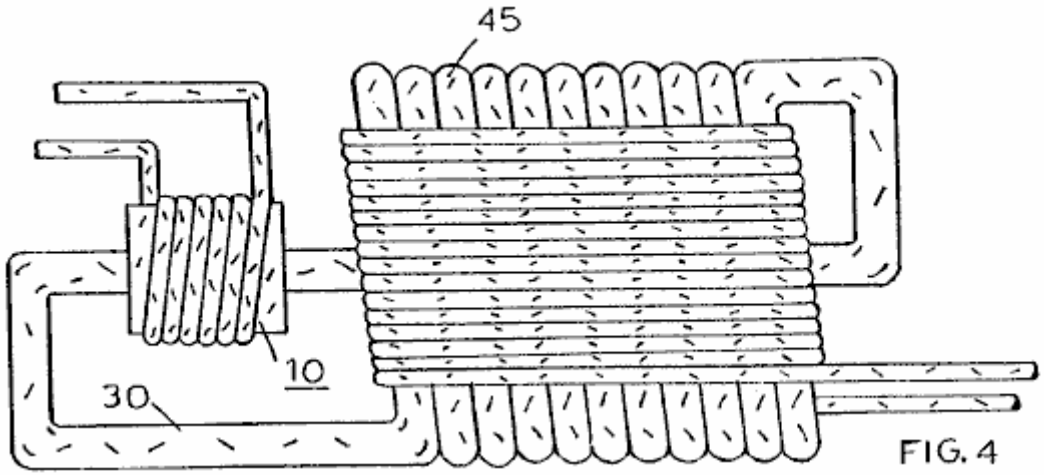

FIG. 4

Fig.4 shows an electrical power generator which operates exactly the same as those shown in **Fig.1** and **Fig.2**. Here, the arrangement is for use in an environment where there is a high moisture content. An insulating coating **45**, completely covers pipe **30** as well as all of the electrical windings. **Fig.4** also illustrates the fact that increasing the number of turns for any given wire diameter increases the voltage/current output of the device. In this physical configuration, both vertical and horizontal directions are used which allows a large-diameter pipe to be used with a substantial number of turns of heavy-gauge high-current wire.

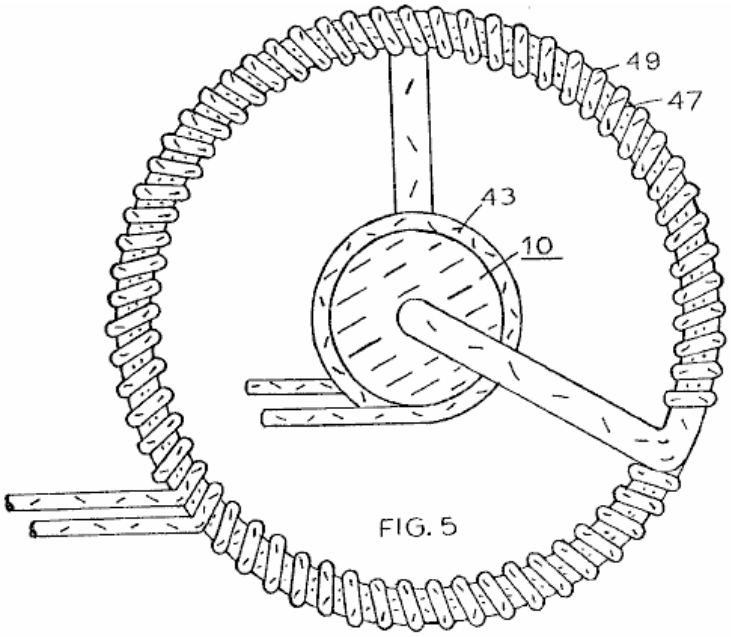

FIG. 5

Fig.5 shows a coil arrangement **49**, which uses the entire magnetic flux in the closed-loop tubing **47**. This is a co-axial arrangement with the primary winding **43** as a central core.

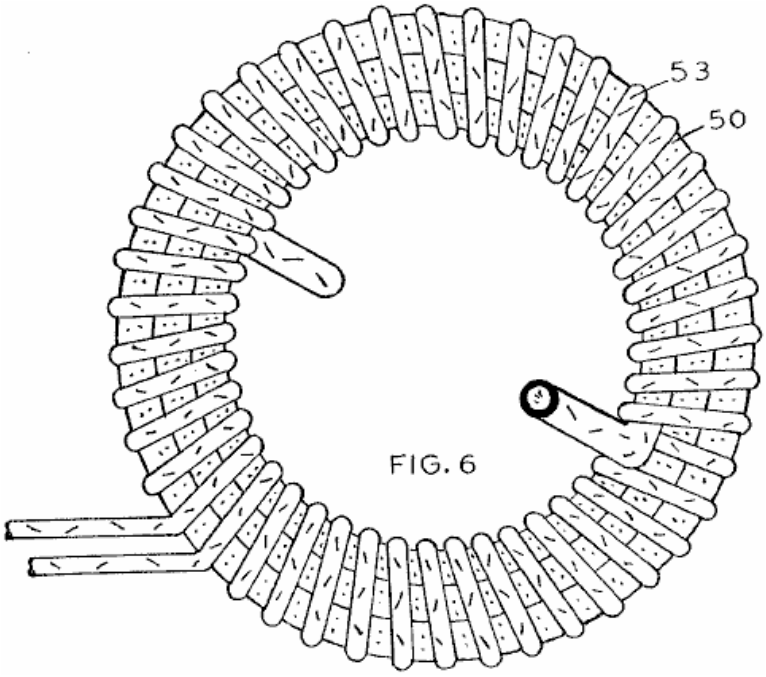

FIG. 6

Fig.6 illustrates a concentric spiral configuration of the tubing **50**, with the secondary windings **53** covering it completely.

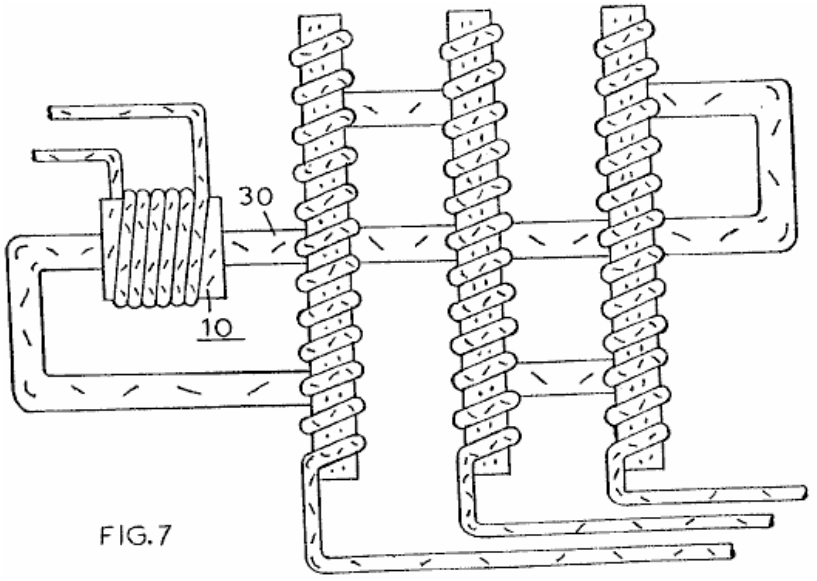

FIG. 7

Fig.7 shows an arrangement where the particle accelerator **10** is wound over the tubing **30** in much the same way as in **Fig.1** and **Fig.2**. However, in this arrangement, the tubing **30** is a continuous closed loop arranged in a series-parallel configuration where there are three secondary windings providing three separate outputs while the tubing **30** runs in series through those three windings.

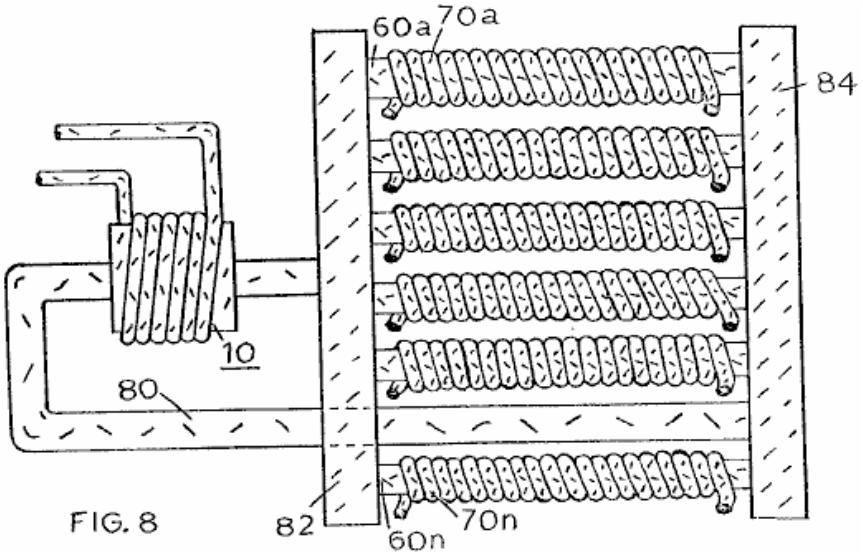

FIG. 8

Fig.8 shows a configuration which is the reverse of that shown in **Fig.7**. Here, there are several pick-up coils wound in series and unlike the earlier configurations, the tubing **80** is not continuous. In this arrangement, there is an input manifold **82**, and an output manifold **84**, and several separate tubes **60a, 60b, 60c, ….. 60n** interconnecting those two manifolds. Each of those separate tubes has it's own separate secondary coil **70a, 70b, 70c, ….. 70n** wound on it.

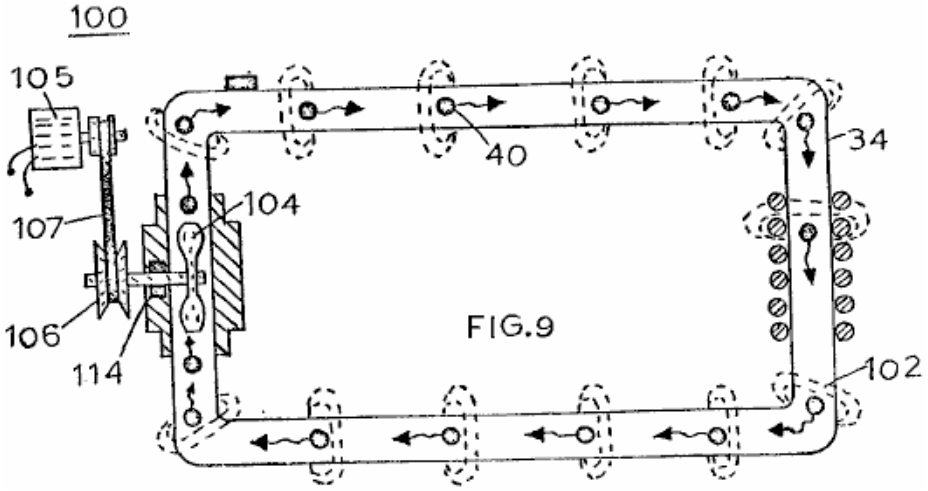

FIG.9

The magnetic particle accelerator **10**, can be different in design to that shown in **Fig.1**. **Fig.9** shows a mechanical particle accelerator **100**. In this arrangement, the magnetic particles **102** are permanently magnetised prior to being encapsulated in the non-magnetic pipe **110**. The particles 102 are accelerated by fan blade or pump **104** rotated by mechanical drive assembly **106**. The mechanical drive for assembly **106** may be a belt-drive pulley **112**, or similar device driven by an electric motor. A sealing bearing **114** keeps the particles **102** inside the pipe **110**.

It has been stated that the magnetic particles traversing the secondary coils, generate a voltage/current in them. It must be understood, however, that that the particles are actually traversing the magnetic field of those coils.

Also, the pipe **30** has been described as a non-magnetic pipe. There are certain non-magnetic pipes which would not work with this invention. Pipe **30** must be capable of passing magnetic lines of force.

A significant feature of each of the various embodiments already described, is the generation of the magnetic particles which are encapsulated within the tubing.

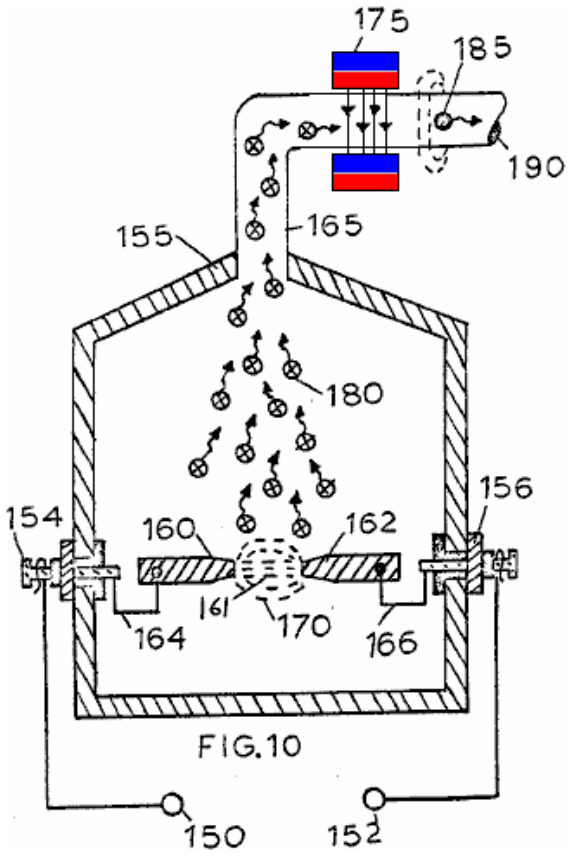

FIG.10

Fig.10 shows an apparatus for carrying out the process of vaporising material to produce suitable particles which are then magnetised by being subjected to a magnetic field. The chamber **155** is an evacuated chamber having

electrodes, made from magnetisable metal, **160** and **162**. A voltage is applied between terminals **150** and **152**, and this drives a current through terminals **154** and **156**, to spark-gap electrodes **160** and **162**, generating an arc which vaporises the tip material of the electrodes, producing particles **180**. These particles rise and enter tube **190**, passing through a magnetic field generator **175**. This gives each particle a magnetic charge and they continue on their way as magnetically-charged particles **185**, passing through port **190** to reach the electrical particle generator described above.

In the simplified embodiment shown in **Fig.1** and **Fig.2**, as well as the other preferred embodiments mentioned, it was indicated that a low voltage was applied to the particle accelerator **10**. Upon acceleration, a high voltage/current would be induced in the secondary pick-up coil **20**. A most significant advantage of the present invention is that the voltage amplification is not related to the shape of the waveform of the input voltage. Specifically, if the input is DC a DC voltage will be output. An AC input will produce an AC output. A pulsed voltage input will produce a pulsed voltage output and an input voltage of any other configuration will produce an output having that same configuration.

The Work of Russ Gries.

Russ Gries has produced a video presentation and analysis of the above Stan Meyer patent. http://www.youtube.com/watch?v=OnAmTmxBpAQ .

The very experienced Alex Petty is joining with Russ in working on replicating Stan's system and Alex's web site is at www.alexpetty.com. A discussion forum linked to this is at http://open-source-energy.org/forum/ and there is information at http://www.overunity.com/index.php?topic=5805.285 and high-resolution pictures can also be seen in Russ' video at http://www.youtube.com/watch?v=JOarpi6sDD4. Russ' own website is at http://rwgresearch.com/ and an additional video of the most recent developmental work being undertaken at: http://www.youtube.com/watch?v=adzVQRsS1KY&feature=youtu.be.

There are various important things which are commented on and Russ is to be commended for drawing attention to them. For the moment, please forget about HHO as that is a separate issue. As far as I can see, the patent does not claim that the device is COP>1 but instead that the device is a power transformer which potentially has a greater power output than conventional transformers since there is no Lenz Law reverse magnetic path from the output coil winding to affect the input power.

Having said that, Stan in his video points out ways to boost the power of the device, namely:

1. Increase the strength of the magnetic particles

2. Increase the speed of the magnetic particles

3. Lower the distance between the magnetic particles and the output winding.

The magnetic particles can be produced in various ways, but the most effective appears to be by filling the arcing chamber with argon gas and using iron, nickel or cobalt electrodes. The reason for this is that the electric arc does not only generate minute particles of the electrode material, but it also interacts with the argon, stripping off electrons and causing some of the metal particles to combine with the modified argon gas molecules to form a magnetic gas. That gas will always remain a magnetic gas due to the atomic bonding as it is not just minute particles of metal physically suspended in a gas due to their tiny size.

You will recall from chapter 1, that the very successful ShenHe Wang magnet motor/generator has a magnetic liquid as a key component. Here, Stan is producing a much lighter magnetic gas and the advantage of that lightness is that it can be boosted to very high speeds without any danger. The larger the number of modified argon molecules, the greater the magnetic effect when they pass through a coil of wire. The argon gas can be passed through the arc chamber over and over again so that a very high percentage of the gas is magnetic. Alternatively, if you are sophisticated in the design of the particle generator, you can arrange for the molecules which have become magnetic, to be pulled off into storage by a magnetic field.

Stan talks about pumping the magnetic gas through whatever pipe loop arrangement you decide to use, by a pump, but he promptly moves on to using a magnetic coil to boost the gas forward as the coil has no moving parts and so, no mechanical wear. This is only one reason. The main reason is that with magnetic acceleration, the gas speed can become very high indeed and in his video he talks about the speed of light. However, I personally do not believe that anything remotely like a speed that great could be achieved inside a pipe loop of small diameter. Nevertheless, speeds well in excess of what a mechanical pump can achieve are likely to be produced by magnetic acceleration.

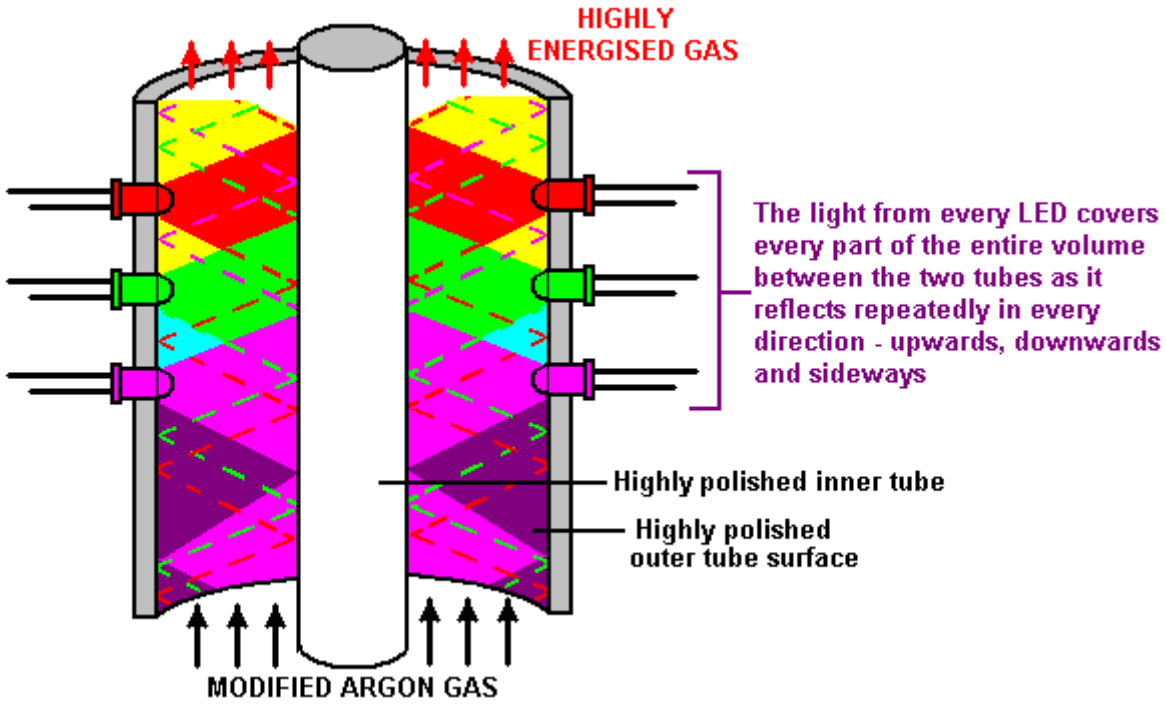
Russ, in his discussion, points out that on most of Stan's surviving prototypes, the coil which is used for the acceleration is constructed using several apparently separate coils, and he speculates that each coil section is powered sequentially, causing a rippling magnetic field. While that is definitely possible, I don't see that a style of coil powering would have any advantage as opposed to powering all of the coils continuously. However, if sequential powering is believed to be an advantage, then the 'Divide-by-N' circuitry of chapter 12 can be used to provide the sequential powering or any more complex sequence.

Stan then points out that the output voltage can be increased by increasing the number of turns on the output coil and/or having additional output coils. This is easily understood conventional electrics. But, he then goes on to point out that the output will also be increased if the electrons of the modified argon molecules are raised to a high orbital level. This places the electromagnetic electrons (as described in chapter 11) closer to the output coils and presumably also allows the gas to be accelerated to a greater speed by the driving magnetic field.

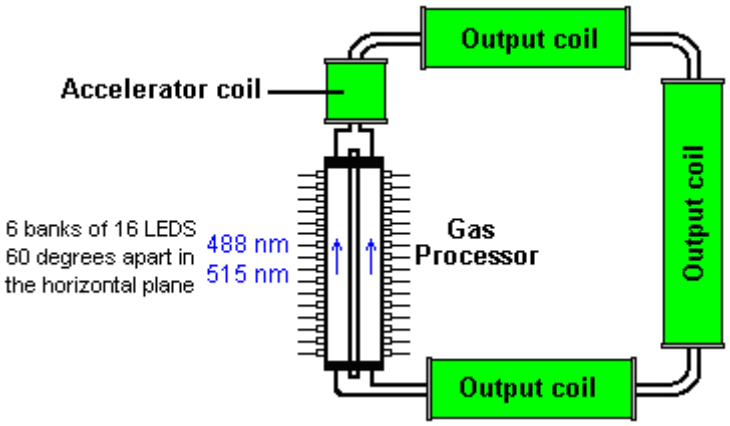
This power boosting of the gas is achieved using Stan's "Gas Processor" described in chapter 10. The Gas Processor pumps electromagnetic energy into the gas through the use of banks of Light-Emitting Diodes which produce light of the correct wavelength to add energy to that particular gas.

If you check on the internet for the wavelength of argon, you find conflicting information, with some sites saying that the wavelength is 1090 nanometres ("nm") and most others saying both 488 nm and 514.5 nm. Most LEDs produce a band of frequencies, so it would be a case of picking LEDs whose band of frequencies include the wanted wavelength.

The Gas Processor itself, consists of a central tube which is polished to a mirror finish on the outside, surrounded by a larger tube which is highly polished on the inside. The LED light is then bounced between these polished surfaces until it is absorbed by the gas which is passed through the gap between the two tubes. This is not easy to illustrate, but it might be shown like this:



In Stan's design, he uses six columns of sixteen LEDs, with each column of LEDs spaced out evenly around the outer tube. So, to boost the Magnetic Particle Generator to greater power levels, a Gas Processor is placed in the loop of tubing:



The Gas Processor normally has a coil mounted at each end and it may be convenient to use coils in those positions as accelerator coils. It may also be an advantage to apply a pulsed high-voltage between the inner and outer tubes of the Gas Processor. As it stands, this looks as if it has a high possibility of being a COP>1 electrical device.

The E-Stress Power Generation System

On the seventh of September 2013 a man with the ID of 'harisingh' published the following information. I have tried to contact him to ask his permission to publish his work, but without any success. I have no information on it other than what is shown here. What he says is:

The E-Stress Power Generating System is a most intriguing over-unity power generating project. It is extremely versatile while being relatively easy to construct and it is readily upgradable.

The Golden Key or Golden Mean is the principle which allows this device to draw power directly from the e-field's relative vacuum energy density using induction-less coils. What makes this design so unique can be seen from the following illustrations. What makes this dual induction-less coil so special is that it nullifies the effects of electrostatic induction using only a fraction of the power required to sustain the charge-displacement which creates the affecting E-field. In conventional electronic circuits, coils and capacitors are generally kept away from each other, but in this circuit, their interaction is the key to success !

The E-Stress Amplifier consists of three cylindrical capacitors and two induction-less coils with external circuitry designed to start-up and maintain the entire system and load. The interior and exterior capacitors, **CDI** and **CDE**, are charged up and kept charged by a voltage source **Vc** which is in the range of 50 to 90 volts DC. The charge on these capacitors remains for a long time, governed by the resistance of the dielectric, (provided that there are no accidental short circuits) so, the energy required to maintain the charge on these capacitors is minimal.

The third capacitor **Cr**, is sandwiched between the interior and exterior capacitors and is independent of **Vc**. When the other two capacitors, **CDI** and **CDE**, become charged, capacitor **Cr** becomes charged as well but at a slightly lower voltage due to dielectric voltage drop. This charging effect is a result of electrostatic induction. Separating the concentric capacitors are two special induction-less coils. When current passes through these coils, the electrostatic induction forces are temporarily neutralised, allowing the charged capacitor **Cr** to discharge and oscillate with an exterior power coil or transformer as shown in **Fig.7**. The induction-less coils **Lo** are pulsed with DC at the same rate as the natural resonant frequency of the tank circuit (**Cr-Lr**). Keeping the pulsing rate within 10% of the tank circuit's resonant frequency will maintain maximum output power. Because of the flexibility in the construction parameters, determining the resonant frequency and power capabilities will be difficult without advanced analysing equipment. So to overcome these difficulties, a variable-frequency oscillator can be used as it allows ready determination of the appropriate frequency range needed. A steady constant load will make this determination easier as well. When the maximum output power is reached, you can measure the resistance of the oscillator's variable resistor to aid in determining, and finally setting, oscillation at the natural resonant frequency of the tank circuit. An additional 1K ohm variable resistor can be connected in series with the 100K variable resistor shown, to allow easy "fine" tuning.

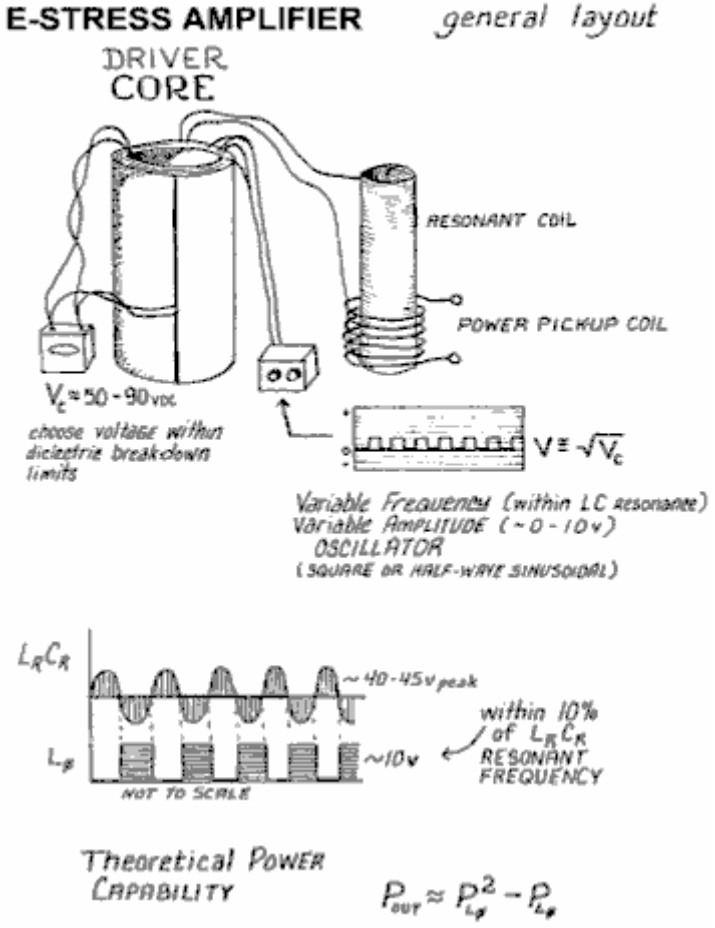


Fig.1 shows the general layout of the entire E-Stress Power System. This diagram illustrates the driver core and the variable frequency oscillator which determines the tank circuit resonance. **Fig.1** also shows the DC power source of around 50 to 90 volts, which initially charges the "core" capacitor **CDI** / **CDE**. Also shown in this diagram is the resonant coil and power output or "pickup" coil.

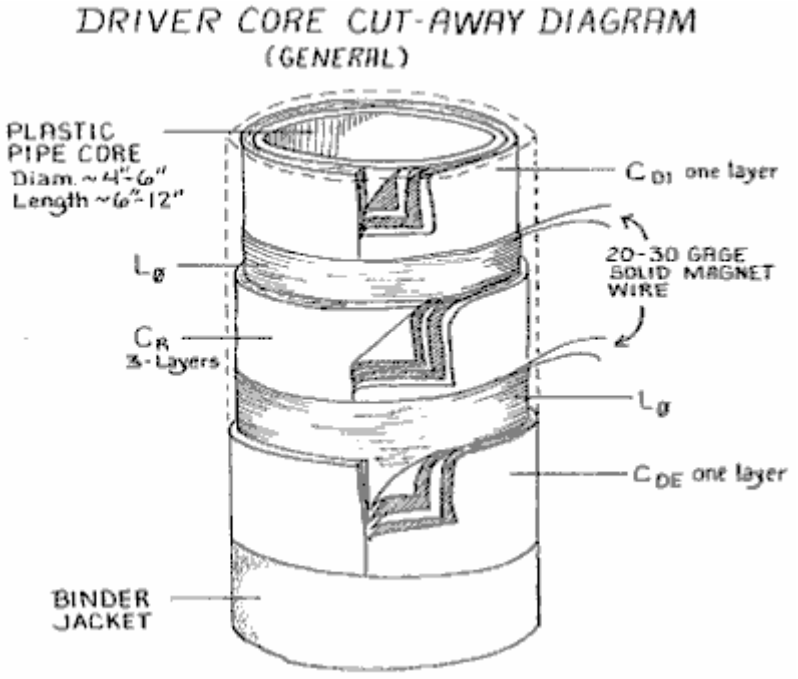

Fig.2 shows the "driver core" in a cutaway, perspective diagram. The PVC plastic "core" material can be a 6 inch (150 mm) diameter foot long (300 mm) piece of PVC pipe in this scaled-down model system. In this diagram, please note the inner and outer one-layer capacitor capacitors **CDE** and **CDI**. Also note that the middle capacitor

(**Cr**) is a three-layer capacitor made from heavy aluminium foil or stainless steel. The induction-less coils can be seen in two places on either side of capacitor **CR**. The induction-less coils are made from solid gauge #20 to #30 magnet wire (0.812 mm to 0.255 mm diameter enamelled copper wire).

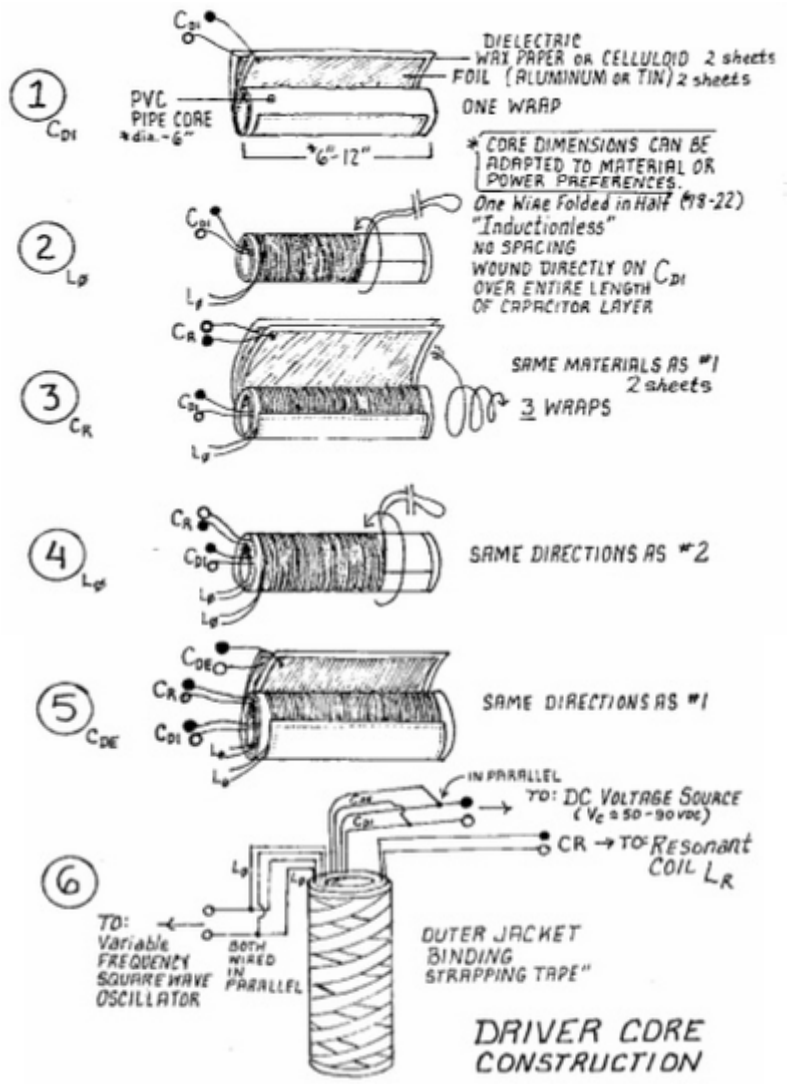

Fig.3 above, illustrates how the centre driver "core" is constructed. There are six basic steps to constructing the driver "core" assembly. First begin with the PVC pipe as shown and begin wrapping the first capacitor **CDI**. Step two shows the first induction-less coil **L1**. Note that for the induction-less coil, the wire is "folded" back and the two conductors are wound together as shown. This coil is single-wound with #18 to #22 gauge wire (1.024 mm to 0.644 mm diameter). Step three shows the centre capacitor **Cr**. This capacitor is created in the same manner as the previous capacitor except that it has three layers of turns. Step four illustrates the second induction-less coil which is wound in the same direction as the first coil. This second coil **Lo** is single-layer. Step five is the final capacitor **CDE**, which consists of a single wrap, and is wrapped in the same direction as the two previous capacitors. The final step, six, is to wrap the entire assembly with strapping tape to form an outer jacket when finished.

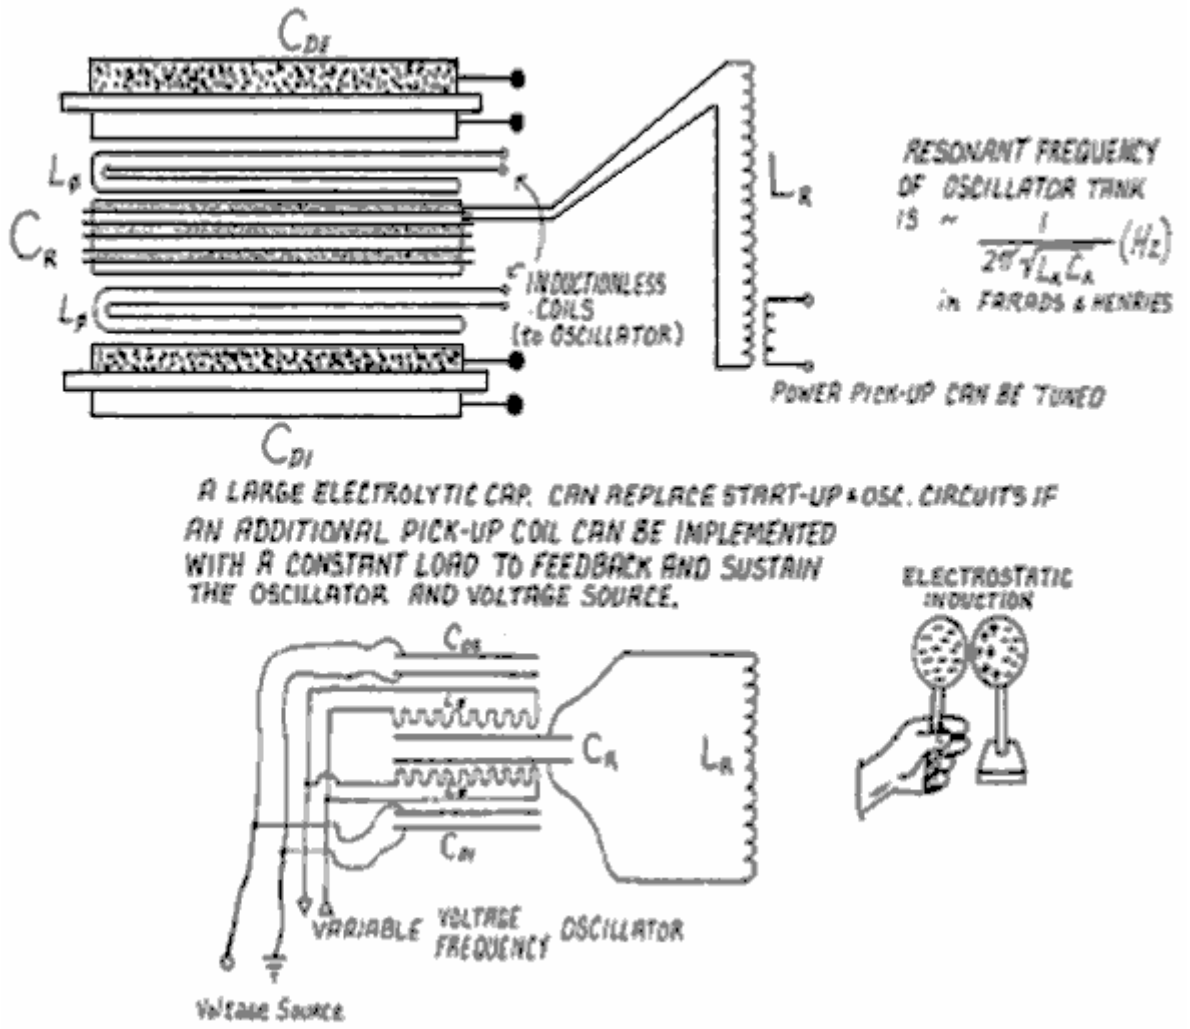

Fig.4 above, is an electrical diagram of the main capacitor "core" and the coil hookups of the E-Stress Power System. Note the parallel connections of the inner and outer capacitors **CEI** / **CDE**, which connect to the 90 volt DC power source. Also note the parallel connections of the induction-less coils which connect to the variable frequency oscillator circuit. The centre capacitor **Cr** is shown connected to the resonant power coil **Lr**.

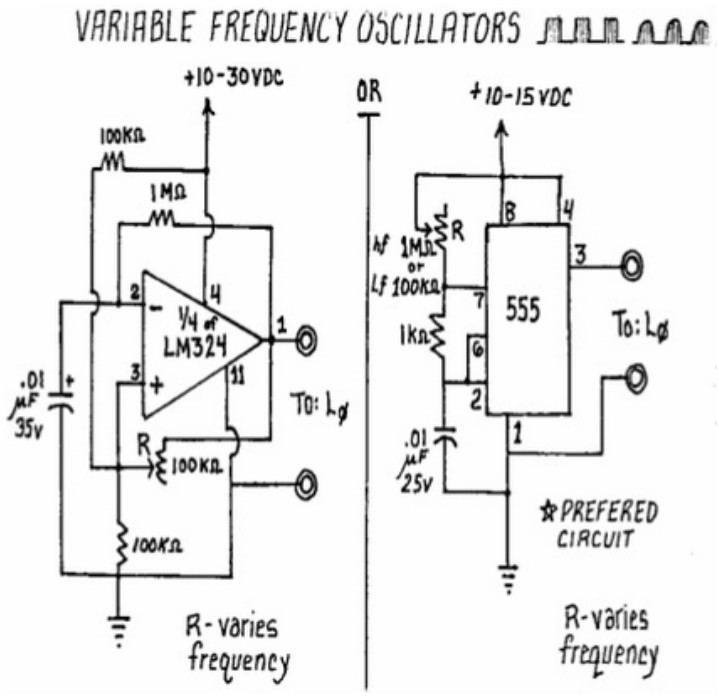

Fig.5 above, displays the two different types of variable frequency oscillators which are used to drive the induction-less coils. The first oscillator displayed consists of an LM324 Op-amp configured to produce feedback and thus oscillate. The second example oscillator consists of an LM555 timer IC. Either example oscillator can be used to drive the induction-less coils.

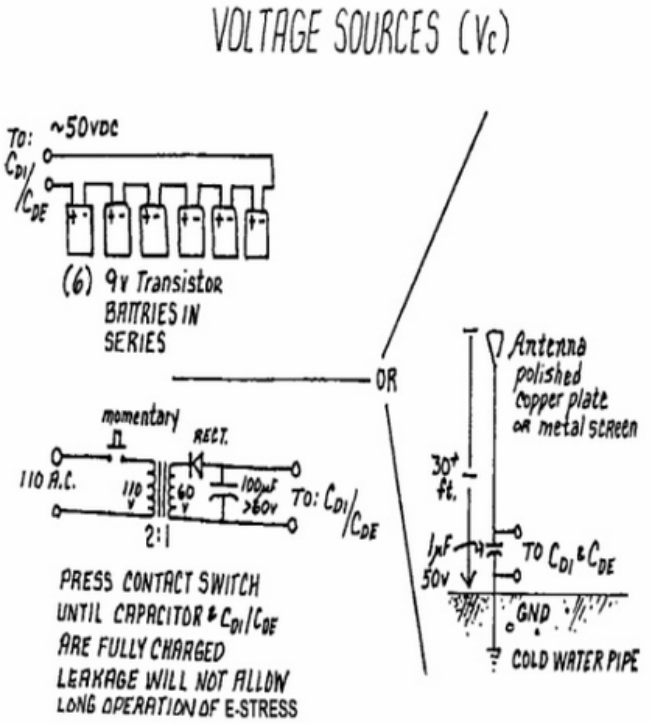

Fig.6 above, shows the DC voltage source **Vc** which is applied to the **CDE** / **CDI** capacitors which are connected in parallel to form the electrostatic field. The DC voltage source could be one of the three types of voltages sources as shown. A battery could be used, which consists of six nine volt batteries. You could also fabricate an AC to DC power source or you could elect to create your own antenna DC source as shown. The battery method affords a quick means to test the circuitry and is safe as well.

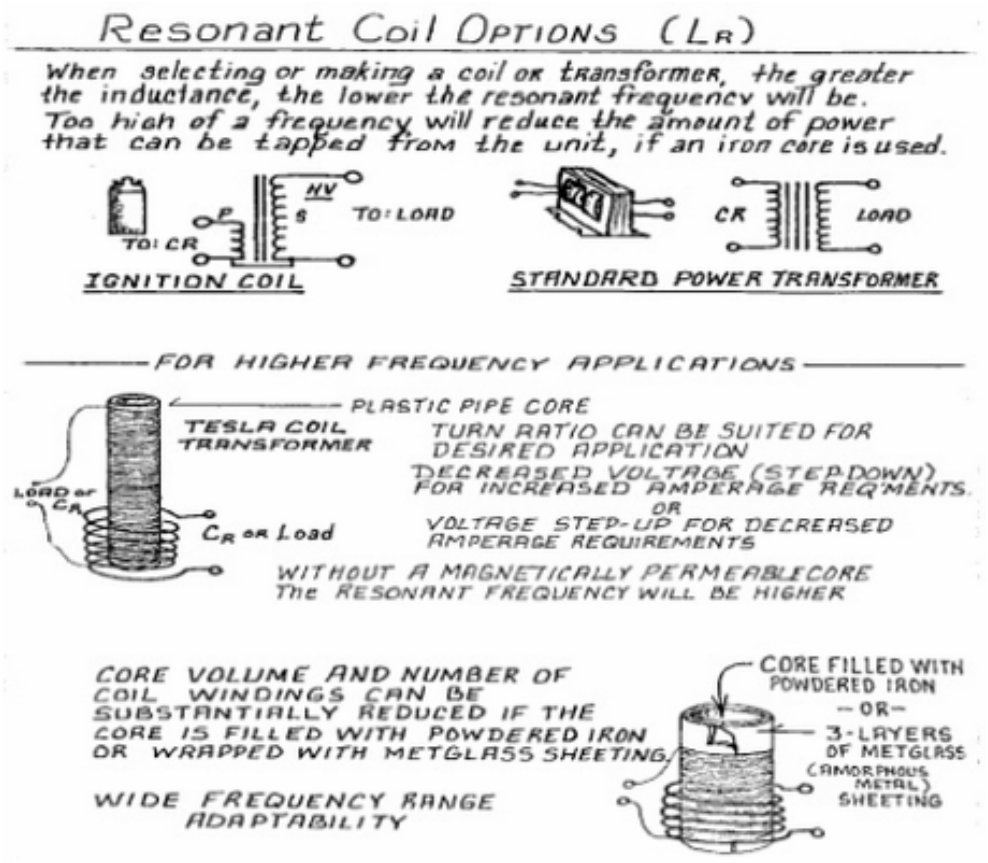

Fig.7 above, illustrates the options for the two different types of resonant coil **Lr**. Basically, there are two coil options: the standard iron core power transformer and the high frequency Tesla type coil such as the ignition type coil. You will need to determine the type of output you wish to have in the overall design. For conventional designs you would most likely construct the standard transformer shown at the bottom of the diagram, which consists of a core filled with powdered iron or Metglass.

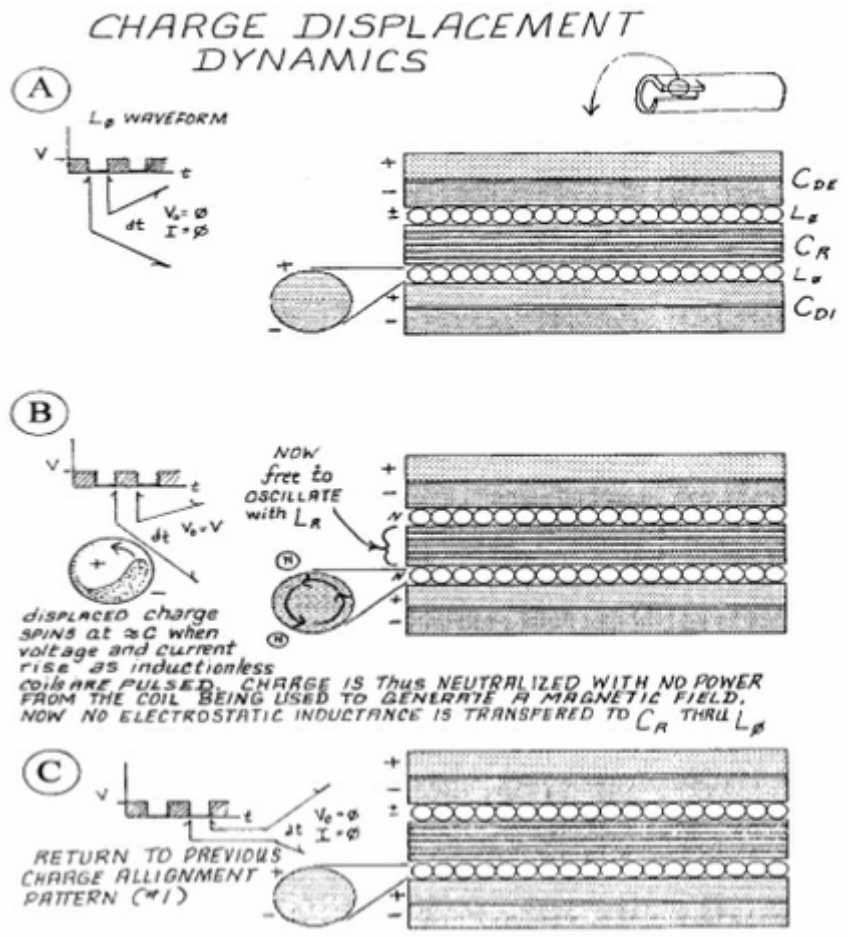

Fig.8 above, discusses the charge displacement dynamics involved in the E-Stress Amplifier power system. Diagram **A** illustrates the induction-less coil **Lo** waveform. Diagram **B** depicts the displaced charge spins when the voltage and current rise as the induction-less coils are pulsed, while diagram **C** shows the waveform during the return to the previous charge patterns, starting the cyclic over again.

Chapter 4: Gravity-Powered Systems

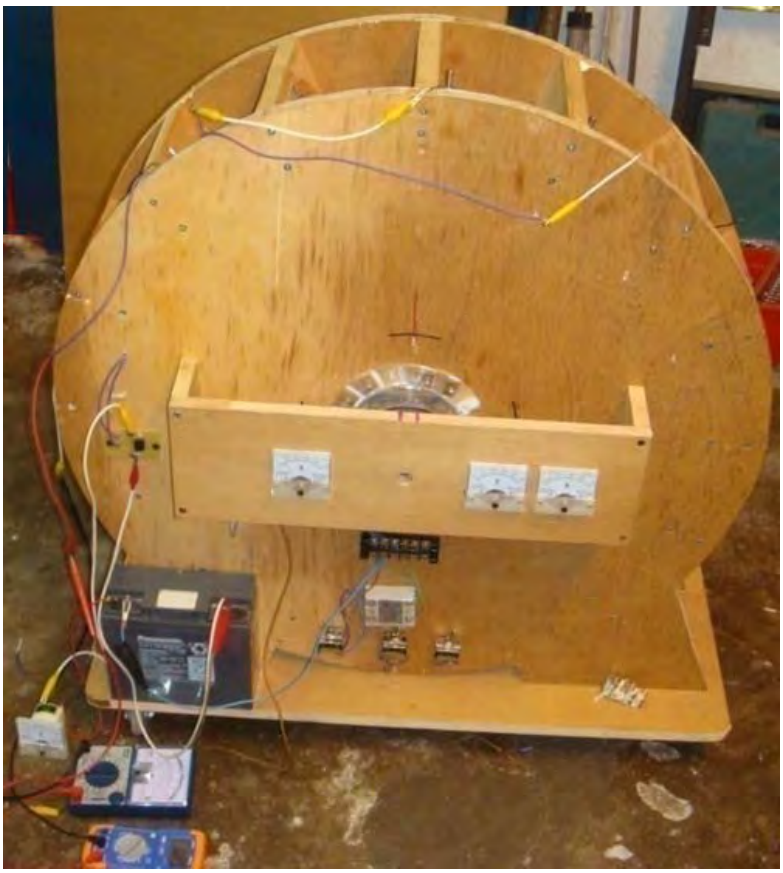
Note: If you are not at all familiar with basic electronics, you might find it easier to follow parts of this chapter if you read chapter 12 first.

Lawrence Tseung's COP=3.4 Pulsed-Flywheel Generator.

It is generally not realised that excess energy can be obtained from pulsing a flywheel or other gravitational device.

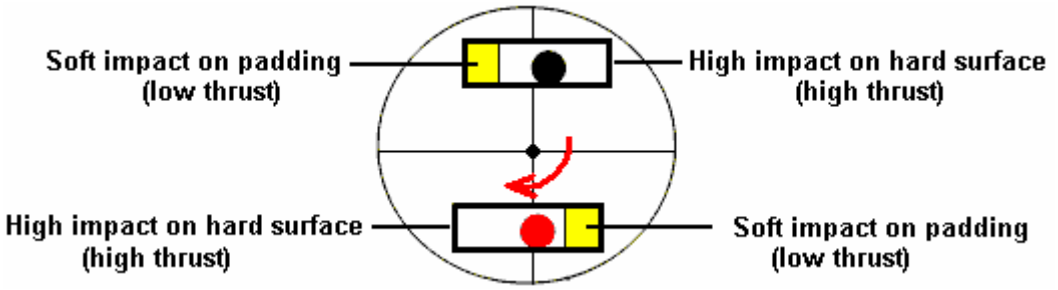
This fact has recently been stressed by Lawrence Tseung who refers to the extra energy obtained in this way as being "Lead-out" energy. This gravitational feature has been part of university Engineering courses for decades, where it has been taught that the loading stress on a bridge caused by a load rolling across the bridge is far less than the stress caused if that same load were suddenly dropped on to the bridge.

This impulse technology has been known for some time and it is demonstrated driving a canoe in the video at http://www.youtube.com/watch?v=aKWPht3fU-o but Lawrence points out the potential for using it as a method for gaining excess energy for practical use. In October 2009, Lawrence and his band of helpers ran public demonstrations of an early prototype electrical pulsing system which produces excess output energy of COP = 3.3, that is, with 3.3 times more output energy than the user has to put into it to make it work:



Video: http://www.youtube.com/watch?v=tiafQ9R-REs&feature=mfu_in_order&list=UL Lawrence is busy developing this device further as he intends to construct one with a output energy excess of several kilowatts.

Behind this device is Lawrence's "Lead-out" theory and for this he suggests a simple arrangement to demonstrate the principle. He presents the case of a rotor which has two substantial weights contained in two cylinders attached to the rotor:

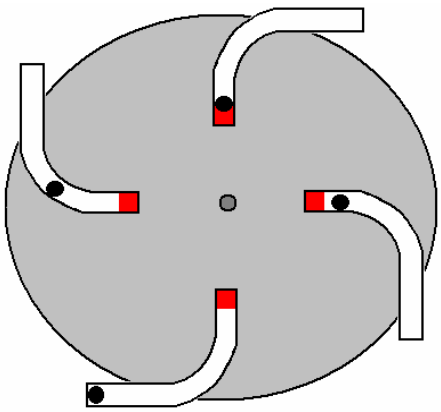


As the disc rotates, the ball falls down the length of the tube. At one end, the tube has a rigid cap which causes a significant impact when the ball hits it. The other end of the tube is padded and that cushions the impact which causes a net imbalance in the impacts and that maintains the rotation.

There is a prototype implementation on YouTube but the implementation is not adequate and the disc stops rotating after five minutes. The YouTube video slot is located at: http://www.youtube.com/watch?v=zykButGc22U&feature=related and there are two significant problems with that particular build. Firstly, the tube rotation is too slow to be effective and instead of the weight falling under gravity and accelerating to a good speed before the impact, the weight just rolls gently down a minor slope and does not make a major impact.

Secondly, the weights are far too small for the size of the wheel and there are only two weights providing impacts very widely spaced apart as the wheel rotates only slowly. One man made a ten-foot version and it rotated steadily for ten months after which time his wife insisted that it be taken apart as it was too noisy.

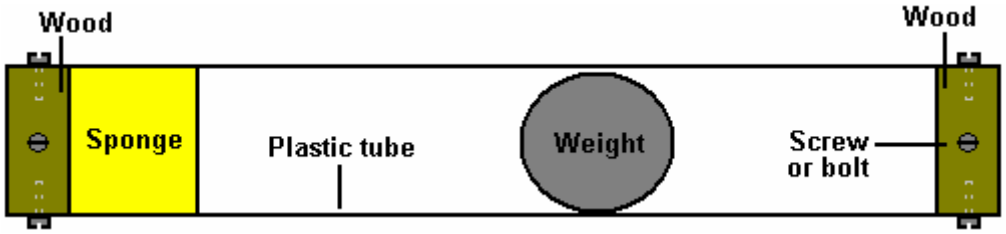
I would suggest some modifications to the wheel as Lawrence is far too busy with developing his COP>1 pulse implementation. Firstly, the movement of each weight should be delayed until the tube is much nearer the vertical. This can be achieved by curving part of the tube like this:



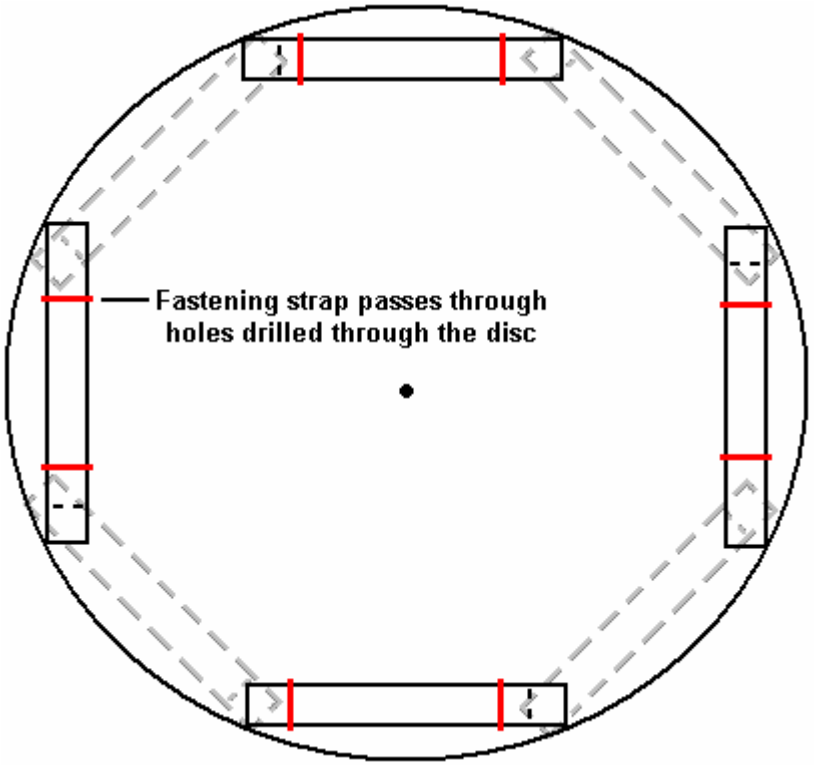
This way, the ball does not start rolling until the main part of the tube is near vertical. This allows a much greater acceleration and impact. The weighted ball should be much larger, say 2" (50 mm) in diameter and made of lead, in order to generate a significant thrust. Also, the cushioned ends of the tubes should be aligned with the pivot of the wheel so that any residual impact does not generate a turning force in the wrong direction. there is a negative turning effect due to the lever arm of the bottom weight. This turning force is only there for a small arc of rotation as the weight will roll inwards as soon as the tube section rises above the horizontal and as the tube then transitions into a circular curve, the movement inwards is gentle. It probably would be better if the tubes were angled slightly more in the clockwise direction, rather than exactly as shown in the diagram.

Secondly, there should be eight tubes on the disc, four on each side and one side staggered by 45 degrees so that there is a driving impact every 45 degrees instead of the 180 degrees of the version shown in the YouTube video. With that arrangement of four times as many impacts, each substantially greater, and no significant reverse impacts, the wheel has a much better chance of successful rotation without needing to be particularly large. The wheel itself should not be light as it acts as a flywheel and a pulsed flywheel has already been shown to produce excess power. The wheel bearings should be ball races and not the closed variety because those ones are packed with grease and have a serious resistance to rotation. Instead, the open-sided variety of ball bearing should be used as they rotate very freely.

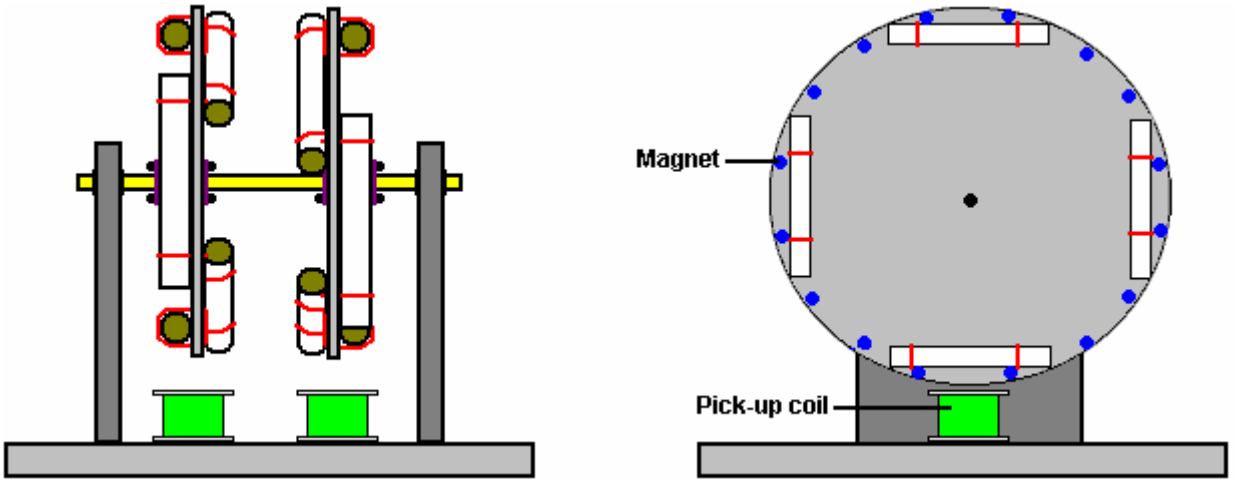
Using straight tubes for illustration, each tube could be like this:



Here, a wood disc is fitted to each end of a piece of plastic tube and held securely in place with screws or bolts which pass through small holes drilled in the plastic pipe and screw into the wooden disc. A piece of thick sponge is glued to the disc at one end and the heavy weight inside the tube is not a tight fit so that it can move very freely inside the tube. Four of these tubes are fitted to each side of each disc used in the device as shown here:



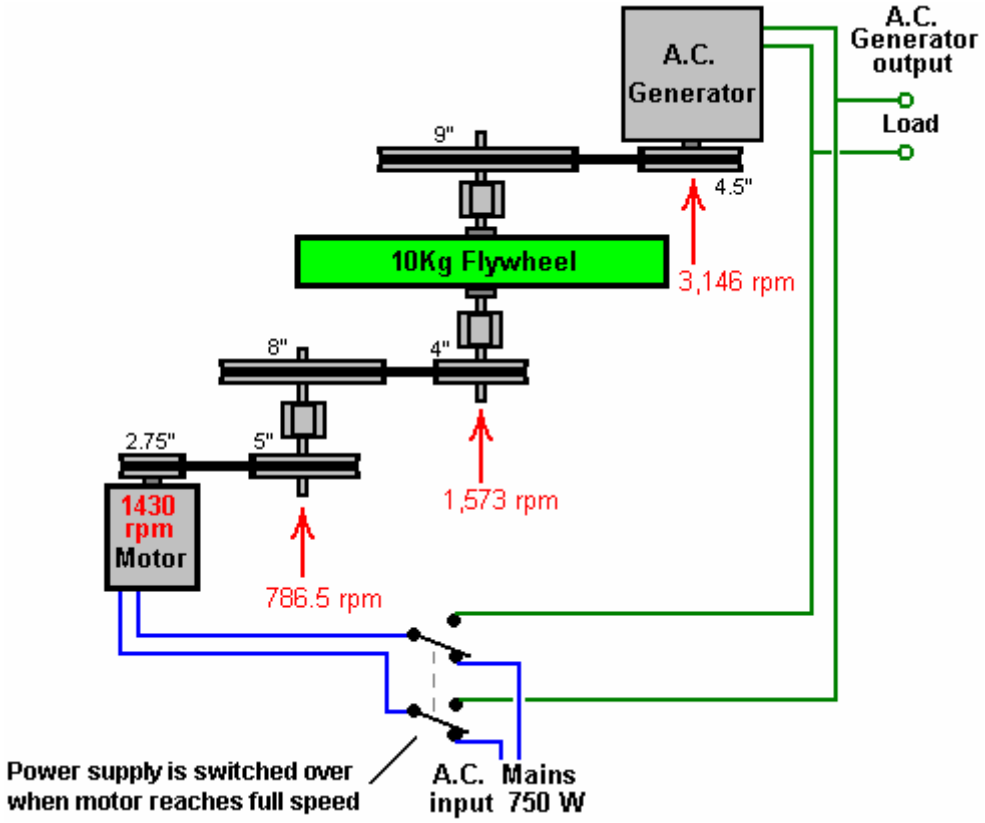
The four tubes attached to the back of the disc are 45 degrees away from the tubes mounted on the front of the disc. Each tube is attached securely in place with straps which pass through the disc and are secured on the far side. The tubes can also be glued in place to further strengthen the attachment. These eight tubes give an unbalanced impact for every 45 degrees of rotation. If two of these discs are attached to a common rotor shaft, then the second disc can be positioned 22.5 degrees around from the first one. That arrangement gives an unbalanced impact for every 22.5 degrees of rotation. If three discs were placed on a common rotor shaft and evenly positioned, then there would be an unbalanced impact every 15 degrees of rotation, which is 24 impacts per rotation. A two-disc arrangement might look like this:



If the rotor spins well, then it would be worth while attaching a series of magnets to the discs, being careful to keep each disc perfectly balanced. One or more air-core coils can then be used to determine if current can be drawn from the device without stopping the rotation. The coils should not have a magnetic core as that would cause a major drag on the rotation whether current was being drawn or not.

Chas Campbell's Flywheel System.

Recently, Mr. Chas Campbell of Australia demonstrated electrical power gain with a flywheel system which he developed:



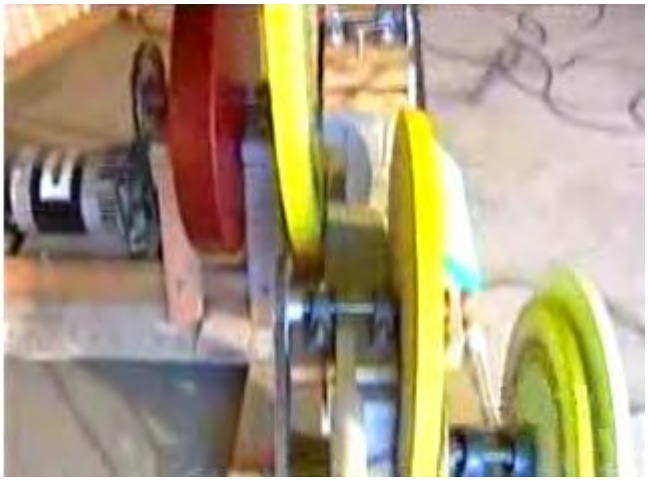
But what this diagram does not show, is that a couple of the drive belts are left with excessive slack. This causes a rapid series of jerks in the drive between the mains motor and the flywheel. These occur so rapidly that they do not appear noticeable when looking at the system operating. However, this stream of very short pulses in the drive chain, generates a considerable amount of excess energy drawn from the gravitational field. Chas has now confirmed the excess energy by getting the flywheel up to speed and then switching the drive motor input to the output generator. The result is a self-powered system capable of running extra loads.

Let me explain the overall system. A mains motor of 750 watt capacity (1 horsepower) is used to drive a series of belts and pulleys which form a gear-train which produces over twice the rotational speed at the shaft of an electrical generator. The intriguing thing about this system is that greater electrical power can be drawn from the output generator than appears to be drawn from the input drive to the motor. How can that be? Well, Mr Tseung's gravity theory explains that if a energy pulse is applied to a flywheel, then during the instant of that pulse, excess energy equal to **2mgr** is fed into the flywheel, where "**m**" is the mass (weight) of the flywheel, "**g**" is the gravitational constant and "**r**" is the radius of the centre of mass of the flywheel, that is, the distance from the axle to the point at which the weight of the wheel appears to act. If all of the flywheel weight is at the rim of the wheel, the "r" would be the radius of the wheel itself.

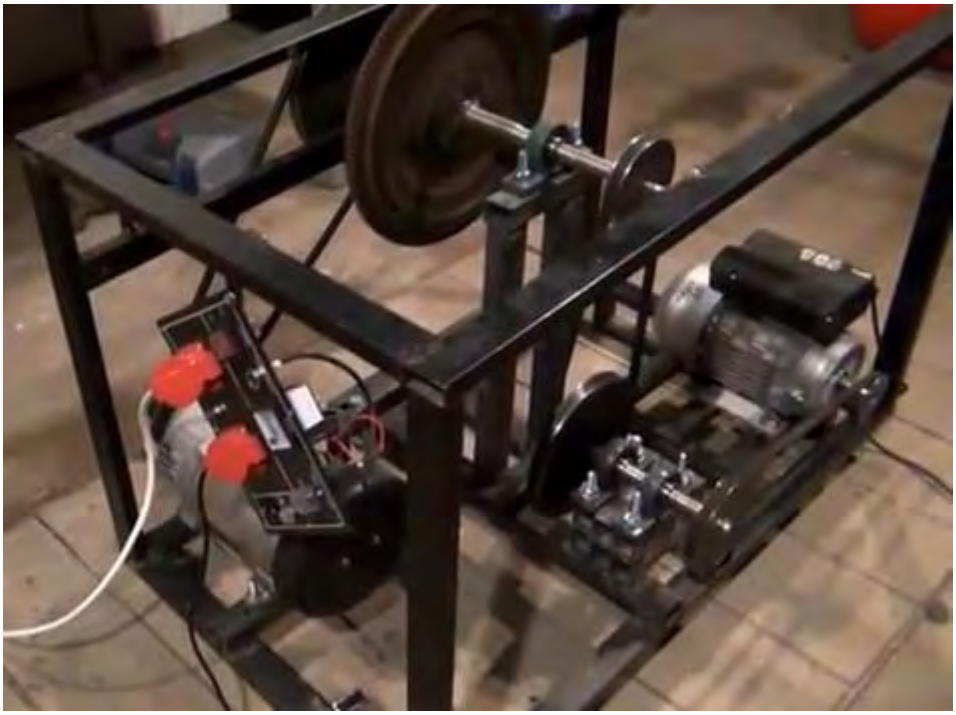
This means that if the flywheel (which is red in the following photographs) is driven smoothly at constant speed, then there is no energy gain. However, if the drive is not smooth, then excess energy is drawn from the gravitational field. That energy increases as the diameter of the flywheel increases. It also increases as the weight of the flywheel increases. It also increases if the flywheel weight is concentrated as far out towards the rim of the flywheel as is possible. It also increases, the faster the impulses are applied to the system.

However, Jacob Bitsadze points out that another mechanism comes into play even if all of the belts are correctly tensioned. The effect is caused by the perpetual inward acceleration of the material of the flywheel due to the fact that it rotates in a fixed position. He refers to it as being 'the rule of shoulder of Archimedes' which is not something with which I am familiar. The important point is that Chas Campbell's system is self-powered and can power other equipment.

Now take a look at the construction which Chas has used:

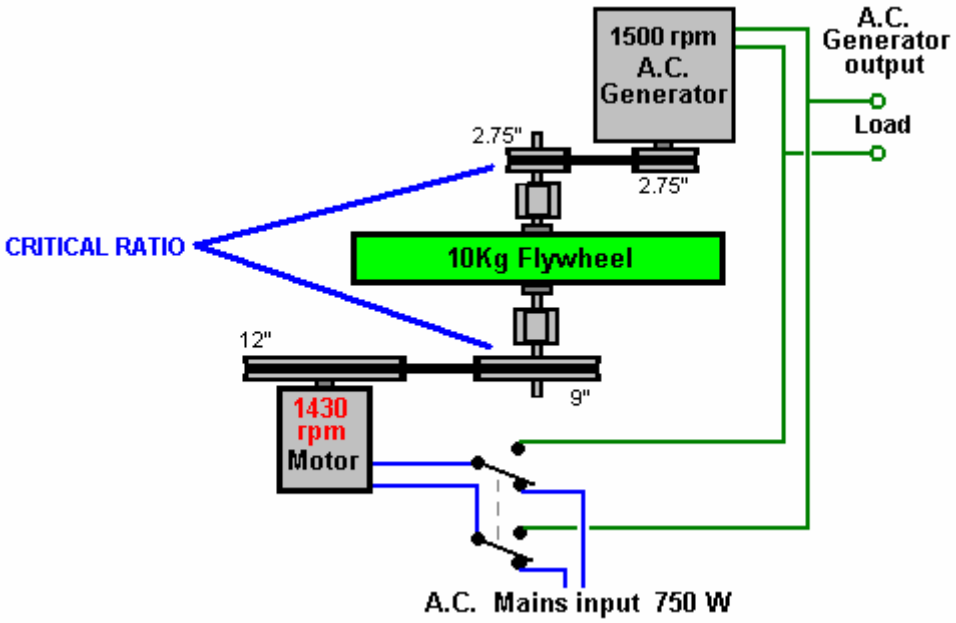


You notice that not only does he have a heavy flywheel of a fair size, but that there are three or four other large diameter discs mounted where they also rotate at the intermediate speeds of rotation. While these discs may well not have been placed there as flywheels, nevertheless, they do act as flywheels, and each one of them will be contributing to the free-energy gain of the system as a whole. A replication video with 750 watts input and 2340 watts output is here: http://www.youtube.com/watch?v=98aiISB2DNw and this implementation does not appear to have a heavy flywheel as you can see from this picture, although the largest pulley wheel looks as if it contains considerable weight:



Jacob Byzehr's Analysis.

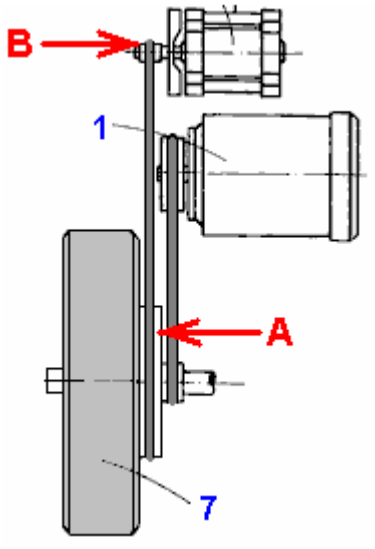
In 1998, Jacob lodged a patent application for a design of the type shown by Chas Campbell. Jacob has analysed the operation and he draws attention to a key design factor:



Jacob states that a very important feature for high performance with a system of this kind is the ratio of the diameters of the driving and take-off pulleys on the shaft which contains the flywheel, especially with systems where the flywheel rotates at high speed. The driving pulley needs to be three or four times larger than the power take-off pulley. Using Chas' 1430 rpm motor and a commonly available 1500 rpm generator, the 12:9 step-up to the shaft of the flywheel gives a satisfactory generator speed while providing a 3.27 ratio between the 9-inch diameter driving pulley and the 2.75" diameter power take-off pulley. If a generator which has been designed for wind-generator use and which has it's peak output power at just 600 rpm is used, then an even better pulley diameter ratio can be achieved.

The Self-powered Generator of José Luis García del Castillo

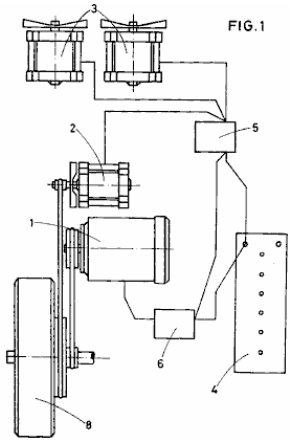
In 1998, Spanish patent ES 2,119,690 was granted to José Luis García del Castillo. I suspect that the auxiliary generators shown in the patent are only there to get the patent accepted by the patent examiner, rather than because they are actually needed. If that is correct, then the design is almost the same as Chas Campbell's design, although built in a more compact form:



As Jacob Byzehr points out, an energy gain is achieved through inertial acceleration caused by having the pulley wheel "A" attached to the flywheel shaft, larger than the pulley wheel "B" attached to the shaft of the generator. As drawn, there is a major difference in those diameters. Here is an attempted translation of the patent:

Patent: ES 2119690 Date: 1 Oct 1998 Inventor: José Luis García del Castillo

AUTONOMOUS ENERGY REGENERATION SYSTEM



Abstract

The system comprises an electric motor drive (1), a main generator (2), auxiliary generators (3), a battery (4), a charging regulator (5), and a speed regulator (6). The system is intended to generate its own operating power, and provide an extra supply for other purposes.

DESCRIPTION

Field of the invention

The present invention refers to a self-contained system of energy regeneration, which in addition has several advantages set out below.

Background of the invention

It has been known for many years, how to construct machines which can generate electric current. These are known by the generic name of "electric power generators", consisting of rotating machine that transforms

mechanical power into electrical power as a result of alternative action between a magnetic field and a moving conductor.

However, the various types of generator which make up the current state of the art, require the help of a motor, which transforms mechanical power into electrical energy, and that motor requires an independent power source which must be supplied continuously.

Thus, a system capable of generating its own power supply as well as providing an extra power supply for other purposes, is not known in the current state of the art.

Summary of the invention

The applicant for the present patent has designed an self-contained energy regeneration system, capable of producing its own operating energy in addition to generating a surplus which can be used in electrical networks using voltage converters required for any electrical installation, whether in homes, offices, warehouses etc.., with it is possible to reach places where it is difficult to install the power grid, allowing its use as an alternative source of energy other than solar or wind power.

Other applications would be in the automotive field, as a power source for motorcycles, cars, etc. by connecting the system to the propelling motor, and thus achieving the necessary motion of the vehicle.

Overall, the system is comprised of the following basic components:
1. An electric traction motor.
2. A main generator.
3. Various auxiliary generators.
4. A battery or accumulator.
5. A load and output-power controller.
6. A speed controller.

The electric drive motor supplies the necessary electromotive force needed for the system to operate, the generator supplies power to the system, charging the battery and providing direct power to the traction motor when needed, or if the battery is fully charged, then just to power the motor. It can go provide direct mechanical power by using pulleys and belts, gears or any other means.

The auxiliary generators are responsible for supplying backup power and can use propellers or be in the form of a turbine operating by the action of the wind or by gears attached to a flywheel placed in the traction motor.

The function of the battery is to provide the power needed to start the motor and in addition, to supply any extra power that the engine may need during operation. The battery is recharged by the main generator which is driven directly by the motor. The function of the charge controller is to prevent the battery becoming overcharged. The function of the speed controller is to control the speed of the drive motor.

The present invention offers the advantages described above, as well as others which will be understood from the example embodiment of the system described in detail below, to facilitate understanding of the features stated above, and introducing at the same time, various in addition to the present specification. It should be understood that the drawings are only by way of example and they do not limit the scope of the present invention in any respect, being just an example of one form of construction.

Brief description of the drawings

In the drawings:

Fig.1, is a diagram of the system as one example of a practical embodiment of the invention.

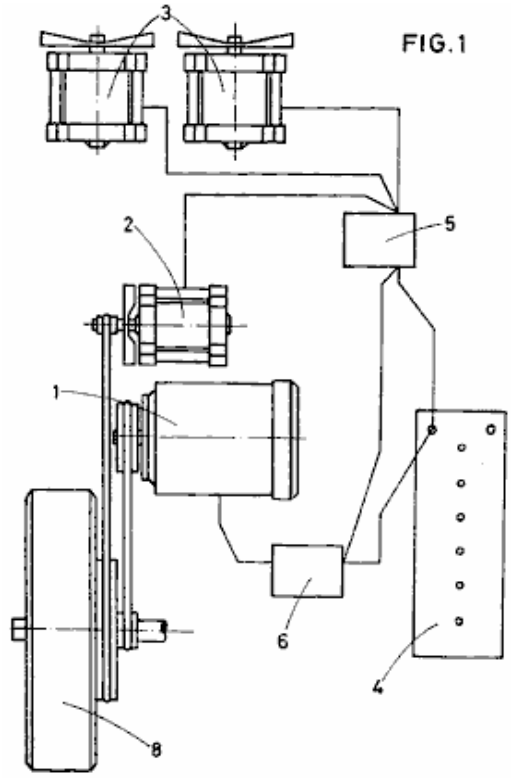


Fig.2 shows an alternative embodiment of this invention.

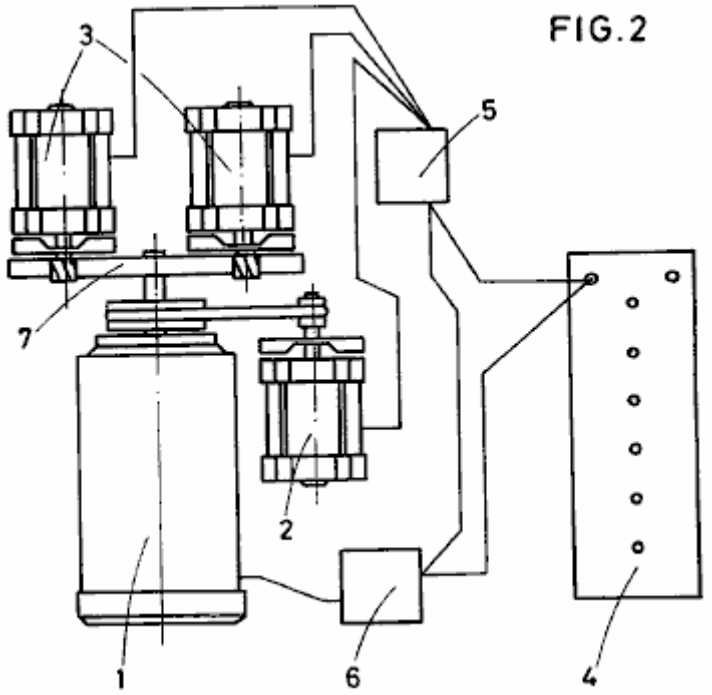
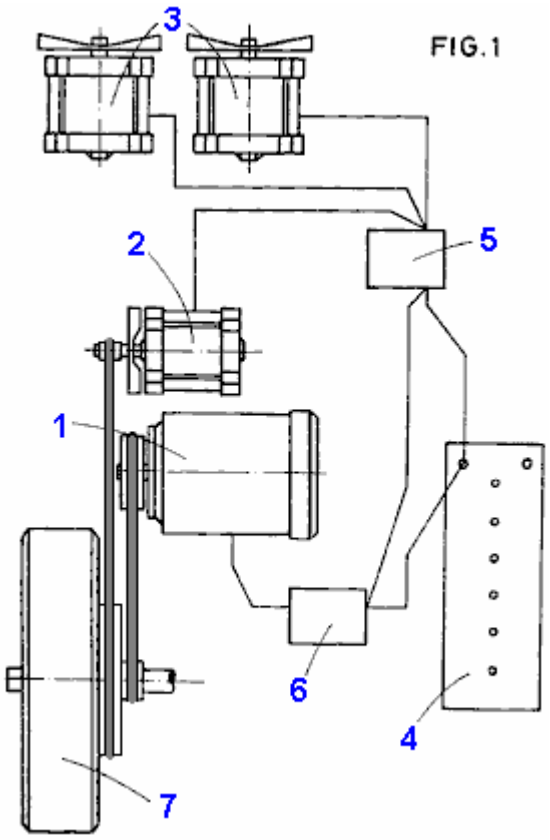


Description of a preferred embodiment of this invention

As shown in the drawing, the self-contained system of energy regeneration, in accordance with an embodiment of the present patent, comprises an electric traction motor (**1**), a main generator (**2**), several auxiliary generators (**3**), a battery or accumulator (**4**), a charge controller and power supply (**5**), and a motor speed controller (**6**).



The electric drive motor (**1**) provides the necessary electromotive force for operating the system, and its voltage and power are selected in accordance with whatever size of system you wish to construct.

The main generator (**2**) supplies power to the system, firstly, to recharge the battery (**4**), and secondly, direct power to the motor (**1**) if it requires it. When the battery (**4**) is fully charged, its charge is maintained by power from the motor, supplied by suitable pulleys or other method of transmission of mechanical power.

The speed of revolution of the generator must be arranged through choice of the gearing between the motor and the generator, so that when the motor is operating at its maximum speed and drawing its maximum current, that the generator is spinning fast enough to supply that current. The main generator (**2**) will be therefore connected electrically to the battery (**4**) and mechanically to the motor (**1**). The auxiliary generators (**3**), are in the form of a turbine, operating by wind action or by gears attached to a flywheel (**7**), driven by motor (**1**), as shown in **Fig.2**. These auxiliary generators (**3**) provide reserve power for the system.

The battery (**4)**, must have a capacity which exceeds the maximum power of the motor (**1**), and its role in the system is to provide the power needed to start the motor (**1**), and to supply any extra energy which the motor (**1**), may need during operation. The battery is recharged directly by the main generator (**2**) which is driven by the motor (**1**).

The charge controller and power distributor (**5**) is positioned between the main generator (**2**), the auxiliary generators (**3**) and the battery (**4**). Its job is to regulate the current draw from the battery (**4**), to prevent excessive current draw. It also distributes any surplus power as a direct feed to the generator (**2**) and the drive motor (**1**) when it needs additional current. The auxiliary generators (**3**) can either provide additional power to the motor (**1**), or their power output may be used for any other power needs.

The speed regulator (**6**), is intended to regulate the speed of the motor (**1**), this adjustment is gradual, and is adjusted to match the intended use of the system.

System applications can be many and diverse, noteworthy among which are uses in the automotive field, where it can be used as a means for propelling cars and other motor vehicles, with the motor (**1**) connected to a drive wheel which propels the vehicle. In these applications, the auxiliary generators (**3**), can be fitted with propellers or be turbine-shaped, so that the passing wind provides extra energy to the electrical system. With electric vehicles, only the main generator is connected to a drive wheel.

Other applications for this system are in the field of energy supply, i.e. use in electrical networks. The advantage of using this patented system is that the power supply is practically inexhaustible and clean, and subject only to component wear and tear during operation.

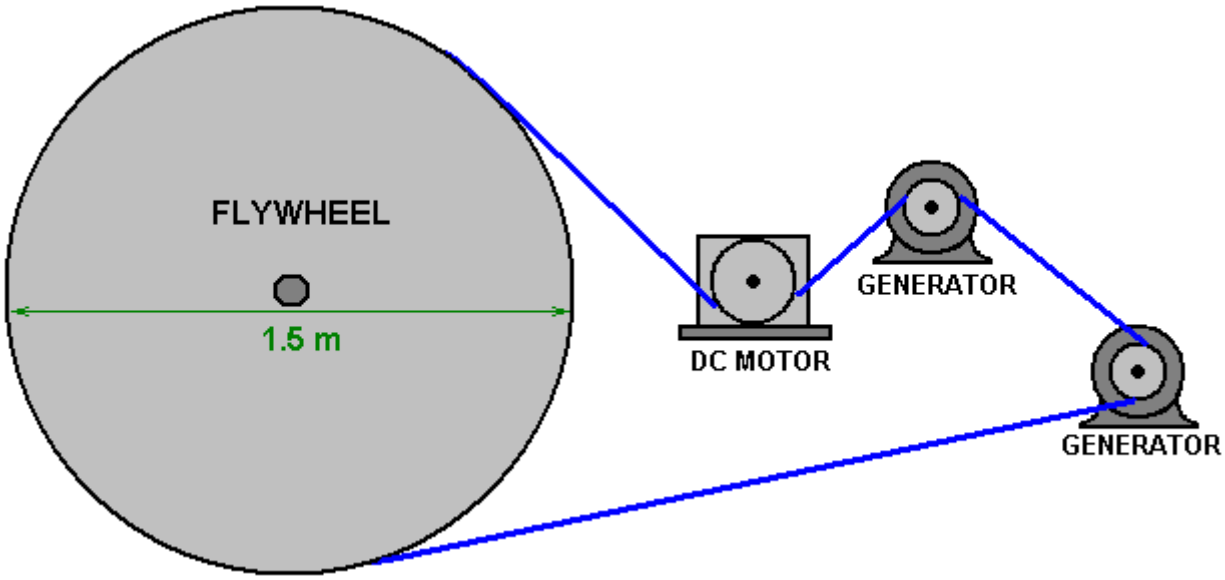
Its operation is as follows:
Battery (**4**) provides the energy needed to start the motor (**1**), and allows for the possibility of increased electrical input being needed at certain times during operation of the system. The battery (**4**) is electrically connected to the motor (**1**) through the speed controller (**6**), which is fed from the main generator (**2**) by the load distribution controller (**5**). The generator (**2**), is driven directly by the drive motor (**1**), and the transmission of motion from one component to another is through gears, belts and pulleys, or any other conventional means.

The auxiliary generators (**3**) are electrically connected to the charge controller (**5**), and the battery (**4**), and their movement by the wind generates their own energy, having turbine blades or propellers, or through being spun by the flywheel (**7**) which is connected directly to the motor (**1**). The energy produced by these auxiliary generators (**3**) may be used for charging other batteries for later use, or used directly to power other electrical equipment or electrical installation networks. Through voltage converters it is possible to convert the voltage produced by the system to a voltage which is suitable for use in other equipment.

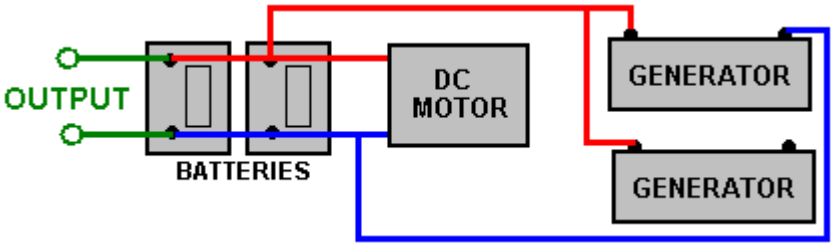
The Wilson Self-Powered DC Generator

Mr. Wilson of Texas built a self-powered generator system using an old table and some car parts. His construction was shaky, but in spite of that, it powered itself and other equipment. The table which he used was five feet (1.5 m) in diameter and 2-inches (50 mm) thick which means that it will have weighed at least 130 pounds or 60 Kilograms which is a substantial amount, well in excess of that used by Chas Campbell with his AC self-powered system. In this DC construction the system was driven by a standard, unmodified, off-the-shelf DC motor powered by two car batteries wired in parallel to give a larger current capacity. These batteries were kept charged up by two 'generators' from pre-1964 American cars (the closest available today are permanent magnet alternators). These generators also powered additional equipment and Mr Wilson pointed out that three or more generators could be run by the system, giving a substantial level of excess electrical power.

The machine has to be described as 'shaky' because he chose to convert the table top into a V-pulley belt drive flywheel by driving a series of nails into the edge of the wooden disc, with those nails angled to form a V shaped gap through which he ran a pulley belt. After three days of continuous running, those nails started to come out, causing him to power the system down. This unit was built around 1990, and if anyone decides to attempt a replication, then I suggest that the rim of the wooden disc is grooved to take the belt rather than relying on nails. The arrangement was like this:



There was also a belt-tensioning roller which is not shown in the diagram above which assumes that the flywheel has been grooved to take the drive belt. Schematically, the arrangement was like this:



Here, the additional output can be used directly for powering 12-volt equipment or an inverter can be used to provide mains voltage and frequency. A typical inverter looks like this:

The battery power is connected to one end using thick cables to carry the heavy current, and one or more mains sockets are provided at the other end of the case, along with an On/Off switch and power indicators. Inverters come in many sizes and power ratings, generally ranging from 150 watts to 3,000 watts (3 kW). The more expensive ones are specified as "True Sine-Wave Output" but very few present day items of equipment will not run well on the cheaper versions which do not produce a true sine-wave output.

Mr Wilson decided not to patent his design and instead wanted it to be open-source information for anybody to use freely. However, the Jesse McQueen patent shown in chapter 13 looks to be Mr Wilson's design although the flywheel does not appear to be mentioned there. It should be stressed that the generator output needs to be high and so permanent magnet types are considered to be essential for this application. The specialised motor (and consequently, generator) winding methods of 'UFOpolitics' shown in chapter 2, raise efficiencies by a factor of typically 300% or more, and so would raise the output of this system very substantially if they were applied to the motor, or the generators, or both.

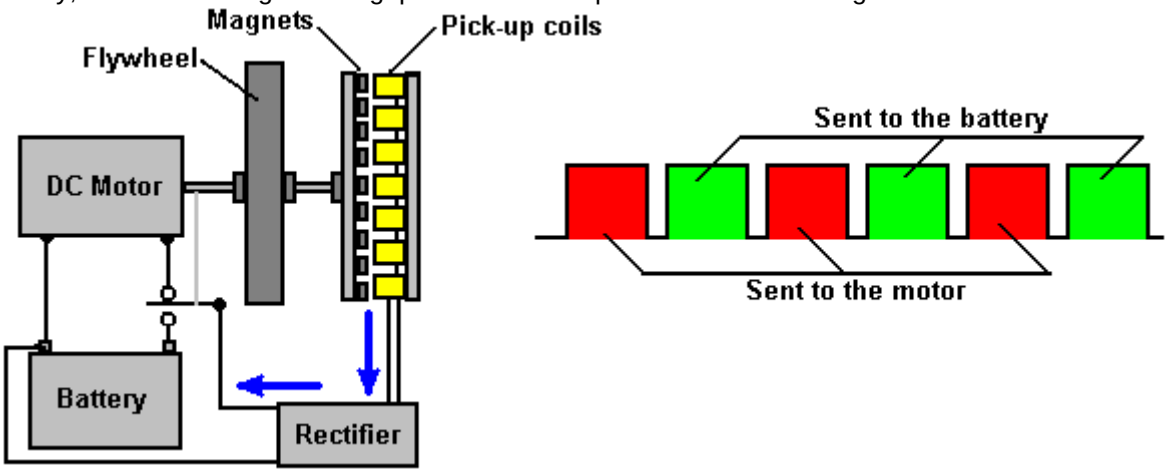
John Bedini's COP=8 Pulsed Flywheel.

The Chas Campbell system is not an isolated case. On page 19 of the book "Free Energy Generation - Circuits and Schematics" John Bedini shows a diagram of a motor/generator which he has had running for three years continuously while keeping it's own battery fully charged. At John's web site http://www.icehouse.net/john1/index11.html about half way down the page, there is a black and white picture of a very large construction version of this motor built by Jim Watson and which had an excess power output of many kilowatts, due to the very large size and weight of it's flywheel. The excess energy is drawn from the Earth's gravity field, and so, two factors are involved.

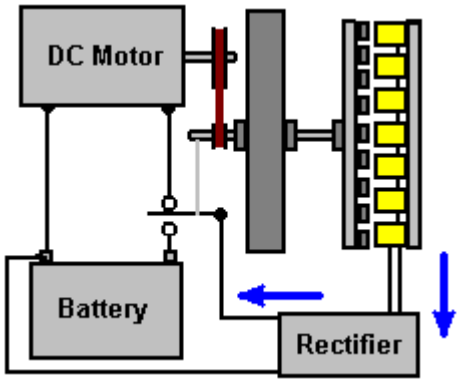
The first is the size, weight and speed of oration of the flywheel itself and the second is the effectiveness of the drive connection between the drive motor and the flywheel. In John's prototype, the flywheel is relatively small, limiting the output power and calling for careful manual tuning of the system, and John shows the motor being directly linked to the shaft of the flywheel, and if that is the case, then in my opinion, that limits the output power considerably as can be seen from the work of Jacob Byhehr earlier in this chapter.

The general strategy is that the motor spins the flywheel and the flywheel shaft spins a disc with permanent magnets mounted on it. The magnets have their South poles facing corresponding helically wound coils which are connected in series. As the magnets pass by the coils, a voltage is generated and current is then drawn from the coils and fed, first to the motor to power it and then secondly to the battery to keep it charged.
John shows his switching mechanism as a mechanical attachment on the flywheel shaft with a conducting sector of about 110 degrees of arc. This gives equal duration pulses being fed back to the motor and then to

the battery, with there being a short gap between each pulse and the following one:



While this is a simple concept, in my opinion, there is scope for improvement. As current is drawn from the output coils, the current flow creates magnetic effects which cause drag which opposes the rotation of the flywheel. This suggests that controlling the timing of the current draw with the switching arrangement used by Robert Adams (chapter 2) would convert that drag into a push which would help the flywheel on its way instead of impeding it. Probably of greater importance would be to gear the drive motor up as Jacob points out. Leaving the generator disc directly attached to the flywheel shaft, the motor might be geared up by, say, a 2:1 ratio:



John's mechanical switching has the advantage of always being synchronised with the flywheel but it has the disadvantage of wear and tear on the mechanical parts. An electronic circuit to replace the mechanical parts should not be difficult to arrange and if you want the feedback from the generator section to be synchronised with the flywheel (which actually does not seem to be in any way necessary), then an optical disc or a magnetic sensor can be used. This generator system of John's can have considerable excess output.

James Hardy's Self-Powered Water-Jet Generator.

As described in more detail in Chapter 2 and Chapter 8, there is a very simple device based on a high-power water pump. In this system, a small quantity of water is pumped around continuously, in the same general style as an ornamental fountain. The difference here is that a high speed jet of water is produced and directed at a turbine wheel. The turbine wheel can be of any type as indicated in the patent which James has been awarded for this design. In the video at present on the web, the water wheel is of very simple design and yet works well – it is shown here:

Small discs are attached to the wheel at widely spaced intervals around it's rim. The water jet hits these and applies an impulse to the wheel, driving it around, but also adding extra energy through those impulses.

The waterwheel is coupled to a standard electrical generator via pulleys and V-belts. The system is started using the mains supply and then when it is running at full speed, the electrical supply for the pump is switched over from the mains to the output of it's own generator. This is exactly the same as Chas Campbell does with his pulsed flywheel and both systems are capable of powering additional standard electrical equipment intended for mains use.

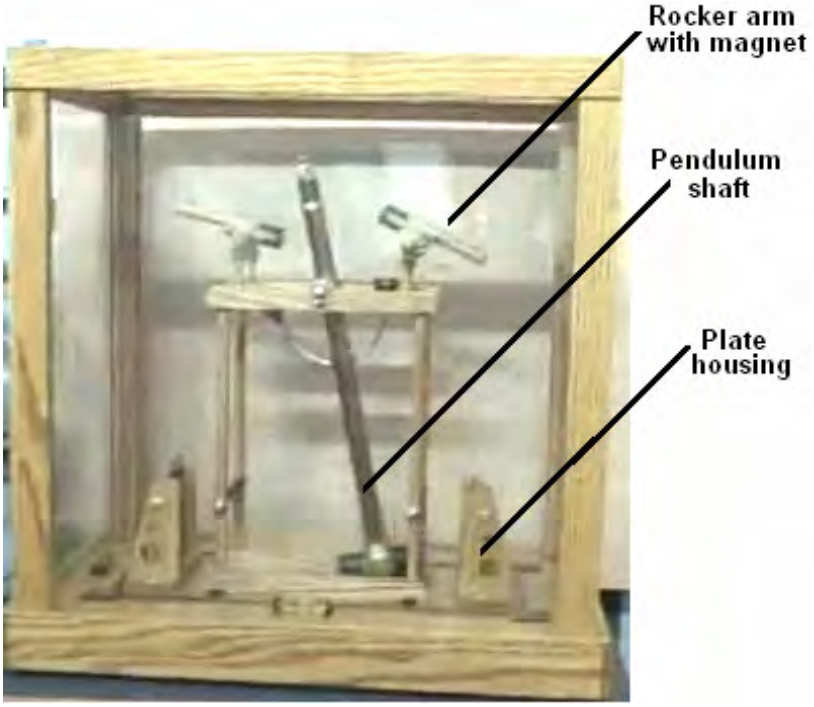
Chas Campbell's flywheel, John Bedini's flywheel and this water-jet generator all demonstrate very clearly that environmental energy is readily available for us to use any time we choose to do so. All that is necessary is for us to construct one of these devices.

The Permanent Magnet Pendulum.

At the present time, there is a short video clip on YouTube, showing a pendulum which has been running unaided for two years: http://www.youtube.com/watch?v=SZjNbjhxgt4 and which uses both gravity and magnetism to keep going. The device is installed in a case with transparent sides:

The pendulum itself looks rather like a sledgehammer due to it's rigid shaft and the additional magnets mounted on the weight. The above picture shows the pendulum at the end of it's swing to the right and the picture below, in it's extreme left hand swing position:

Which indicates the swing covers a fairly short distance. Mounted near the top of the pendulum, there are two pivoted arms which look quite like microphones, due to having large magnets mounted on their innermost ends:



The device operates like this: The pendulum swings to the right and as it does so, it raises a magnet attached to the pendulum shaft by a curved silver arm:

Presumably, the arm is curved to avoid the constructional complications at the pendulum pivot which would be caused by a straight mounting arm attached to the pendulum shaft. The rising magnet attached to the pendulum pushes the magnet end of the rocker arm upwards even though it does not come close to it.

The rocker arm is used to raise and lower a plate which has a magnet mounted in it. The raising and lowering is achieved by having two cords attached to the end of the rocker arm and their other ends attached to the two upper corners of the moving plate:

The plate slides in two slots in the support housing and the plate movement is relatively small:

The tipping up of the lever arm drops the plate down as the pendulum approaches the plate. This introduces a magnetic braking effect where some of the momentum of the pendulum weight is stored in the opposing magnetic fields of the pendulum magnets and the plate magnet. This brakes the pendulum movement and gives it a magnetic push on its opposite swing, sustaining it's swinging day after day after day.

This is a clever arrangement and the device on display has been built to a very high standard of construction. It does not appear to have any additional energy take off, but seems quite likely that air-core coils could be used along the swing path to generate electrical power. The arrangement appears so close to John Bedini's pendulum battery charger that it may well be possible to use a pendulum of this type to charge batteries just as John does.

While this looks like a very simple device, it is highly likely that it requires exact adjustment of the length of the lever arms, the magnetic gap sizes in relation to the strength of the magnets, etc. etc. Repeated small adjustments are probably needed to get the device operating smoothly and sustaining the pendulum swing. All in all though, it is a very interesting device.

Jerzy Zbikowshi's Mechanical Power Amplifier.

We come now to a device which I would love to describe as "impossible" but reluctantly, I can't actually do that. On the surface, this device has every appearance of being impossible, and yet it has been measured in a laboratory as being 147% efficient. Perhaps the laboratory measurements are wrong, however, there seems to be very little scope for measurement error as the device is so basically simple. My problem is that if the results are 100% genuine, which is distinctly possible, then a series of these arranged in a circle, each driving the next one, it would create a self-powered device and I can't explain where the driving power would come from. I can understand pretty much every other device in this eBook, but this one has me stumped. As I don't have any basis for claiming to be a genius, I am sharing the information here and I will let you decide if it can work as the patent claims that it does.

The patent in question is the very innocent looking US 7,780,559 entitled "Chain Transmission" which innocently states that it is a single-chain system for rotating a large gearwheel at the same rate as a smaller, driving gearwheel, and without question, that is exactly what it does. At this point, my Engineering training jumps in and says "sure, but the overall mechanical efficiency will be less than 100% and while the larger gearwheel does rotate at the same rate, it will do so far less powerfully, and you have exactly the same effect as driving the second shaft with a small gearwheel which has a large gearwheel bolted to it.

The only problem with this is that testing appears to show that this is not the case and in fact, (probably due to the larger lever arm of the larger gearwheel radius) the arrangement has an output power which was measured in the prototype as being 47% greater than the input power. OK, so how does it work?

In the diagram shown here, a small-diameter driving wheel marked "**1**" has exactly the same number of teeth as the much larger driven wheel marked "**2**". As they are linked by a chain, these two wheels rotate at exactly the same rate, that is, the revolutions per minute are exactly the same for each of those two wheels.

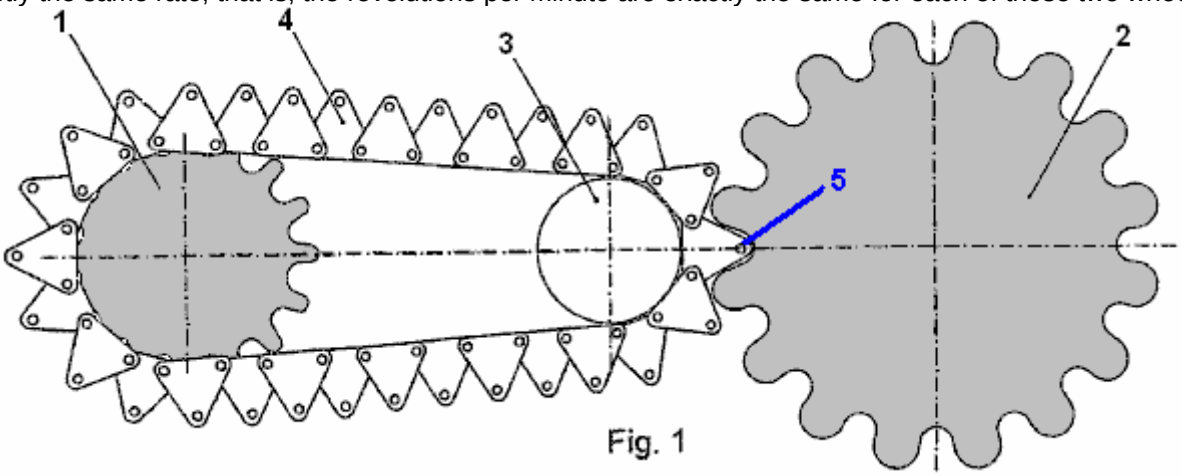


Fig. 1

The way that the chain manages to push the larger teeth of the large wheel is by having the driving roller "**5**" raised by a triangular link "4" so that it has the same rotational pitch as the teeth on the larger wheel.

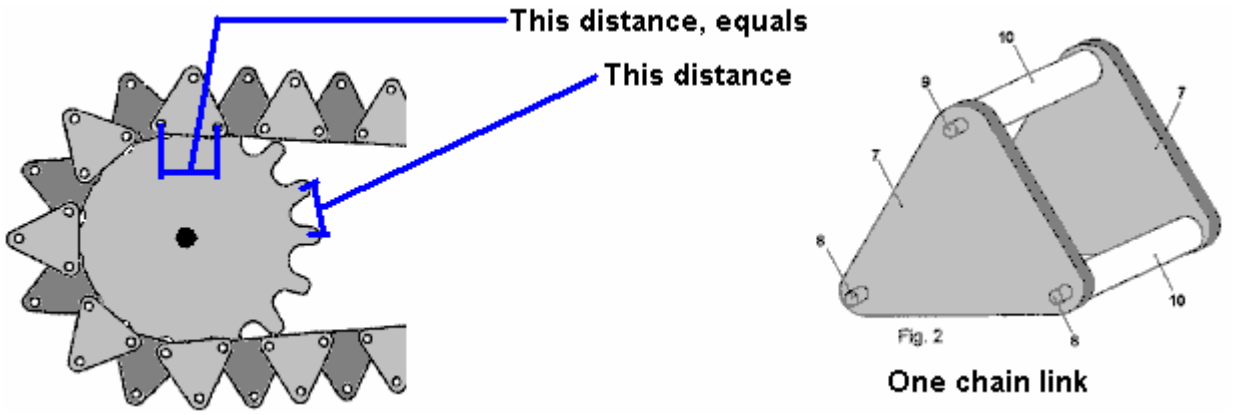

Fig. 2

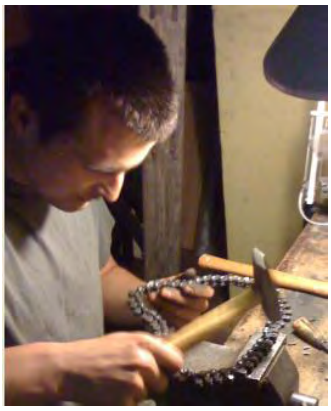
One chain link



My immediate reaction to this is to say that as the triangular links in the drive chain have a somewhat narrower base than their height, that this will cause the driving roller "**5**" to have a less powerful drive than the driving wheel "1". But if the lab measurements made on the prototype are correct, then that increased level arm effect is not sufficient to overcome the gains caused by the increased radius of the larger wheel. The lab measurements were made at the certified laboratory of the Institute of Electrical Machines and Drives of the Technical University of Wroclaw, Poland. A video presentation in Polish can be seen at http://www.focus.pl/video/film/perpetuum-mobile/. It is difficult to see how this chain drive could be COP>1 but it has the advantage that anyone with good mechanical construction skills can test it without the need for any knowledge of electronics.

Gravitational Effects.

We are all familiar with the effects of gravity. If you drop something, it falls downwards. Engineers and scientists are usually of the opinion that useful work cannot be performed on a continuous basis from gravity, as, they point out, when a weight falls and converts it's "potential energy" into useful work, you then have to put in just as much work to raise the weight up again to its starting point. While this appears to be a sound analysis of the situation, it is not actually true.

Some people claim that a gravity-powered device is impossible because, they say that it would be a "perpetual motion" machine, and they say, perpetual motion is impossible. In actual fact, perpetual motion is not impossible as the argument on it being impossible is based on calculations which assume that the object in question is part of a "closed" system, while in reality, it is most unlikely that any system in the universe is

actually a “closed” system, since everything is immersed in a massive sea of energy called the “zero-point energy field”. But that aside, let us examine the actual situation.

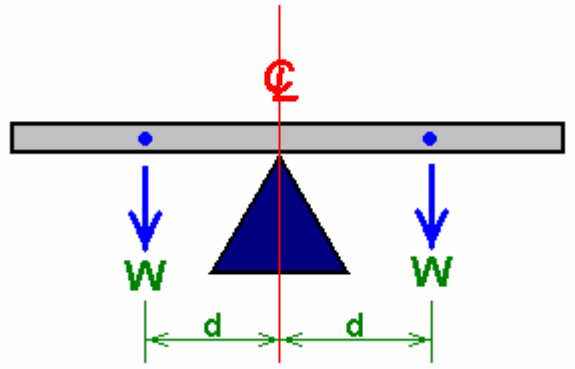
Johann Bessler made a fully working gravity wheel in 1712. A 300 pound (136 Kg) wheel which he demonstrated lifting a 70 pound weight through a distance of 80 feet, demonstrating an excess power of 5,600 foot-pounds. Considering the low level of technology at that time, there would appear to be very little scope for that demonstration to be a fake. If it were a fake, then the fake itself would have been a most impressive achievement.

However, Bessler acted in the same way as most inventors, and demanded that somebody would have to pay him a very large amount of money for the secret of how his gravity wheel worked. In common with the present day, there were no takers and Bessler took the details of his design to the grave with him. Not exactly an ideal situation for the rest of us.

However, the main argument against the possibility of a working gravity wheel is the idea that as gravity appears to exert a direct force in the direction of the earth, it therefore cannot be used to perform any useful work, especially since the efficiency of any device will be less than 100%.

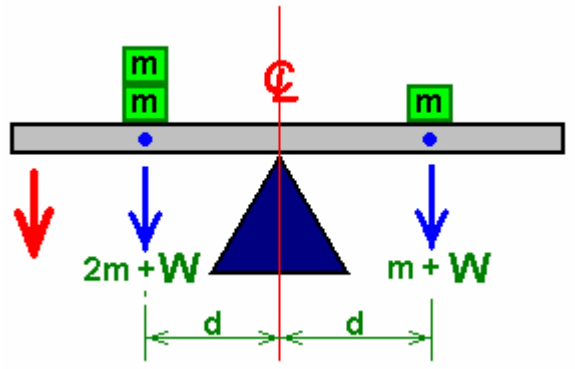
While it is certainly agreed that the efficiency of any wheel will be less than 100% as friction will definitely be a factor, it does not necessarily follow that a successful gravity wheel cannot be constructed. Let us apply a little common sense to the problem and see what results.

If we have a see-saw arrangement, where the device is exactly balanced, with the same length of a strong plank on each side of the pivot point, like this:



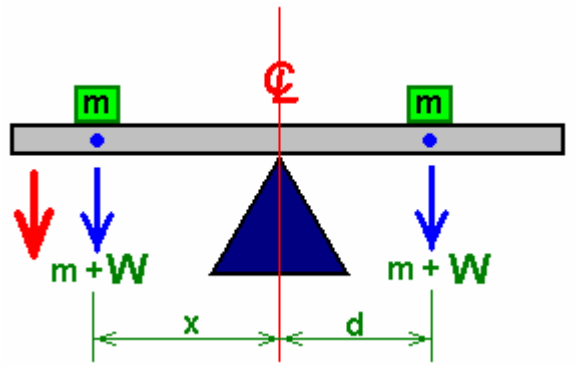
It balances because the weight of the plank (“**W**”) to the left of the support point tries to make the plank tip over in a counter-clockwise direction, while exactly the same weight (“**W**”) tries to tip it over in a clockwise direction. Both turning forces are d times W and as they match exactly, the plank does not move.

The turning force (d times W) is called the “torque”, and if we alter the arrangement by placing unequal weights on the plank, then the beam will tip over in the direction of the heavier side:



With this unequal loading, the beam will tip down on the left hand side, as indicated by the red arrow. This seems like a very simple thing, but it is a very important fact. Let me point out what happens here. As soon as the weight on one side of the pivot is bigger than the weight on the other side (both weights being an equal distance from the pivot point), then the heavy plank starts to move. Why does it move? Because gravity is pushing the weights downwards.

One other point is that the distance from the pivot point is also important. If the added weights “**m**” are equal but placed at different distances from the pivot point, then the plank will also tip over:



This is because the larger lever arm "**x**" makes the left hand weight "**m**" have more influence than the identical weight "**m**" on the right hand side.

Do you feel that these facts are just too simple for anyone to really bother with? Well, they form the basis of devices which can provide real power to do real work, with no need for electronics or batteries.

The following suggestions for practical systems are put forward for you to consider, and if you are interested enough test out. However, if you decide to attempt to build anything shown here, please understand that you do so entirely at your own risk. In simple terms, if you drop a heavy weight on your toe, while other people may well be sympathetic, nobody else is liable or responsible for your injury - you need to be more careful in the future ! Let me stress it again, this document is for information purposes only.

The Deflected-Weight Generator of Mikhail Dmitriev.

Mikhail is a Russian experimenter who has worked for many years developing and testing gravity-powered devices. His persistence has paid off and he has been very successful. His work is shown on Sterling Allan's web site http://peswiki.com/index.php/Directory:Mikhail_Dmitriev_Gravity_Wheel where there are videos and photographs of several of his prototypes. It is envisaged that large versions which generate 6 to 12 kilowatts of excess power will become available for purchase in 2011. Each of his various designs is based on the principle of having weights attached to a wheel and arranging for those weights to be offset outwards when falling and offset inwards when rising. Because of the different lever arms involved, that gives a force imbalance which causes the wheel to rotate continuously and if the weights are of a considerable size, then the rotation is powerful and can be used to generate electrical energy.

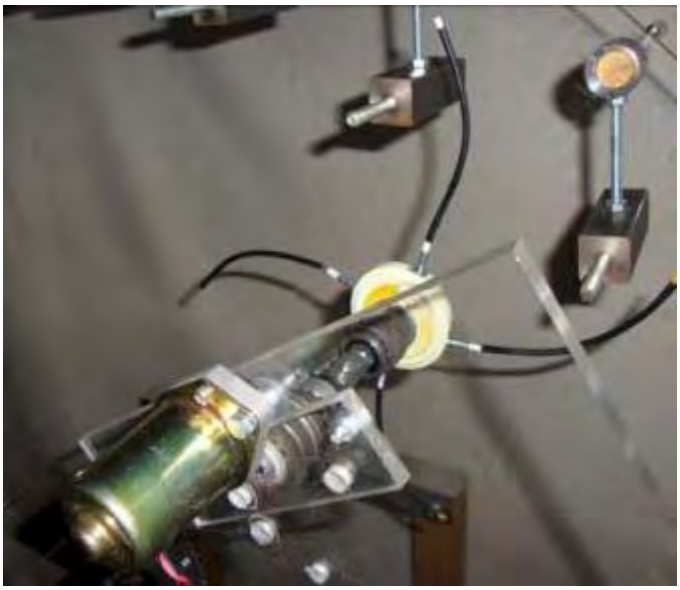
In order to arrange for the weights to be offset as the wheel goes around, each weight is suspended on a pivoted arm:

For the device to operate as required, that suspension arm needs to be moved to (say) the right when falling and be centred or deflected to the right when rising. Mikhail has chosen to use a small amount of electrical power to make this happen, because the energy provided by gravity in turning the wheel far outweighs the small electrical input needed to make the wheel rotate.

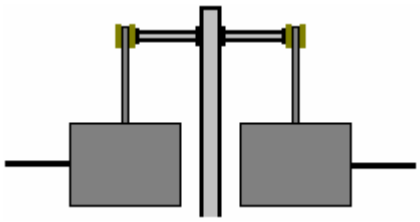
Several mechanisms for making this happen have been tested as you can see from Sterling's presentation. One method is to push the lever arms to the right with a simple rotating disc which has deflector arms attached to it:

After being given the sideways push, each weight stays off centre until it reaches the bottom of it's travel. Please remember that while the weights show here are tiny, a full-size working device will have weights which weight a total of perhaps 130 kilograms and the forces involved are then large. The picture above is a little difficult to make out as the rotating disc is transparent and the support for the rotating arms is also transparent. The horizontal metal arm is there to support the transparent panel on which the 'arms wheel' bearing is mounted.

An alternative method is to use a small motor which drives the arms directly as shown here:

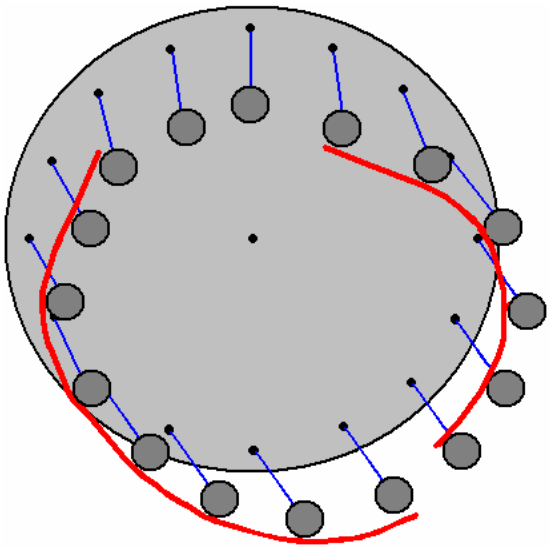


Each weight is held rigidly and so when the motor arm presses against it, the lever arm is pushed out sideways without the weight twisting away from the motor arm. These prototype weights are not heavy, but when a working unit is being built they will have considerable weight, so to get a well balanced arrangement, it might be advisable to have weights on both sides of the wheel so that there is no offset axial load placed on the shaft which supports the wheel:



Mikhail's arrangement works well when it relies on the swinging movement of the weights to keep them off centre during the time when they are falling and you can watch a video of that happening. However, it

makes one wonder if it would not be possible to arrange for this movement without the need for a motor, although using a motor is a very clever and sensible method of ensuring rotational power. Perhaps if two stationary deflectors were used, one to keep the weights out to the right when falling and one to keep them out to the right when rising, a viable system might be created. Perhaps something like this:

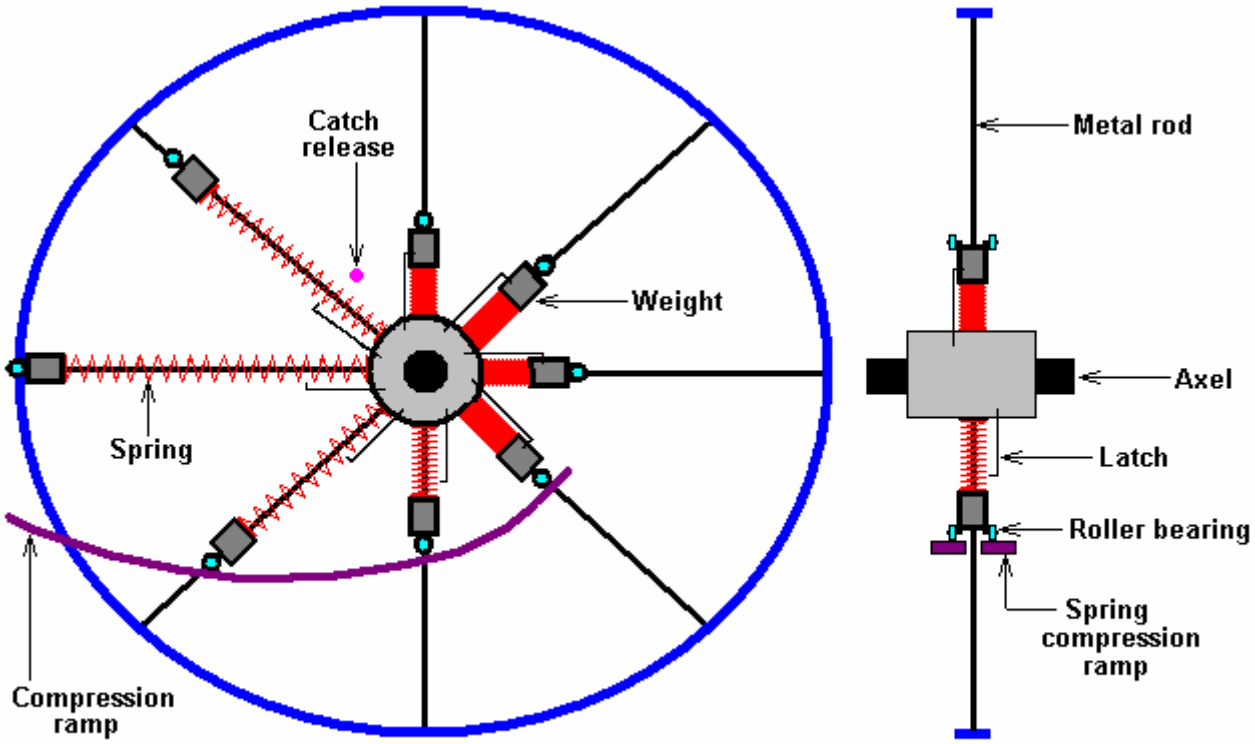


Admittedly, the deflector pieces would have a smoother shape than drawn here, but the principle is shown in spite of the poor quality of the diagram. Where heavy weights are involved, each could have a roller bearing pressing between the weight and the deflector shield in order to minimise friction as the weight slides past. Alternatively, the deflector shield could be faced with powerful magnets opposing similar magnets attached to the weights which would give a no-contact, very low friction movement. A fairly similar idea is part of the next entry from Dale Simpson.

Dale Simpson's Gravity Wheel Suggestion.

The design of gravity-operated machines is an area which has been of considerable interest to a number of people for quite some time now. The design shown here comes from Dale Simpson of the USA. It should be stressed that the following information is published as open-source, gifted to the world and so it cannot be patented by any individual or organisation. Dale's prototype wheel has a diameter of about five feet, utilising weights of a substantial value. The overall strategy is to create excess torque by having the weights slide along metal rods radiating from a central hub somewhat like the spokes of a cart wheel. The objective is to create an asymmetrical situation where the weights are closer to the hub when rising, than they are when falling.

The difficulty with designing a system of this type is to devise a successful and practical mechanism for moving the weights in towards the hub when they are near the lowest point in their elliptical path of movement. Dale's design uses a spring and a latch to assist control the movement of each weight. The key to any mechanical system of this type is the careful choice of components and the precise adjustment of the final mechanism to ensure that operation is exactly as intended. This is a common problem with many free-energy devices as careless replication attempts frequently result in failure, not because the design is at fault, but because the necessary level of skill and care in construction were not met by the person attempting the replication. Here is a sketch of Dale's design:



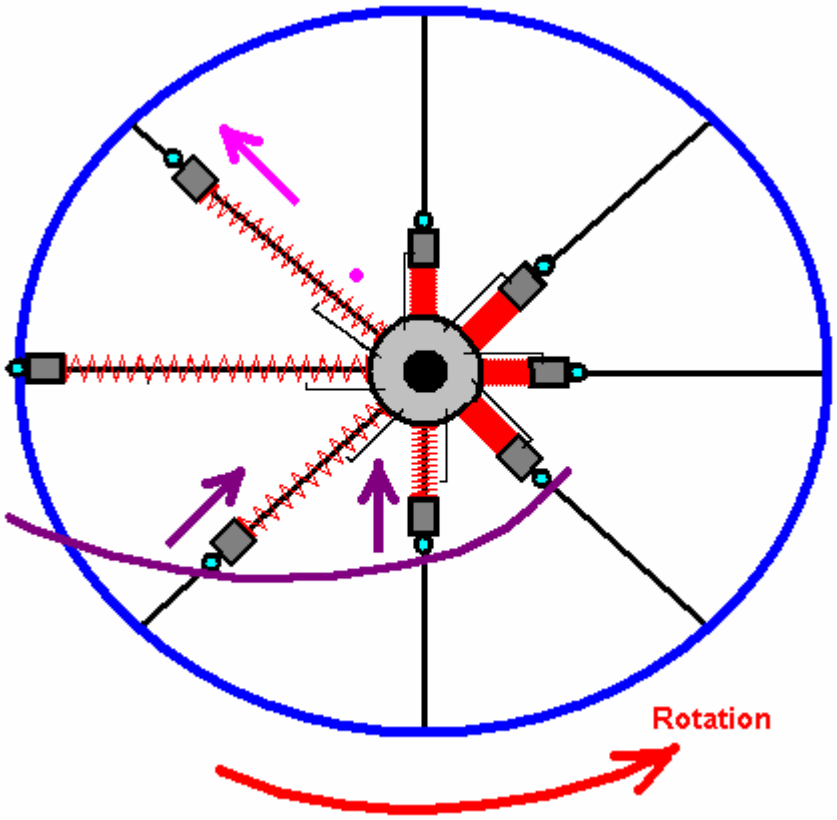
The wheel has an outer rim shown in blue and a central hub shown in grey. Metal spokes shown in black run out radially from the hub to the rim. Eight spokes are shown in this diagram as that number allows greater clarity, but a larger number would probably be beneficial when constructing a wheel of this type.

The wheel as shown, rotates in a counter-clockwise direction. Each weight, shown in dark grey, has a pair of low-friction roller bearings attached to it. There is also a spring, shown in red, between the weight and the hub. When a weight reaches the 8-o'clock position, the roller bearings contact a spring compression ramp, shown in purple. This ramp is formed of two parts, one on each side of the spokes, providing a rolling ramp for each of the two roller bearings. The ramp is formed in a curve which has a constant rate of approach towards the hub of the wheel.

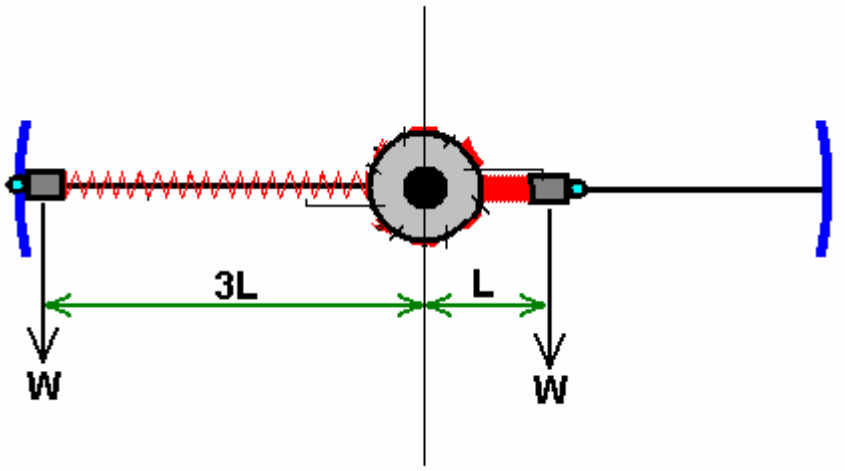
The ramp is positioned so that the spring is fully compressed when the weight has just passed the lowest point in its travel. When the spring is fully compressed, a latch holds it in that position. This holds the weight in close to the hub during its upward movement. The springs are not particularly powerful, and should be just strong enough to be able to push the weight back towards the rim of the wheel when the spoke is at forty five degrees above the horizontal. The "centrifugal force" caused by the rotation assists the spring move the weight outwards at this point. The push from the spring is initiated by the latch being tripped open by the latch release component shown in pink.

The weights have an inward motion towards the hub when they are pushed by the wheel's turning motion which forces the roller bearings upwards along the spring-compression ramp. They have an outward motion along the spokes when the catch holding the spring compressed is released at about the 11-o'clock position. The latch and the release mechanism are both mechanical - no electronics or electrical power supply is needed in this design.

These details are shown in the diagram below:



The question, of course is, will there be enough excess power to make the wheel rotate properly? The quality of construction is definitely a factor as things like the friction between the weights and their spokes needs to be very low. Let us consider the forces involved here:



Take any one weight for this calculation. Any excess rotational energy will be created by the difference between the forces attempting to turn the wheel in a clockwise direction and those forces trying to turn the wheel in a counter-clockwise direction. For the purpose of this discussion, let us assume that we have built the wheel so that the compressed-spring position is one third of the spring-uncompressed position.

As the weights are all of the same value “W”, the see-saw turning effect in a clockwise direction is the weight (“W”) multiplied by it’s distance from the centre of the axle (“L”). That is, W x L.

The turning effect in the counter clockwise direction is the weight (“W”) multiplied by it’s distance from the centre of the axle (“3W”). That is, W x 3 x L.

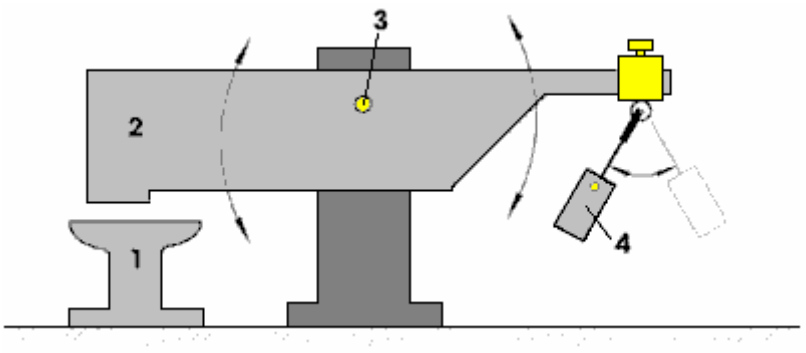
So, with WL pushing it clockwise, and 3WL pushing it counter-clockwise, there is a net force of (3WL - WL), i.e. a net force of 2WL driving the wheel in a counter-clockwise direction. If that force is able to push the weight in towards the hub, compressing the spring and operating the spring latch, then the wheel will be fully operational. There is actually, some additional turning power provided by the weights on the left hand side of the diagram, both above and below the horizontal, as they are a good deal further out from the axle than those with fully compressed and latched springs.

The only way of determining if this design will work correctly is to build one and test it. It would, of course, be possible to have several of these wheels mounted on a single axle shaft to increase the excess output power available from the drive shaft. This design idea has probably the lowest excess power level of all those in this document. The following designs are higher powered and not particularly difficult to construct.

Veljko Milkovic's Pendulum/Lever System.

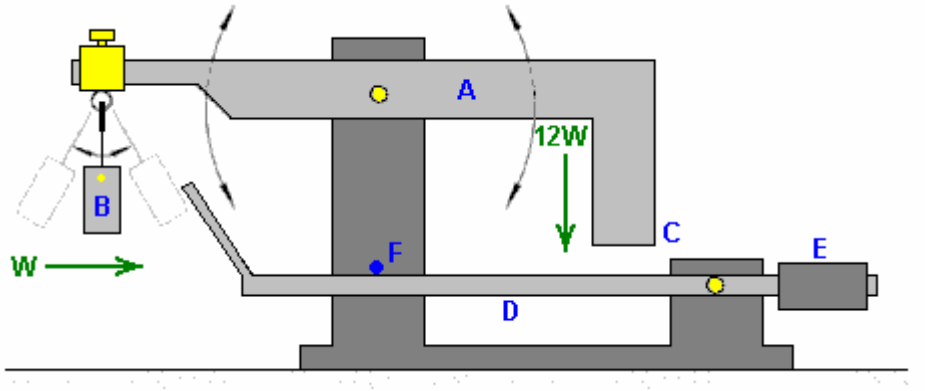
The concept that it is not possible to have excess power from a purely mechanical device is clearly wrong as has recently been shown by Veljko Milkovic at http://www.veljkomilkovic.com/OscilacijeEng.html where his two-stage pendulum/lever system shows a COP = 12 output of excess energy. COP stands for "Coefficient Of Performance" which is a quantity calculated by diving the output power by the input power **which the operator has to provide** to make the system work. Please note that we are talking about power levels and not efficiency. It is not possible to have a system efficiency greater than 100% and it is almost impossible to achieve that 100% level.

Here is Veljko's diagram of his very successful lever / pendulum system:



Here, the beam **2** is very much heavier than the pendulum weight **4**. But, when the pendulum is set swinging by a slight push, the beam **2** pounds down on anvil **1** with considerable force, certainly much greater force than was needed to make the pendulum swing.

As there is excess energy, there appears to be no reason why it should not be made self-sustaining by feeding back some of the excess energy to maintain the movement. A very simple modification to do this could be:

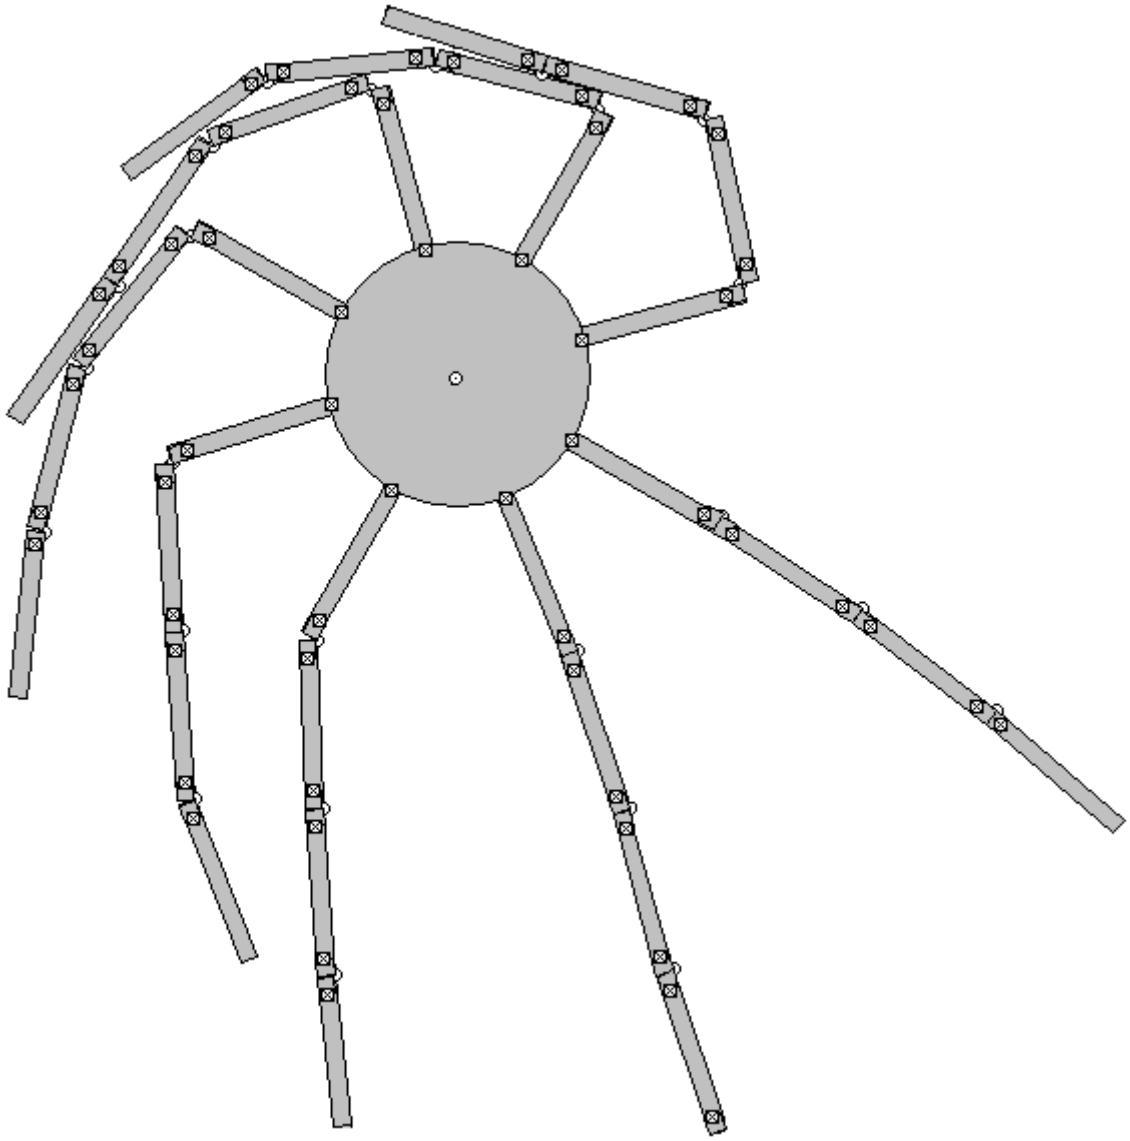


Here, the main beam **A**, is exactly balanced when weight **B** is hanging motionless in it's "at-rest" position. When weight **B** is set swinging, it causes beam **A** to oscillate, providing much greater power at point **C** due to the much greater mass of beam **A**. If an additional, lightweight beam **D** is provided and counterbalanced by weight **E**, so that it has a very light upward pressure on its movement stop **F**, then the operation should be self-sustaining.

For this, the positions are adjusted so that when point **C** moves to its lowest point, it just nudges beam **D** slightly downwards. At this moment in time, weight **B** is at its closest to point **C** and about to start swinging away to the left again. Beam **D** being nudged downwards causes its tip to push weight **B** just enough to maintain its swinging. If weight **B** has a mass of "**W**" then point **C** of beam **A** has a downward thrust of 12**W** on Veljko's working model. As the energy required to move beam **D** slightly is quite small, the majority of the 12**W** thrust remains for doing additional useful work such as operating a pump.

Amr Al-Hossary's Patent.

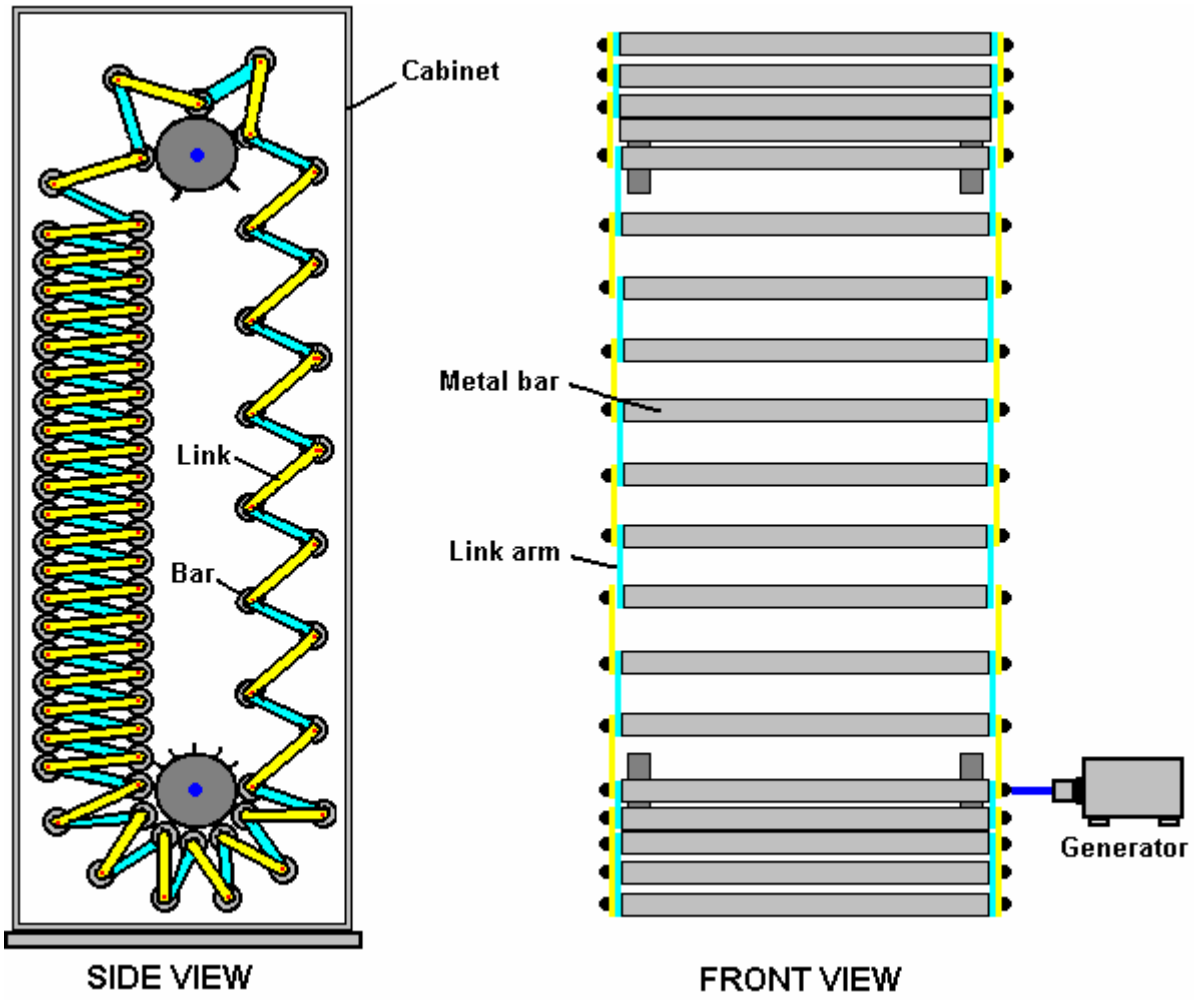
If that is the case, then the design should perhaps be modified along the lines of the patent application of Amr Al-Hossary where the hinged plates are attached directly to the rotor. That way, the plate lever arm definitely comes into play:



Here, the hinged arms or plates will also give an impact impulse when they open out to their full extent and that provides additional turning power. However, the imbalance between the two side is not a major amount and so this design is not likely to provide a large amount of torque for driving external loads.

Murilo Luciano's Gravity Chain Suggestion.

Murilo Luciano of Brazil, has devised a very clever, gravity-operated power device which he has named the "Avalanche-drive". Again, this design cannot be patented as Murilo has gifted it to the world as a royalty-free design which anybody can make. This device continuously places more weights on one side of a drive shaft to give an unbalanced arrangement. This is done by placing expandable links between the weights. The links operate in a scissors-like mode which open up when the weights are rising, and contract when the weights are falling:



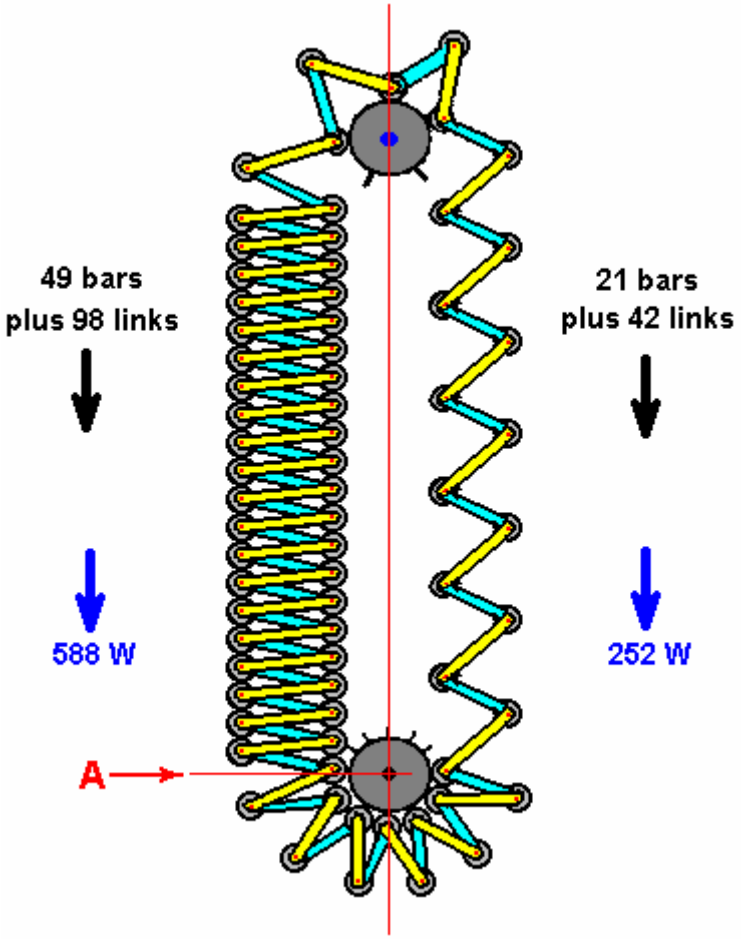
In the arrangement shown here, the weights are shown as steel bars. The design is scaleable in both height, width and the mass and number of weights. In the rough sketch above, the practical details of controlling the position of the bars and co-ordinating the rotation of the two support shafts are not shown in order to clarify the movement. In practice, the two shafts are linked with a pair of toothed sprockets and a chain. Two sets of vertical guides are also needed to control the position of the bars when they are in-between the four sprockets which connect them to the drive shafts, and as they go around the sprocket wheels.

In the sketch, there are 79 bar weights. This arrangement controls these so that there are always 21 on the rising side and 56 on the falling side (two being dead-centre). The resulting weight imbalance is substantial. If we take the situation where each of the linking bars weighs one tenth as much as one of the bar weights, then if we call the weight of one link "W", the rising side has 252 of these "W" units trying to turn the sprockets in a clockwise direction while 588 of the "W" units are trying to turn the sprockets in an counter-clockwise direction. This is a continuous imbalance of 336 of the "W" units in the counter-clockwise direction, and that is a substantial amount. If an arrangement can be implemented where the links open up fully, then the imbalance would be 558 of the "W" units (a 66% improvement) and the level arm difference would be substantial.

There is one other feature, which has not been taken into account in this calculation, and that is the lever arm at which these weights operate. On the falling side, the centre of the weights is further out from the axis

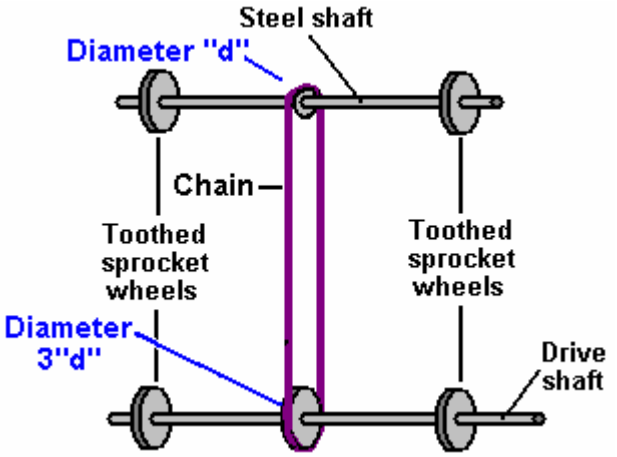
of the drive shafts because the link arms are nearly horizontal. On the rising side, the links are spread out over a lesser horizontal distance, so their centre is not as far out from their supporting sprocket. This difference in distance, increases the turning power of the output shafts. In the sketch above, an electrical generator is shown attached directly to one output shaft. That is to make the diagram easier to understand, as in practice, the generator link is likely to be a geared one so that the generator shaft spins much faster than the output shaft rotates. This is not certain as Murilo envisages that this device will operate so rapidly that some form of braking may be needed. The generator will provide braking, especially when supplying a heavy electrical load.

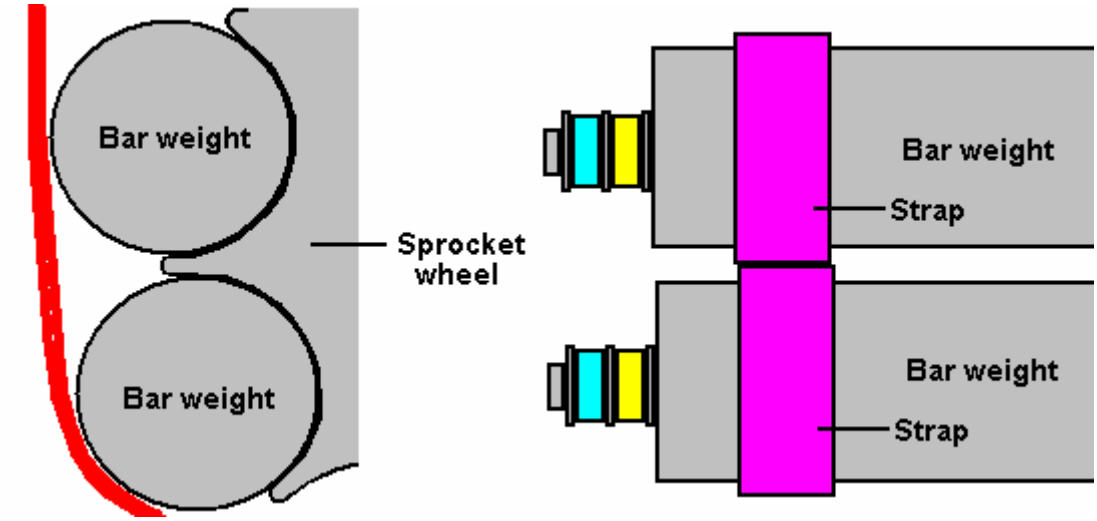
This diagram shows how the two side of the device have the unbalanced loading which causes a counter-clockwise rotation:



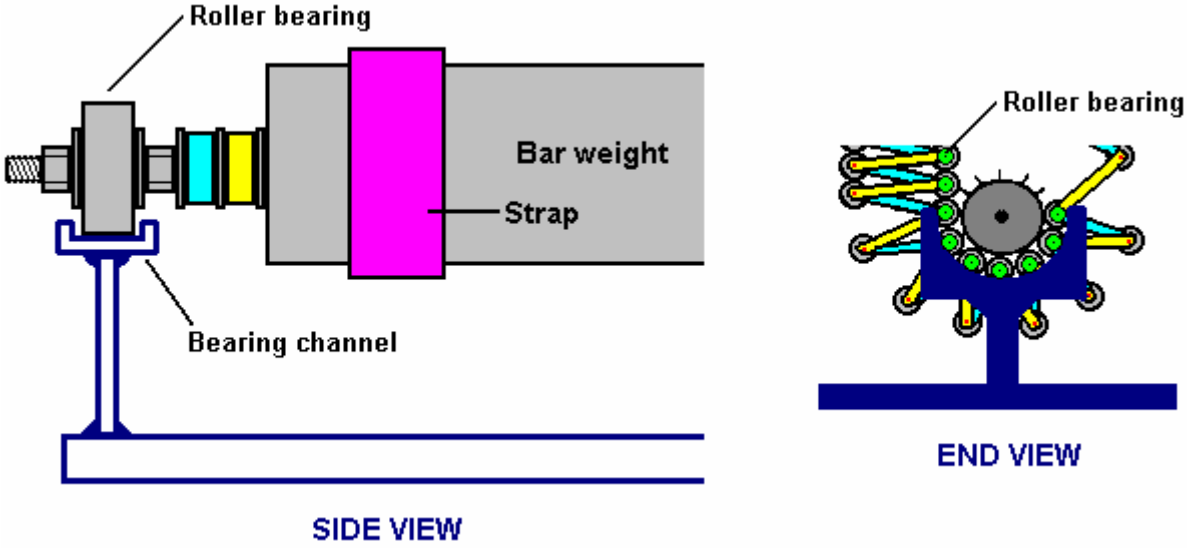
The diagrams shown above are intended to show the principles of how this device operates and so for clarity, the practical control mechanisms have not been shown. There are of course, many different ways of controlling the operation and ensuring that it works as required. One of the easiest building methods is to link the two shafts together using a chain and sprocket wheels. It is essential to have the same number of bar weights passing over the upper sprocket wheels as pass under the lower sprocket wheels. On the upper sprocket wheels, the bars are spread out, say, three times as far apart than they are on the lower sprocket wheels, so the upper sprockets need to rotate three times as fast as the lower ones. This is arranged by using a lower drive-chain sprocket wheel which has three times the diameter of the upper one.

The driving force provided by the weight imbalance of the two columns of rod weights needs to be applied to the lower sprocket wheels at point "**A**" in the diagram above. For this to happen, there has to be a mechanical connection between the stack of bar weights and the sprocket wheel. This can be done in different ways. In the above concept diagrams, this link has been shown as a sprocket tooth or alternatively, a simple pin projection from the sprocket wheel. This is not a good choice as it involves a considerable amount of machining and there would need to be some method to prevent the bar rotating slightly and getting out of alignment with the sprocket wheel. A much better option is to put spacers between the bar weights and have the sprocket teeth insert between the bars so that no bar slots are needed and accurate bar positioning is no longer essential. This arrangement is shown below:





The description up to here has not mentioned the most important practical aspects of the design. It is now time to consider the rising side of the device. To control the expanded section of the chain, and to ensure that it feeds correctly on to the upper sprocket wheels, the gap between successive bar weights must be controlled.



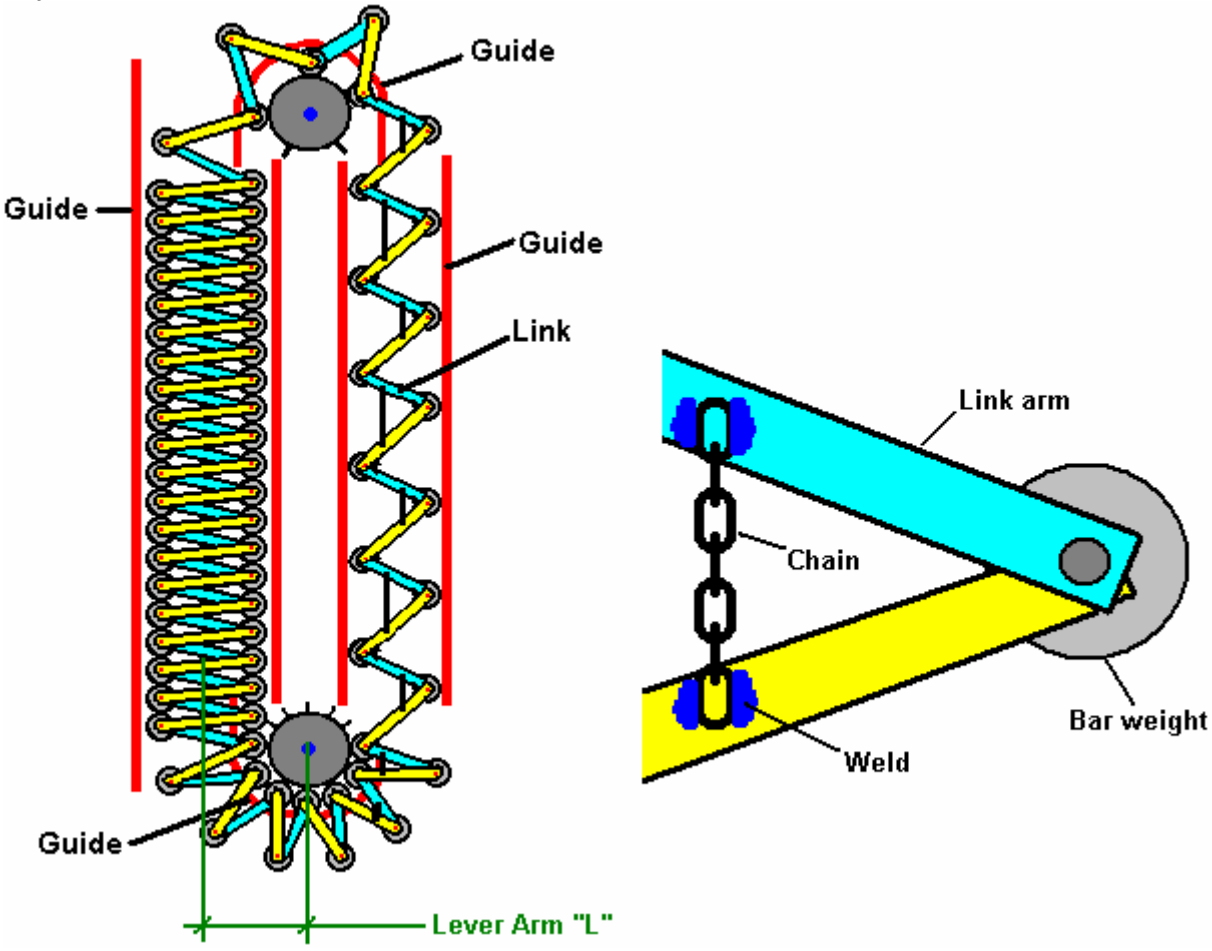
A guiding channel can be used, as shown here, and standard ball-bearings or roller-bearings can be attached to the ends of the weights by using threaded rod (or a bolt with the head inside the weight) and locking nuts.

In the example shown here, which is of course, just one option out of hundreds of different implementations, the bars on the rising side are three times as far apart as those on the falling side. This means that on the upper sprocket wheels, only every third tooth will connect with a bar weight. This is shown in the following diagram. However, if the linked weights were left to their own devices, then the rising side bars would hang down in one straight line. While that would be optimum for drive power, Murilo does not envisage that as a practical option, presumably due to the movement of the links as the bar weights move over their highest point. In my opinion, that arrangement is quite possible to implement reliably provided that the length of the links is selected to match the sprocket distance exactly, however, Murilo's method is shown here.

Murilo's method is to use additional restraining links between the weights. The objective here is to make sure that when the weights spread out on their upward journey, that they take up positions exactly three bar widths apart, and so feed correctly on to the teeth of the upper sprocket wheel. These links need to close up on the falling side and open up on the rising side. They could be fabricated from short lengths of chain or from slotted metal strips with a pin sliding along the slot.

Whichever method is chosen, it is important that the links stay clear of the bars and do not prevent the bars stacking closely together on the falling side as that would prevent them seating correctly on the teeth of the lower sprocket wheels. The easiest precision option for the home constructor is using chain, where two bar weights are positioned on the upper sprocket wheel to give the exact spacing, and the tensioned chain is welded in position, as shown below. Placing the chain inside a plastic tube causes it to take up an "A" shape standing outwards from the links when they move into their closed position. This keeps the chains from getting between the link bars. In addition, the chains are staggered from one pair of link bars to the next, as shown below, as an additional measure to keep the operation both reliable and quiet..

In the diagram below, only a few of these restraining links are shown in order to keep the diagram as simple as possible. It is not a good choice to make the upper bar sprocket wheels three times larger than the lower sprocket wheels as this would force both the rising and falling sections of chain out of the vertical, which in turn introduces friction against the guides. The central 1:3 gearing is needed to make sure that the chains on the rising side are fully stretched and the spacing of the bar weights matches the upper sprocket spacing exactly.

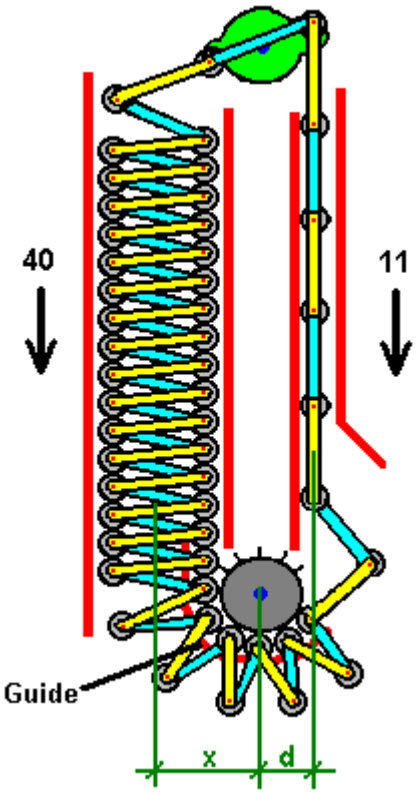


The diagrams have not shown the supporting framework which holds the axles in place and maintains the unit in a vertical position, as this framing is not specialised in any way, and there are many acceptable

variations. A sensible precaution is to enclose the device in an upright box cabinet to make sure that there is no chance of anything getting caught in the rapidly moving mechanism. This is an impressive design of Murilo's, who recommends that in the implementation shown above, that the links shown in blue are made 5% longer than those shown in yellow, as this improves the weight distribution and drive of the lower sprocket wheel..

A washing machine has a maximum power requirement of 2.25 kW and in the UK a suitable 3.5 kW alternator costs £225 and needs to be spun at 3,000 rpm for full output.

While the above description covers Murilo's main design, it is possible to advance the design further, raising its efficiency in the process as well as reducing the construction effort needed to build it. For this version, the main components remain the same, with the upper axle geared to the lower axle as before and the upper axle rotating faster than the lower one. The main difference is that on the rising side, the chain opens up completely. This does away with the need for the chain links, moves the rising weights much closer in and reduces the number of rising weights:



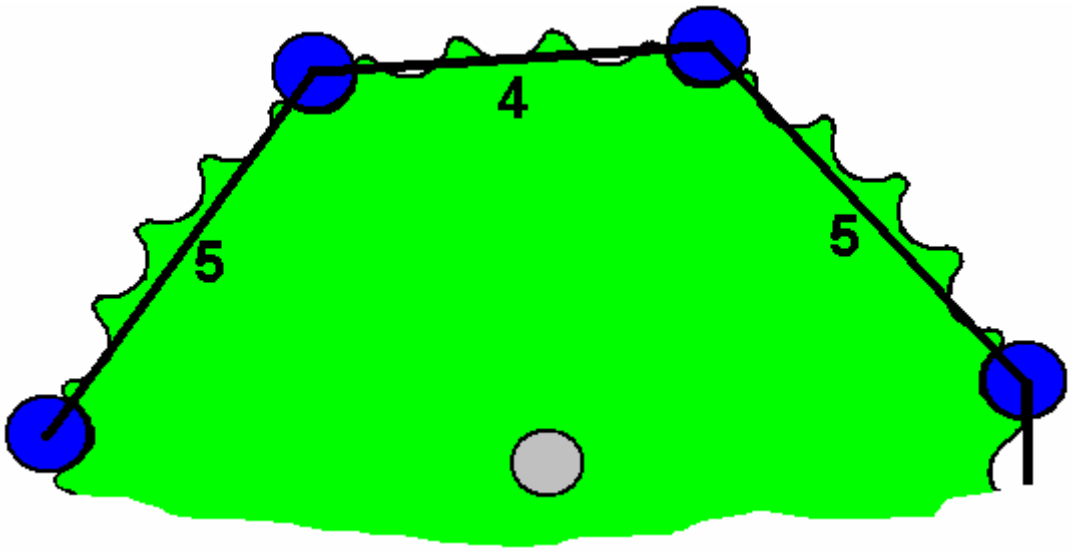
With a reduced number of weights in the diagram above, the weight imbalance is a very substantial 40:11 ratio with the massive advantage of a substantially reduced lever arm "**d**" which is much smaller than the lever arm "**x**" of the falling weights. This is a major imbalance, giving 40x pulling the axle in a counter-clockwise direction and only 11d opposing that movement.

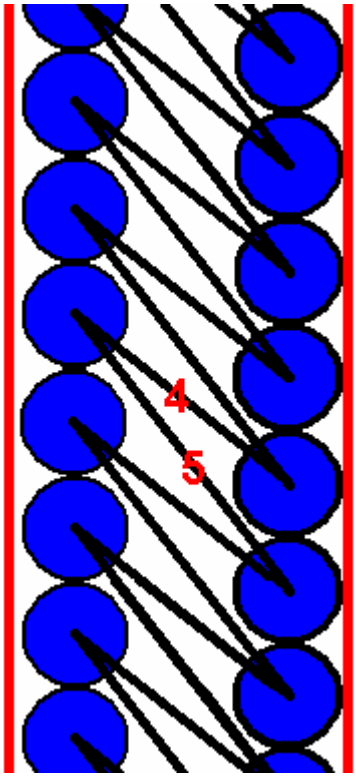
In the description so far, it has been assumed that all components will be made of metal. This is not necessarily the best choice. Firstly, metal moving against metal does make a noise, so guides made robustly of thick plastic or other similar material would be a good choice for the guides for the weights.

The weights themselves could equally well be made from strong plastic piping filled with sand, lead pellets, concrete or any other convenient heavy material. The pipes would then have strong end caps capable of holding the pivots for the links. The sprocket wheels themselves could well be made from thick plastic material which would give a quieter operation and which could be bolted to the power take-off shaft with a bolt placed right through the axle.

Most of the dimensions are not critical. Increasing the diameter of the lower sprocket wheel will increase the power of the output axle but will lower its speed. Adding more weights will increase both the output power and to a lesser degree, the speed, but will increase the overall size of the unit and its overall weight and cost. Making each weight heavier will raise the output power, or reduce the overall size if the weight is contained in fewer weights. Increasing the length of the links means fewer weights on the rising side but will require larger sprocket wheels.

It is not necessary to have all the links the same size. If the lengths are chosen carefully and the indentations in the upper sprocket wheel cover the entire circumference, then every second link can be one indentation shorter which tips the weights into a more compact and effective column on the falling side:





With this arrangement, the outer weights, shown here on the left, press down very firmly on the inside column of weights, making a compact group. If using plastic pipes with concrete then the hinge arrangement for the rods can be very simple, with a bolt set in the concrete as shown below.

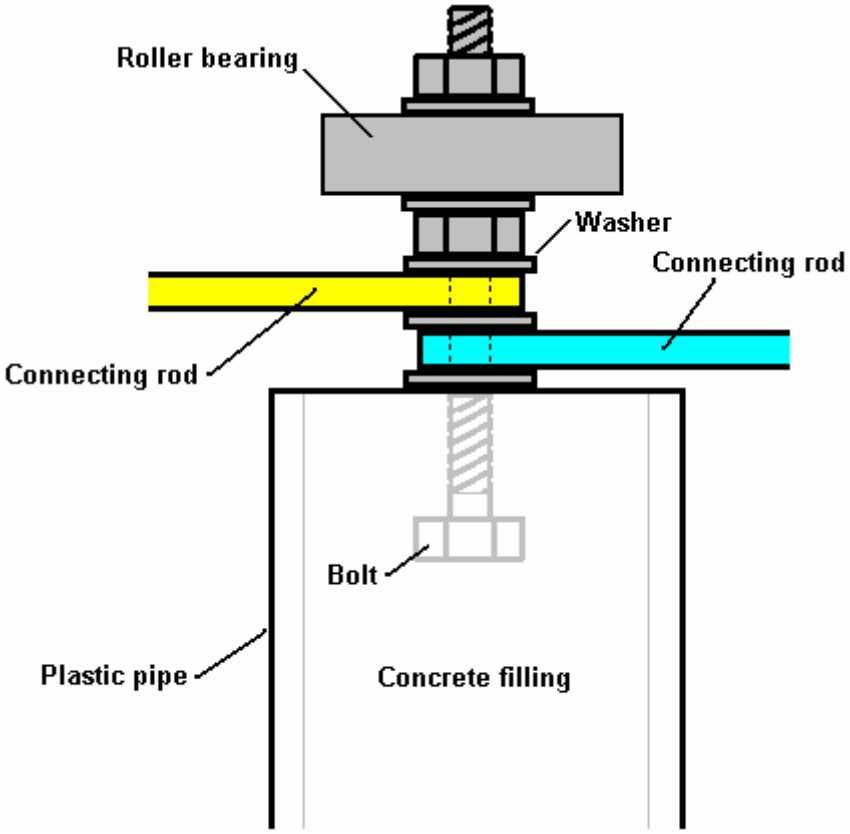
The rods, washers and bolt can be supported on a thin, rigid strip placed across the top of the pipe. When the concrete has gone solid, the strip is removed and the gap produced by its removal then allows free movement of the rods. If this technique is used, then the bar weights are cast in two steps, with a tightly fitting disc pushed part way up inside the pipe so that one end can be filled while the other end remains open and ready for the completion of the other end.

One advantage of using plastic pipes is that if the sprocket wheels are made from a tough high-density plastic material, such as is used for food chopping boards, and the weight guides are also made from tough

plastic, then there should be no metal-upon-metal noise produced during operation, if the bolt holes in the connecting rods are a good fit for the bolts used.

The concrete or mortar used as a filling can be made wet and pliable, since mechanical strength is not an issue here, and a filling with no voids in it is desirable. Even low quality concrete (caused by more water than absolutely necessary) would be more than adequate for this purpose.

The arrangement at the ends of a concrete-filled plastic pipe bar weight could be constructed like this:



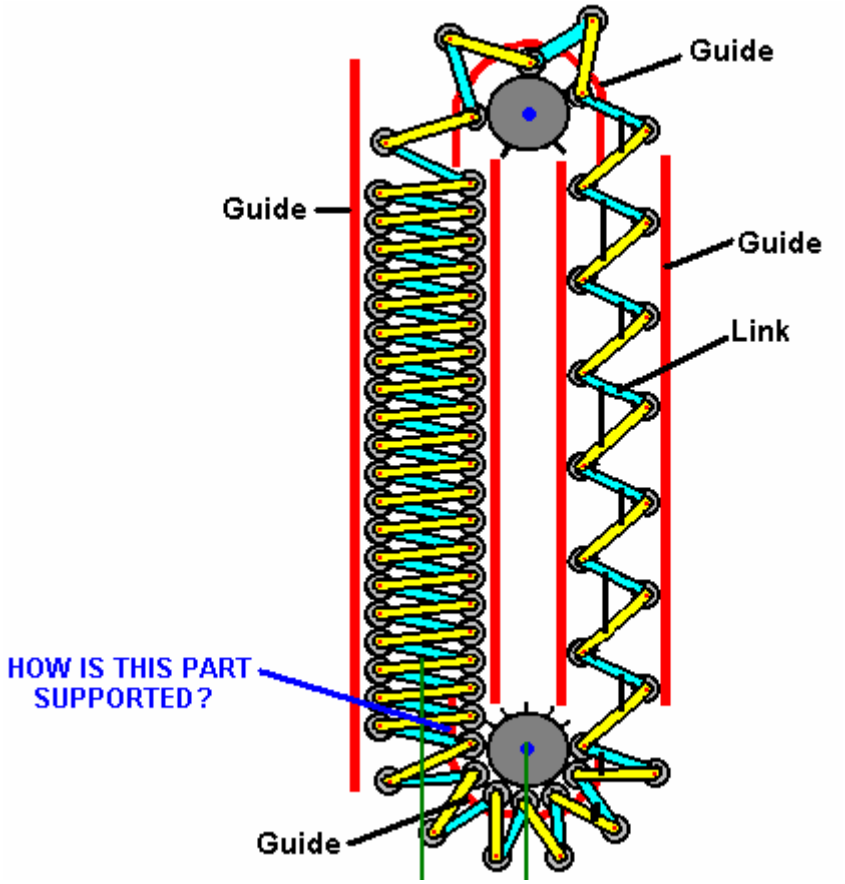
There is a very strong inclination when building a device to make it operate smoothly. Where excess energy is being drawn from the gravity field, the reverse is necessary, with a jerky operation being the optimum. Remember that the extra energy only occurs during the duration of the impulses causing the jerks. It follows then, that in an ideal situation, any device of this type should be driven by a rapid series of strong impulses. In practice, using a heavy flywheel or any similar component which has a high inertial mass, although a rapid series of sharp pulses is being applied to the component and jerky operation is not visible to the human eye, excess energy is still being “led-out” and made available to do useful work.

One other observation which may be of interest, and that it the feedback from builders of gravity wheels which says that the power output from a gravity wheel is greater if the axle is horizontal and the rotating wheel is aligned exactly with magnetic East-West.

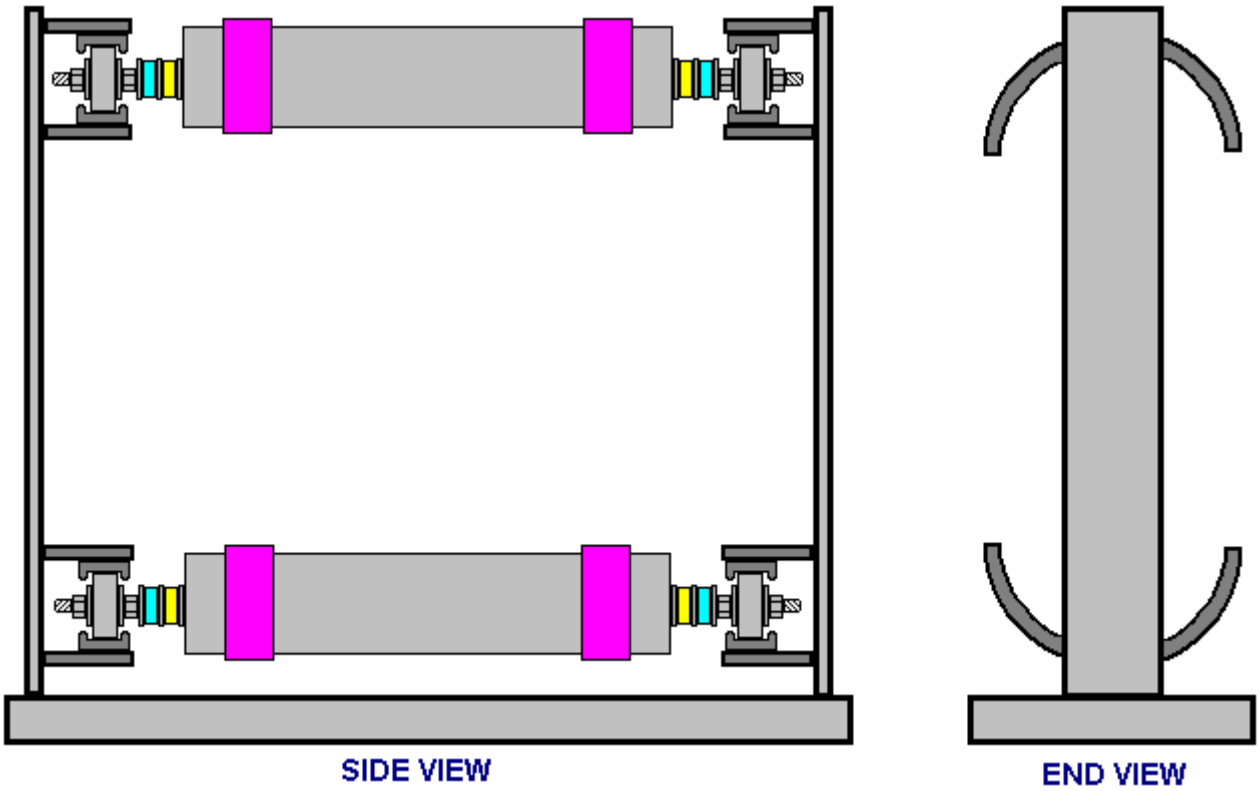
A Practical Construction Query

I have just been asked about the practical issues of mounting the guiding components for the weights. I must apologise for not making it clear that the diagrams in this description are intended to show the overall methods of operation, rather than being a direct construction arrangement. There will be several ways of constructing an implementation of each device. Here is one suggestion for a practical construction method for the gravity chain device.

The query was as follows:

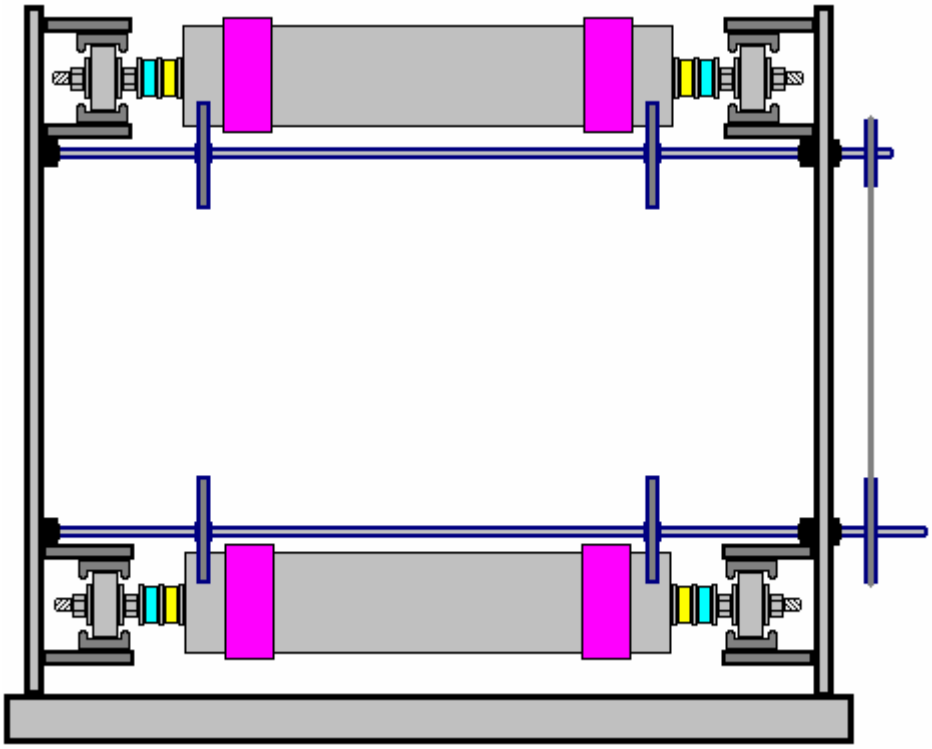


It is pointed out that the lower guide as shown, can't be supported from inside as the weights sweep through the area which would be used for that support. Also, it can't be supported from outside as the connecting rods have to move through the area where that support would be positioned. A solution has been suggested where the lower guide is supported by a strap from the upper guide, the strap running between the inner and outer weights. That is a solution which could work, but it introduces significant unnecessary friction. An alternative method is to place the guides outside the moving weights as shown here:



This method provides a low-friction channel for the roller-bearings to move along. This controls the position of the weights very accurately and the end walls also provide the supports for the axles which synchronise the positions of the weights and provide gearing between the axles if that is required. For clarity, just two of the many weights are shown and the overall proportions distorted so that the diagram will fit on the page.

With the axles, it might look like this:



Here, the axle shafts are geared together outside the end wall and either a chain or a belt drive used. The lower shaft allows a power take-off. The ratio of the diameters of the pulley wheels or sprocket wheels dictates the relative rates of rotation of the two shafts.

Other Gravity-Powered Designs.

Sterling Allan reports on **Bobby Amarasingam**'s design which has 12 kilowatts of excess power: http://pesn.com/2010/12/04/9501738_British_gravity_motor_generates_12_kilowatts/

Also reported by Sterling is the **Smith-Caggiano** gravity/momentum/centrifugal-force generator design. The report is at: http://www.peswiki.com/index.php/Directory:OBM-Global%27s_Angular_Force_Generator

Another of Sterling's reports is on the **Chalkalis Gravity Wheel** which can be seen at:
http://peswiki.com/index.php/OS:_F._M._Chalkalis_Gravity_Wheel

Buoyancy

While we are aware of buoyancy being used to convert wave power into electricity, we seem to neglect the idea of using the very powerful buoyancy forces (caused by gravity) as a direct tool at locations away from the sea. This is definitely a mistake because serious levels of power can be generated from such a system. One such system is:

The "Hidro" Self-Powered Generator of James Kwok.

This design demonstrates yet again, the practical nature of drawing large quantities of energy from the local environment. Commercial versions are offered in three standard sizes: 50 kilowatt, 250 kilowatt and 1 megawatt and licensing partners are being sought. This generator which James has designed can be seen at the Panacea-bocaf.org web site at http://panacea-bocaf.org/hidrofreeenergysystem.htm and on James' own web site at http://www.hidroonline.com/ both of which have video clips explaining how the design works. The method is based on different pressures at different depths of water, gravity, and on the buoyancy of air-

filled containers. The system does not rely on wind, weather, sunlight, fuel of any type, and it can operate all the time, day or night, without causing any kind of pollution or hazard. This particular design calls for a water-filled structure of some height, a source of compressed air and a pulley system, and without wishing to be in any way critical, it seems rather more complicated than it needs to be. If, unlike James, you have not done the mathematics for the system, you would assume that the amount of power generated by a system like this would be less than the amount of power needed to make it operate. However, that is definitely very far from reality as considerable excess power is gained through the natural forces of the local environment which make the system operate. Part of the patent application which James made is shown here:

US 2010/0307149 A1 **Date: 9th Dec. 2010** **Inventor: James Kwok**

HYDRODYNAMIC ENERGY GENERATION SYSTEM

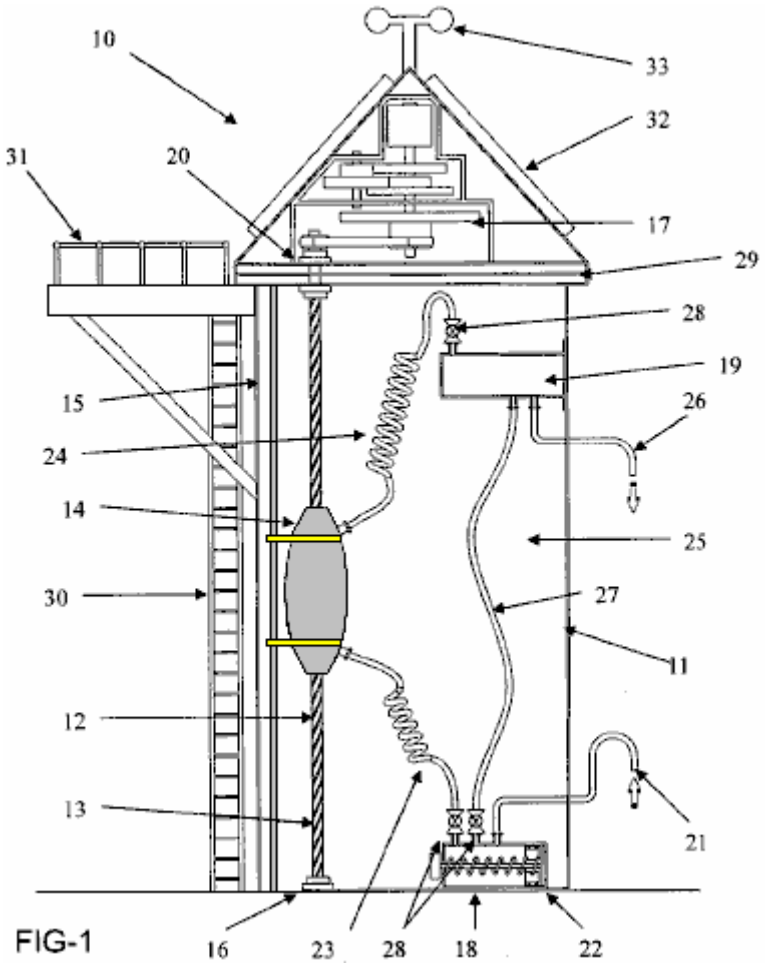


FIG-1

Fig.1 is a cross-sectional view of an embodiment of the energy generation system of the present invention. Here, the energy generation system **10** comprises a vessel **11** in the form of a water tank and a shaft **12** which can rotate about it's longitudinal axis. The shaft **12** is provided with a helical screw groove **13** and is connected at it's lower end to a bearing **16** which allows it to rotate freely about its longitudinal axis.

The upper end of the shaft is connected to a generator **17** which is a flywheel system. The rotational energy of shaft **12** may be transferred to the generator through a ratchet-cog system **20**. A buoyant inflatable capsule **14** is provided along with its guiding mechanism **15** which is in the form of a wire or pole to assist in the smooth vertical movement of buoy **14**.

There is a first air reservoir **18** located in a lower portion of the vessel **11** and a second air reservoir **19** located in an upper portion of the vessel **11**. The first reservoir **18** draws air from the atmosphere, in through air intake port **21**. Once the pressure in the first reservoir has reached a predetermined value, a piston **22** is actuated, forcing air through hose **23** into the buoyant capsule **14**, which, when inflated, begins to move upwards through water tank **11**, as the buoy **14** has become less dense than the fluid **25** (such as fresh

water or saltwater) in tank **11**. This in turn causes rotation of shaft **12**, and activation of the power generator **17**, thereby generating power.

When buoy **14** reaches the upper limit of its travel, the air in the buoy may be forced to flow through a second hose **24** and into the second air reservoir **19**. When air is removed from the buoy it moves downwards through vessel **11** under gravity and with the assistance of ballast (not shown). The downward movement of buoy **14,** causes rotation of the shaft **12**, which drives the generator **17**, thereby generating power.

Air stored in the second reservoir **19** may be vented to the atmosphere through a vent **26** if the pressure in the second reservoir **19** becomes too high. Alternatively, air may flow from the second reservoir **19** into the first reservoir **18** through a third hose **27** so that less air must be drawn into the first reservoir **18** when buoy **14** reaches the lower limit of its travel and must once again be inflated with air from the first reservoir **18**.

The hoses **23**, **24** and **27** are provided with non-return valves **28** to ensure that air will flow in only one direction through the system **10**. Vessel **11** may be provided with ventilation **29** as required and it may also be provided with access stairs **30** and an access platform **31** so that maintenance may be carried out as required. The system may also be provided with a solar energy collection device **32** to generate at least a portion of the energy required to drive piston **22** and the non-return valves **28**. Energy produced by the solar energy collection device **32** may also be used to power a light or beacon **33** to indicate the location of the system **10**.

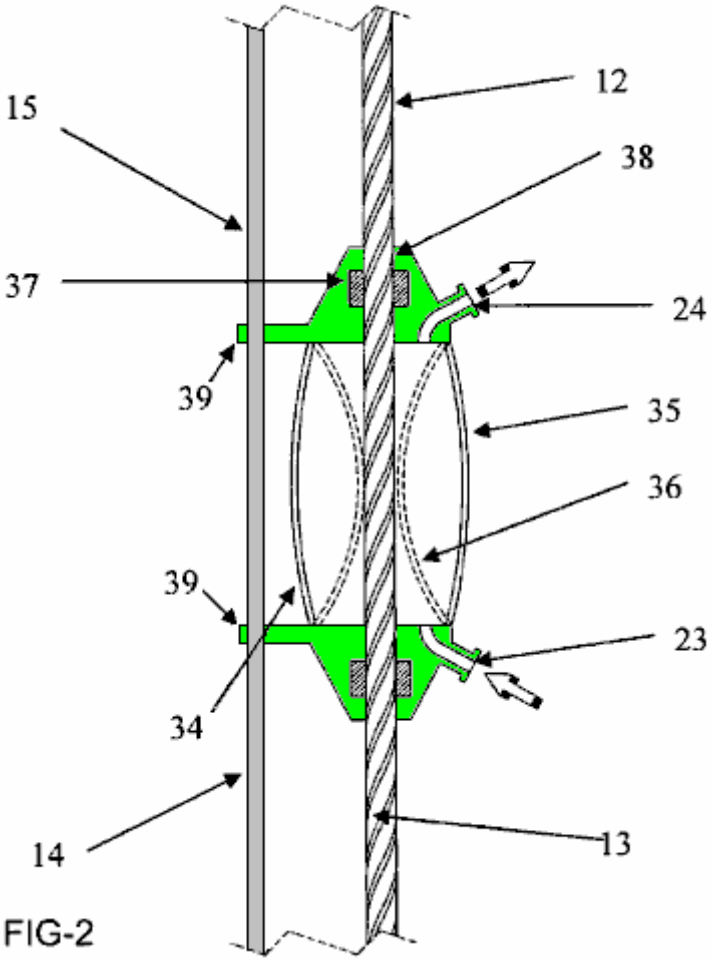

FIG-2

Fig.2 shows one arrangement for buoy **14** comprising an inflatable capsule **34**. This figure illustrates the shape of the walls of the inflatable capsule **34** when inflated **35** and when deflated **36**. Air passes into capsule **34** through hose **23** and exits from the capsule through hose **24**.

The buoy **14** also has a sleeve **37** attached to it. This sleeve has projections which engage with the helical groove **13** of shaft **12**, thereby causing rotation of the shaft when the buoy moves relative to shaft **12**. Sleeve **37** is provided with ballast **38**, such as stainless steel weights that assist in the downward movement of the buoy when it is deflated.

Buoy **14** is attached to a guide pole **15** and the buoy has a pair of arms **39** which slide on the guiding pole **15** and assist in the smooth vertical movement of the buoy.

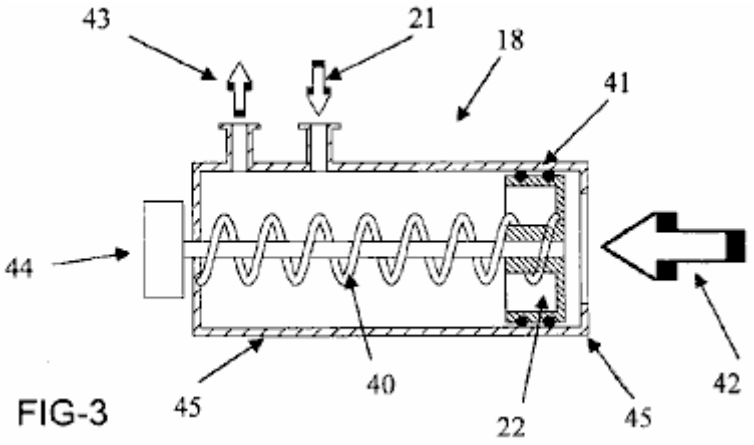

FIG-3

Fig.3 shows one version of the first air reservoir **18**. Air is drawn into reservoir **18** through air intake **21**. The reservoir includes a piston **22** associated with a spring **40**, the piston **22** being provided with seals **41** to prevent leakage of air.

When pressure, such as hydrostatic pressure, is applied in the direction of arrow **42**, the piston moves to the left of the reservoir **18** compressing spring **40** and forcing air out through outlet **43**. A motor **44** is provided to reverse the movement of the piston **22**. Reservoir **18** may be fixed to the floor of the vessel.

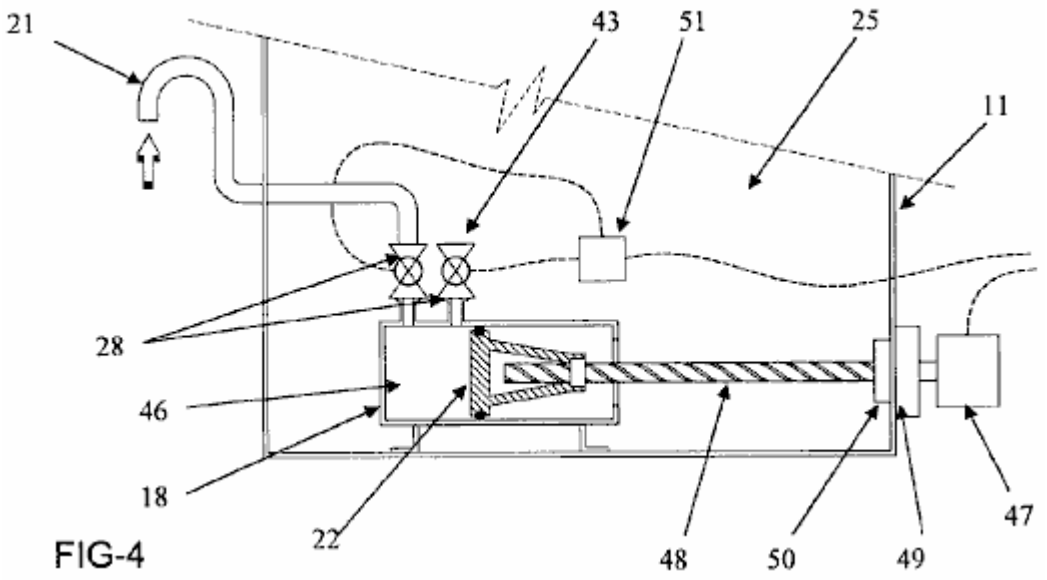

FIG-4

An alternative construction of the first air reservoir **18** is shown in **Fig.4**. In this embodiment, reservoir **18** is housed within a vessel **11** containing a fluid **25**. Air enters reservoir **18** through air intake **21** and is held in a chamber **46**. The reservoir has a piston **22** and the movement of the piston **22** towards the left of the reservoir **18** forces air in the chamber **46** out through air outlet **43**.

Piston **22** is driven by motor **47** which rotates the helically-grooved shaft **48**. The motor is linked to the shaft by a ratchet and cog mechanism **49**, which is provided with a spring loaded seal **50** on the inner surface of vessel **11**. An actuator **51,** may be used to control the opening and closing of non-return valves **28** as well as the actuation of motor **47**.

Fig.5 illustrates a cross-sectional view of an energy generation system according to one of the embodiments of the present invention:

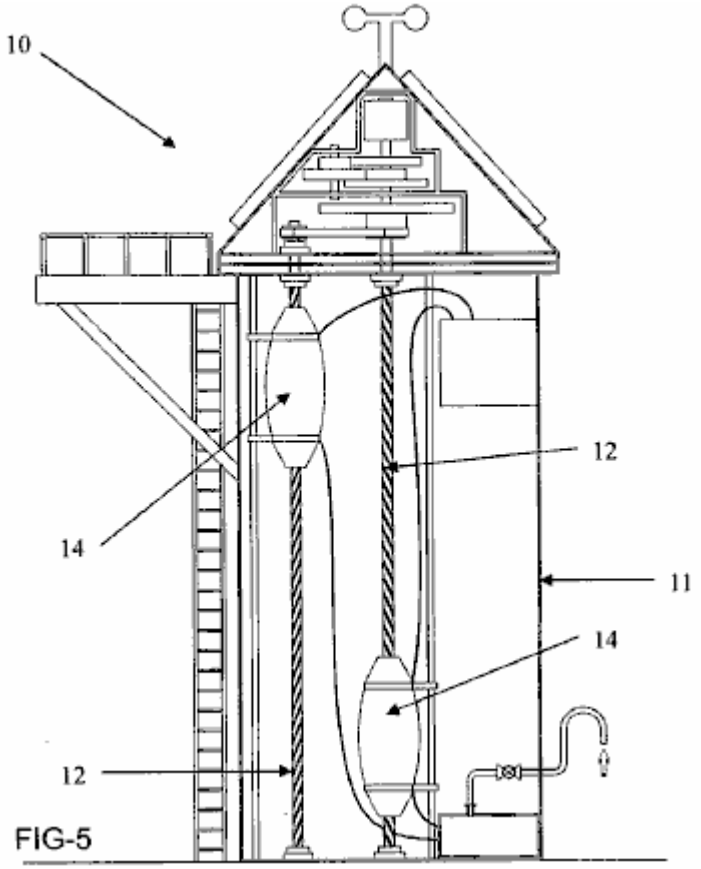

FIG-5

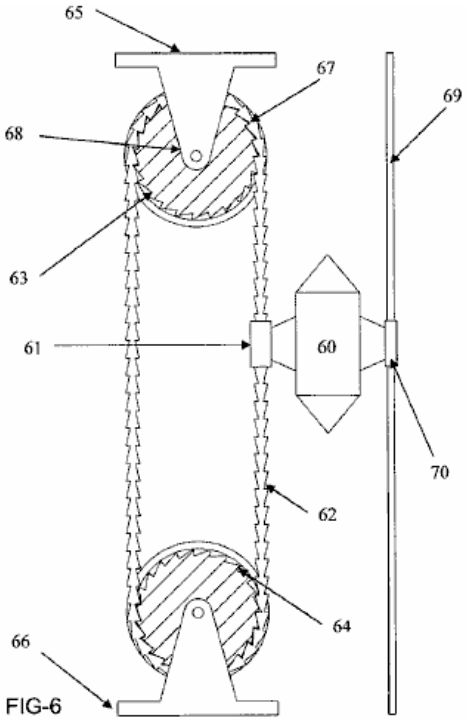

FIG-6

Fig.5 shows an embodiment where which a pair of buoys **14** are present. Each buoy is associated with its own shaft **12** and may move up and down inside vessel **11** independent of one another.

In **Fig.6**, an alternative embodiment of the present invention is illustrated, where the buoy **60** has a connecting method **61** in the form of a cylindrical sleeve through which a guide chain **62** passes. Chain **62** is provided in an endless loop and is located on an upper tracking device **63** and a lower tracking device **64**, both of which are pulleys. The upper pulley **63** may be fixed to an upper wall (not shown) of a vessel (not shown) via a bracket **65**, while the lower pulley **64** may be fixed to a lower wall (not shown) of a vessel (not shown) via a bracket **66**.

The connection mechanism **61** contains ratchets which engage with the links of the chain **62** when buoy **60** moves downwards. Thus, as buoy **60** moves downwards, chain **62** also moves, thereby causing both the upper and lower pulleys to rotate in a clockwise direction. The upper and lower **64** pulleys have a series of indentations **67** corresponding to the shape of the links of the chain **62**. In this way, the chain **62** sits in the indentations **67** and grips the tracking device (**63**, **64**), thereby ensuring that the tracking device (**63**, **64**) rotates.
In the embodiment of the invention illustrated in **Fig.6**, a work shaft **68** is associated with the upper pulley **63** such that rotation of the upper pulley results in rotation of the work shaft **68**. The work shaft **68** is located substantially perpendicular to the direction of travel of the buoy **60**. The work shaft drives a generator to produce power.

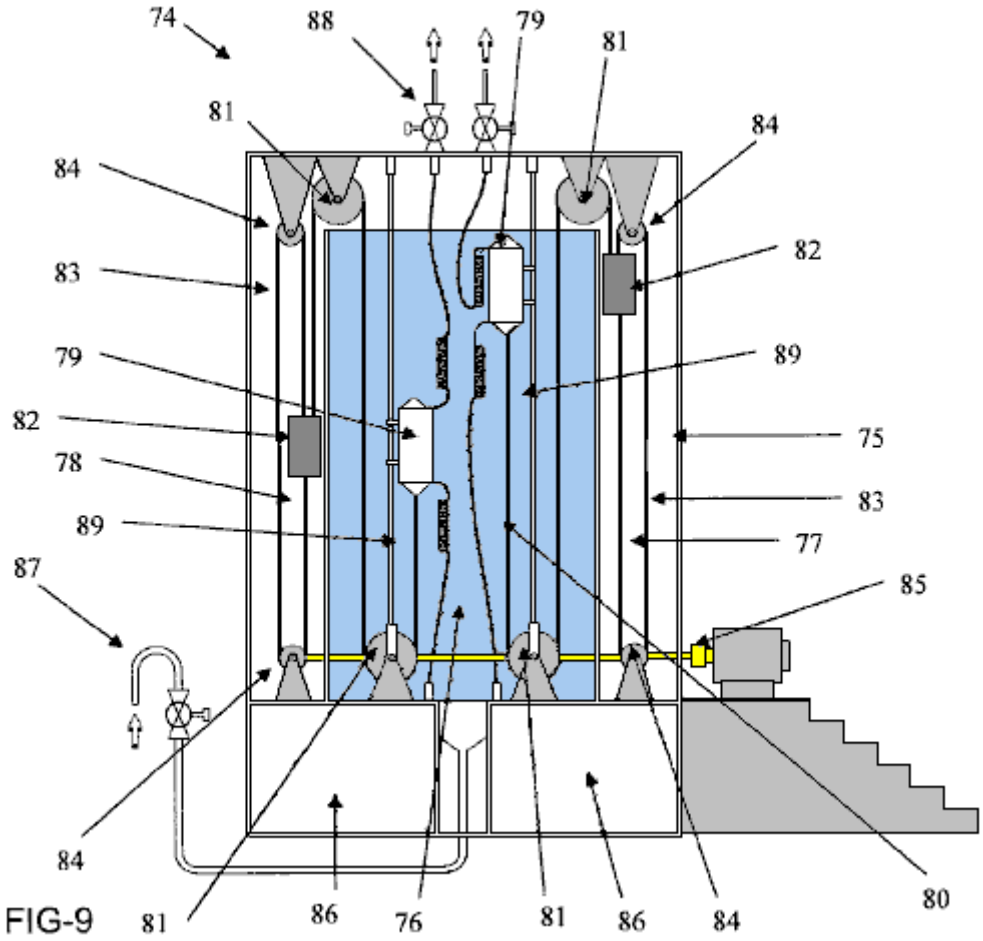

FIG-9

Fig.9 shows an alternative embodiment of this energy generation system **74**. The system is comprised of a vessel **75** having a fluid-filled "wet" compartment **76** and one or more "dry" compartments (in this case, a pair of dry compartments **77**, **78**) with no liquid in them. These dry compartments may be fabricated from any suitable material, such as, concrete, steel, fibreglass, plastic or any combination of materials.

The system also has a pair of buoys **79** each with a deflatable bladder-like construction. The buoys have guide rails **89** which ensure that the buoys move smoothly up and down inside the vessel **75**.

In this embodiment of the invention, air reservoirs **86** are located in the base of the vessel **75**. Air enters the reservoirs **86** through inlet **87**, while air exiting from the buoy **79** is vented through valves **88**. The vented air may either be expelled to the atmosphere or recycled to the reservoirs **86**.

Each of the buoys is designed to be connected to one end of a chain or rope **80**. A weight **82** is connected to the other end of the chain or rope **80**. The chain or rope **80** has a series of pulleys **81** such that when the buoy is inflated and filled with air, the buoyancy is greater than the weight **82** and so the buoy rises in the vessel.

When the buoy **79** is deflated, weight **82** is heavier than the buoyancy and so the buoy sinks in vessel **75**. In the embodiment illustrated here, the weights **82** are located in the dry compartments **77**,**78**. There are several reasons for this, including that, by locating the weights **82** in the dry compartments **77**,**78**, the velocity of the weights **82** in the downward direction is increased, and therefore an increase in the energy produced by the system **74** is experienced.

The weights **82** are associated with second ropes or chains **83**, such that vertical movement of the weights **82** results in the rotation of the second ropes or chains **83** around a pair of sprockets **84**. Rotational energy generated by the rotation of the second ropes or chains **83** is transferred to a power generation device **85** (such as a turbine or the like) in order to generate power (e.g. electrical power)

***

In spite of its mechanical complexity, the Hidro design is offered as a commercial generator with tens of kilowatts of excess power, indicating that buoyancy is a significant method of generating power, based on the fact that water is hundreds of times heavier than air. Due to its weight, movement in water is slow but can be very powerful. The helical groove method of converting the vertical movement of the floats into rotational power is used because of this as it has a very high ratio between shaft turns and movement along the shaft. This can be understood when you consider the fact that a complete revolution of the shaft is caused by the float moving up just one step to the next thread position directly above. The turns ratio for the complete float movement is determined by the angle of the groove cut into the drive shaft.

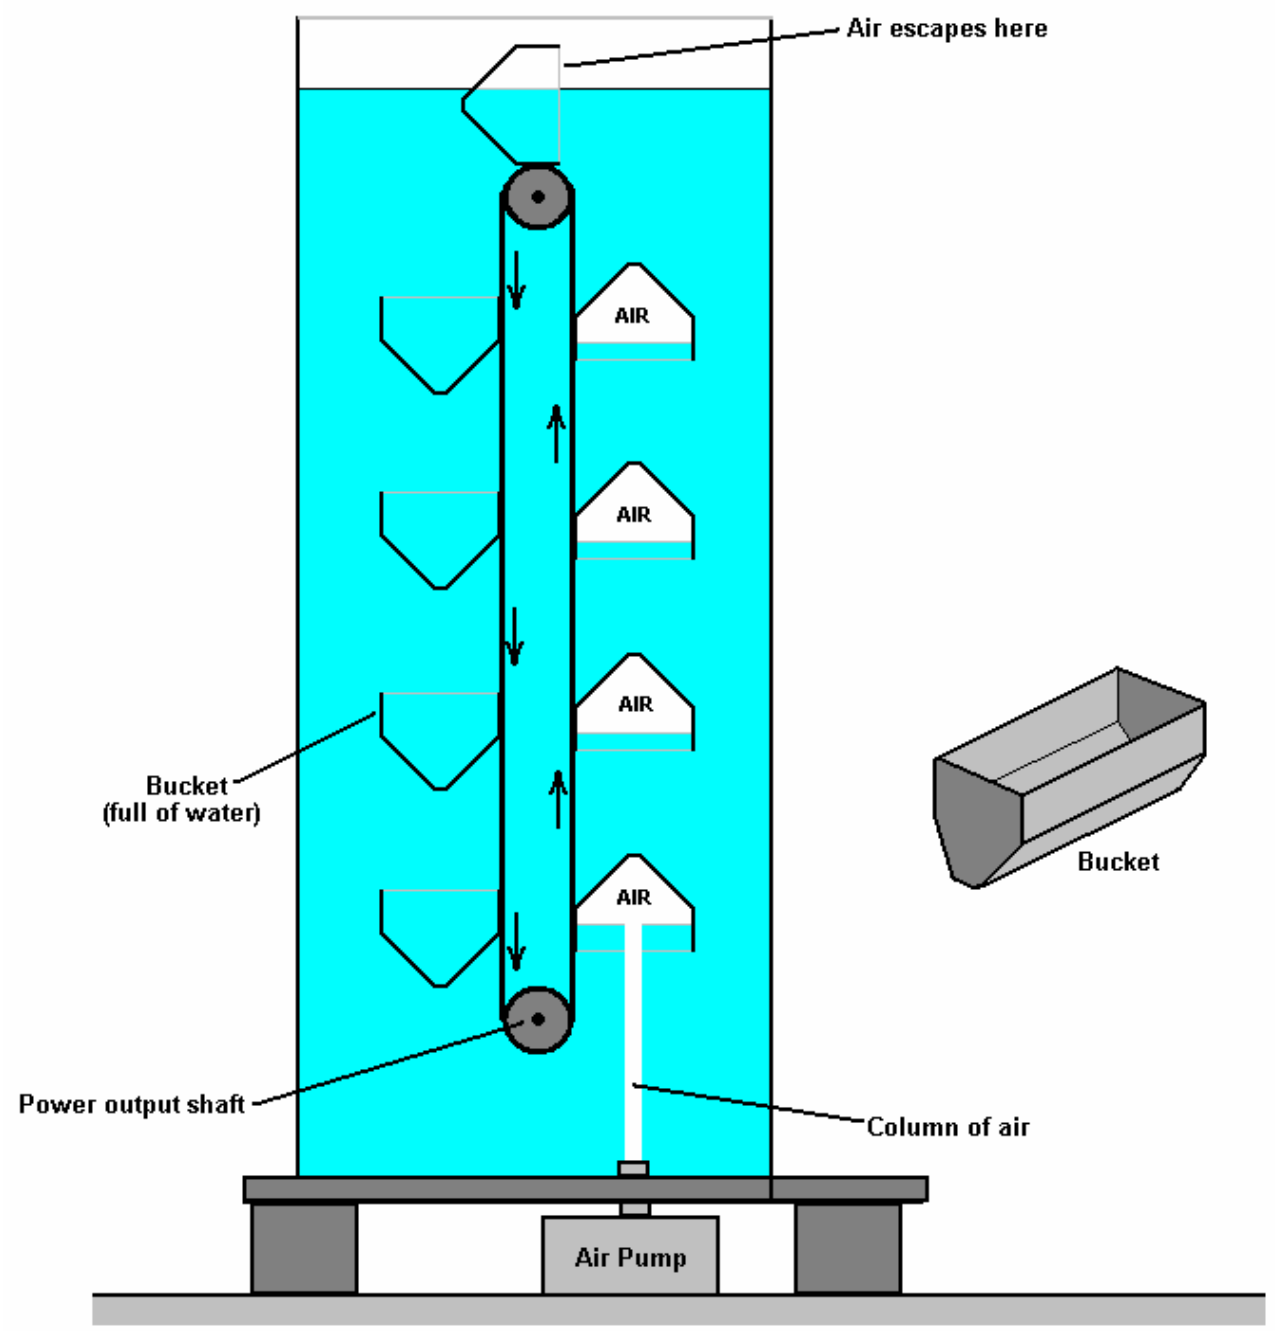
One other thing which needs to be considered for such a project is the weight of the overall structure when filled with water. The overall weight is liable to be many tons and so the footing underneath the generator needs to be very robust. Also, while compressed air is mentioned, giving the impression of cylinders of compressed air or gas, For continuous operation one would expect an air pump to be used. Whether or not an air pump is used, the diameter of the air hoses needs to be considered. Most people think that a gas can flow along a pipe or tube very easily. That is not the case. If you want to get a feel for the constriction caused by a pipe, then take a one metre length of 6 mm diameter plastic tube and try blowing through it. No significant amount of air will pass through the tube even if you blow very hard. The web site http://www.engineeringtoolbox.com/natural-gas-pipe-sizing-d_826.html shows this table:

Capacity of Pipe (MBH ≈ CFH)							
Pipe Size (inches)		Pipe Length (feet)					
Nominal	Inside diameter	10	20	40	80	150	300
1/2	0.622	120	85	60	42	31	22
3/4	0.824	272	192	136	96	70	50
1	1.049	547	387	273	193	141	100
1 1/4	1.380	1200	849	600	424	310	219
1 1/2	1.610	1860	1316	930	658	480	340
2	2.067	3759	2658	1880	1330	971	686
2 1/2	2.469	6169	4362	3084	2189	1593	1126
3	3.068	11225	7938	5613	3969	2898	2049
4	4.026	23479	16602	11740	8301	6062	4287
5	5.047	42945	30367	21473	15183	11088	7841
6	6.065	69671	49265	34836	24632	17989	12720
8	7.981	141832	100290	70916	50145	36621	25895

Notice the major difference in carrying capacity of any of these pipes with just the change from a 10-foot (3 metre) length to a modest 20-foot (6 Metre) length, and those lengths are the sort of lengths needed for many applications. Also, look at the figures for, say, the 0.5 inch (nominal) diameter pipe. With just a 10-foot length, it would take a full two minutes to pump just one cubic foot of air through it. It follows then, that pipes of considerably larger diameter are needed for a project like the ‘Hidro’.

It is possible to construct a much more simple version of the ‘Hidro’, perhaps like this:

A Simple Buoyancy Power Generator



A simple hydraulic, buoyancy-powered generator can be constructed, with two or more horizontal, rotating shafts submerged in water in such a way that they are effectively positioned one above the other. Each shaft has one, and preferably two or more sprocket wheels mounted on it. Each of these sprocket wheels engages with a continuous chain loop which also engages with the sprocket wheel which is positioned vertically above it. These vertical chain loops form a belt-style support for a series of identical buckets. On one side of the vertical belt the buckets have their open face upwards and on the other side the bucket openings are facing downwards. An air pump is positioned directly underneath the set of buckets which have the bucket openings facing downwards. The air pump generates an upward-moving stream of air which collects in the rising buckets, displacing the water filling the bucket. This results in a powerful upward thrust caused by the buoyancy of that bucket, and the thrust causes the bucket to move upwards, rotating both horizontal shafts and bringing another water-filled bucket into position above the air pump. A gearing system transfers the rotation torque thus produced, to a generator which produces electricity for general purpose uses.

This is a generator whose input shaft is rotated through buoyancy caused by air-filled containers submerged in a tank of water or some other suitable heavy liquid. Continuous, powerful rotation of the generator shaft is produced through the use of one or more conventional, commercially available air pumps. An air pump is

used to fill a series of containers which are open at one end and which are attached to what is effectively a belt arrangement created by two strong chain-link loops which mesh with sprocket wheels mounted on two shafts, either, or both of which can be utilised for the extraction of useful power, preferably for driving an electricity generator but not necessarily limited to that function as any powerful torque has many useful applications.

Objectives are to provide a power generation system which is very simple in form and which can be understood, operated and maintained by people with minimal training. Also, a system which uses components which are already readily available, thus avoiding significant manufacturing costs, and one which operates without the need for any kind of complex mechanism or high-precision equipment and which can operate with a wide range of commercially available products.

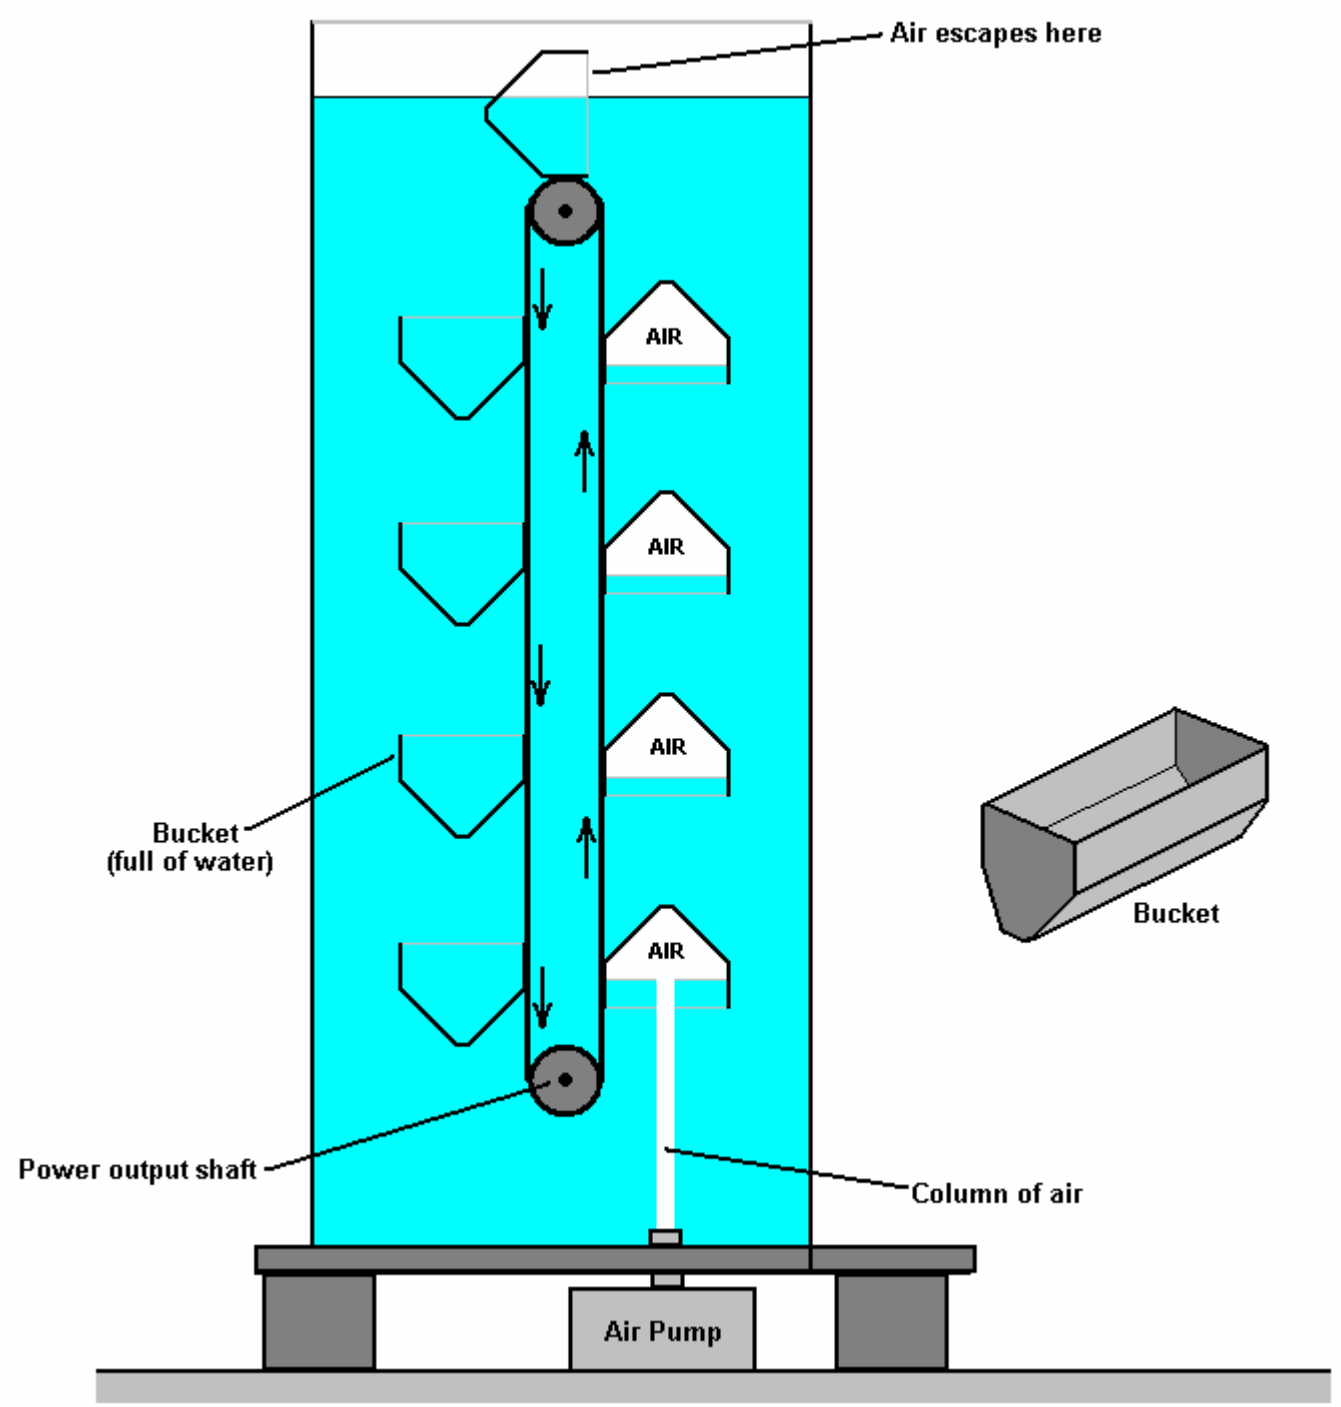


Fig.1, is a simplified partial schematic cross-sectional view showing the main components of the generator as seen from one end.

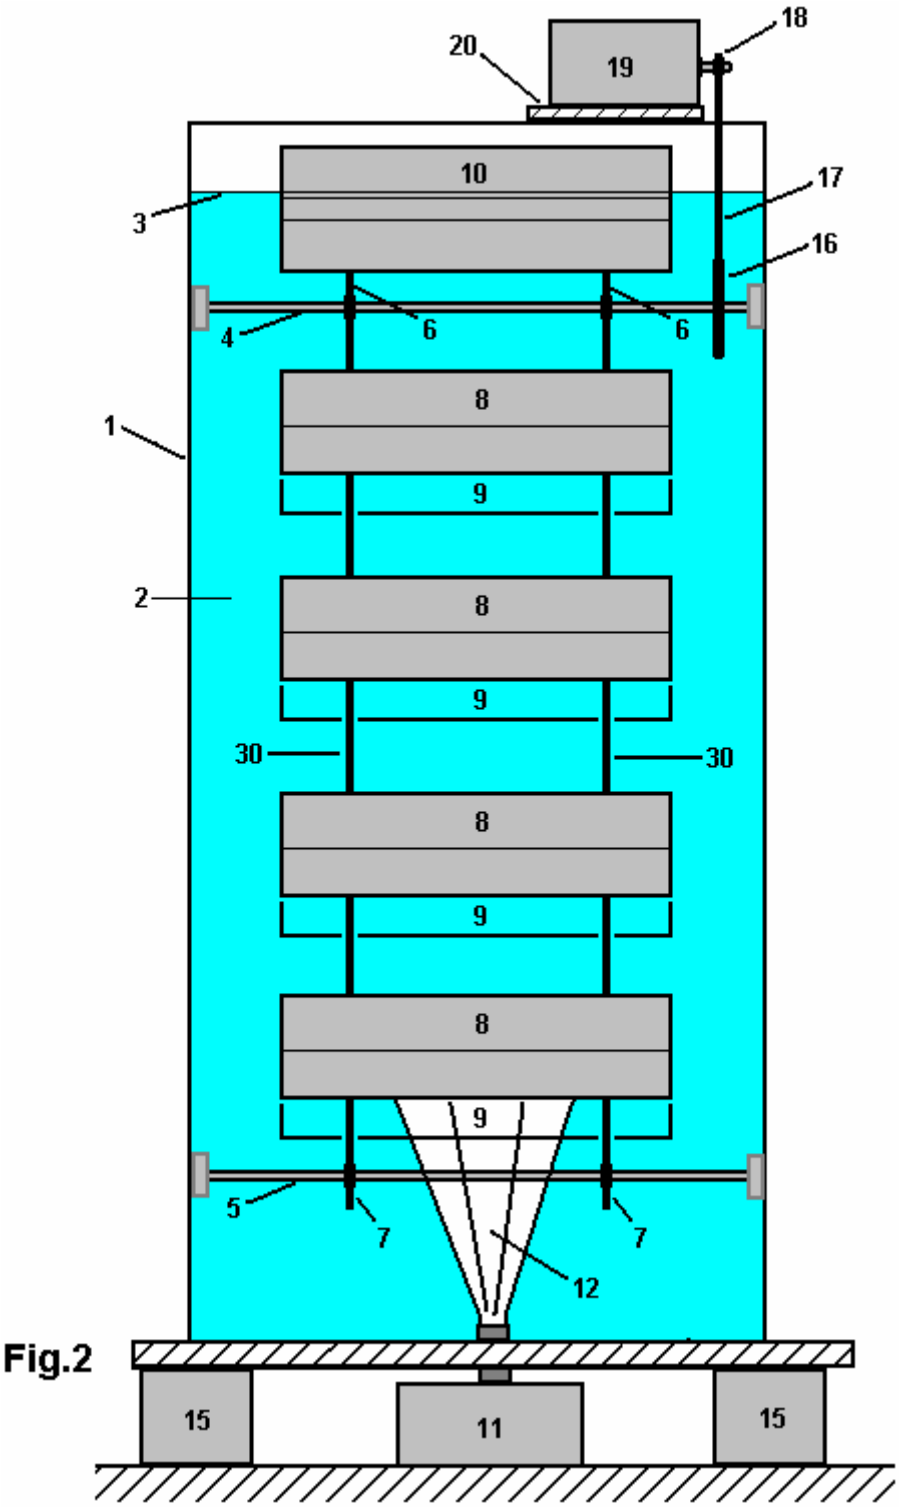

Fig.2

Fig.2, is a cross-sectional conceptual schematic view showing the front view of the generator in its most simple form.

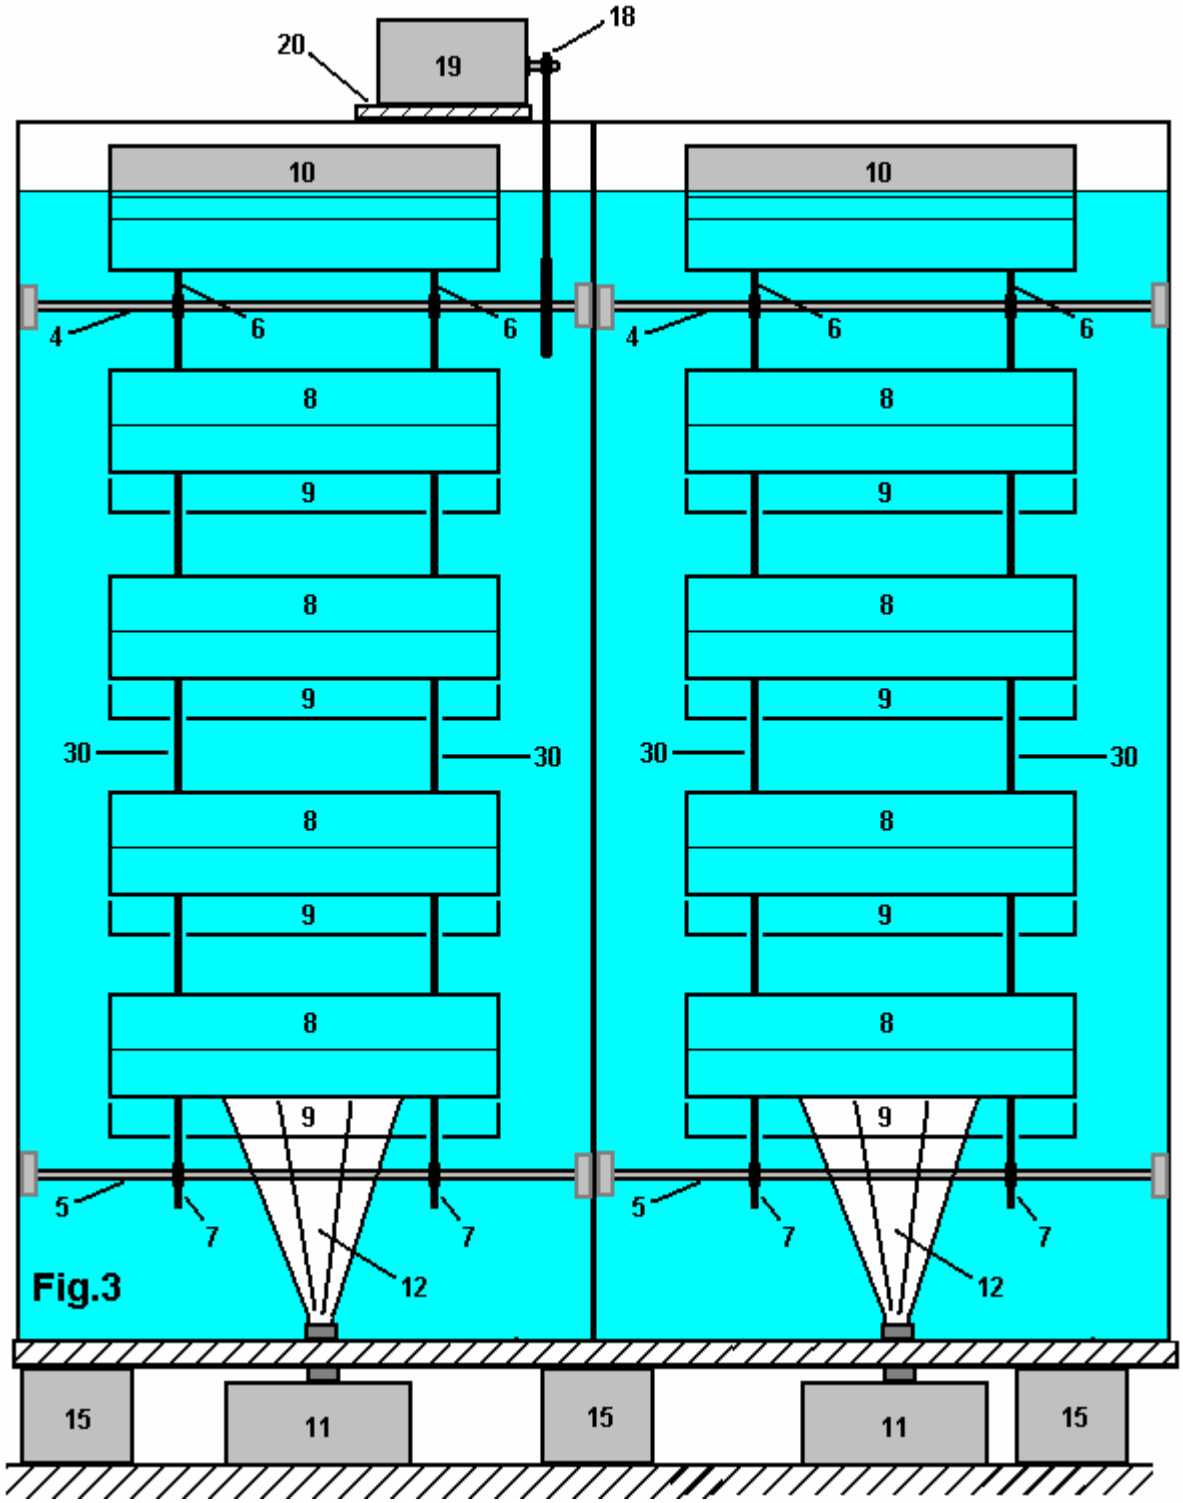

Fig.3, is a cross-sectional conceptual schematic view showing the front view of the generator where more than one set of buckets is used.

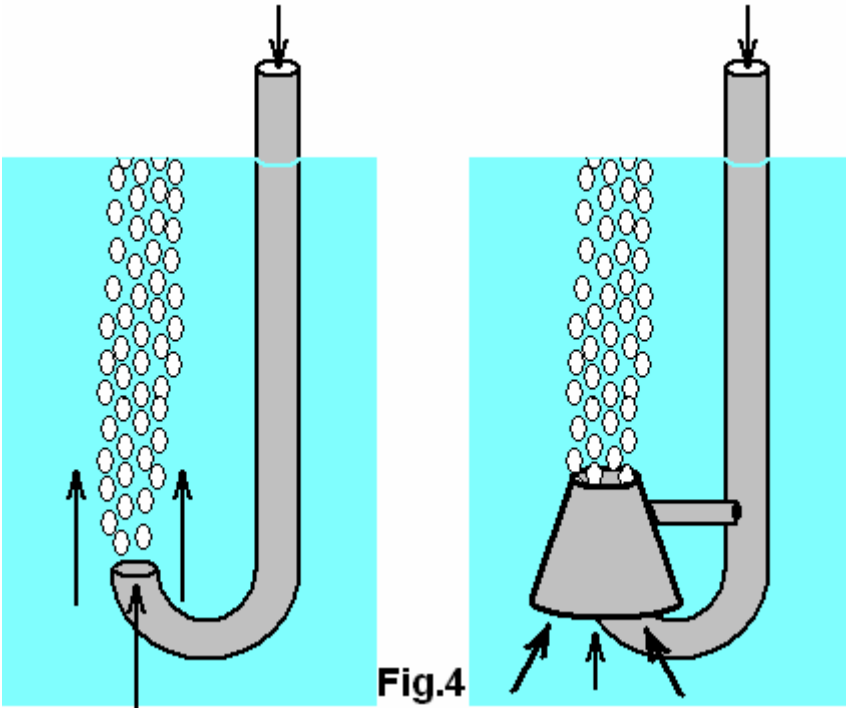

Fig.4

Fig.4, is a perspective conceptual view showing arrangements for a simplified air-feed system which operates from above the tank.

Fig.1, illustrates the overall concept of the generator in its most simple form where lightweight rigid buckets are used to capture the rising air from the air pump. In this Figure, a water tank **1**, holds water or other suitable liquid **2**. The surface of the liquid **3**, is indicated to illustrate the fact that a bucket **10**, which is in the process of turning over at the top of its orbital motion, is positioned so that one edge of the bucket is clear of the surface of the water, which allows the air which was trapped inside the bucket to escape into the atmosphere and the water fill the entire bucket causing only a very minor turbulence when doing so. This is a desirable, but not essential feature as the air trapped in any bucket will escape upwards as soon as the bucket starts its downward movement, positioning its open end upwards, although this causes unnecessary turbulence inside the tank. One possible bucket shape is shown in perspective view, but many different bucket shapes may be used, including flexible membrane types or alternatively, hinged-plate types which have very much reduced resistance to moving through the water when in their collapsed state during their downward movement.

The buckets **8, 9** and **10**, are attached to two strong chains **30**, which mesh with the upper sprocket wheel **6**, mounted on the upper axle **4**, and the lower sprocket wheel **7**, which is mounted on the lower axle **5**. Although it is not visible in **Fig.1**, there are two upper sprocket wheels **6**, two lower sprocket wheels **7**, and two chain loops **30,** although these can be seen in **Fig.2**.

The tank is supported on a robust plate **14**, which itself is supported by a series of pillars **15** which rest on a secure footing **16**, providing operating space underneath the tank for the installation and maintenance of the air pumping equipment. As fresh water weighs 1000 Kg per cubic metre, the weight of the operational generator system is substantial and so this must be allowed for when assessing the footing needed to support the tank and it's contents. While a thin-wall tank is shown in **Fig.1**, many different forms of tank may be utilised, including earth bank and plastic membrane styles, or resurfaced abandoned well shafts. The tank of **Fig.1** presumes that the lower axle **5** is taken out through the wall of tank **1**, using an arrangement similar to that used for the drive shafts which power the screws of ships and other power vessels. While an arrangement of that type provides a drive shaft which is conveniently close to the ground, the much more simple arrangement shown in **Fig.2** where the output power is taken off using the very simple chain and sprocket wheel method utilised for the bucket supports (chain **30,** and sprocket wheels **6** and **7**). In general, the more simple and straightforward any design is, the better it works in practice and the lower any maintenance costs become.

Referring again to **Fig.1**, when activated, air pump **11** produces a stream of air **12**, which flows rapidly upwards. This stream of air **12**, once established, does not have to push against the head of water as immediately above the nozzle of the pump is a rapidly rising column of air, sustained both by the exit velocity from pump **11** and the natural upward movement caused by the relative weights of water and air (as water is

several hundred times heavier than air). This column of air would normally flow straight upwards in calm water, but should it be found that turbulence in the water tends to push the rising air away from its vertical path, baffles can be placed around the pump and positioned so that the air stream is forced to stay within the same section of water taken up by the rising buckets.

The rising air enters the lowest of the rising buckets and collects in it, forcing the water out of the open bottom of the bucket. If the rising bucket is not completely filled with air before the next bucket moves between it and the air pump, the trapped air will expand as the bucket rises and the water pressure reduces due to the lesser depth. Any one bucket with a substantial amount of air in it will create a very significant upward force due to buoyancy, air being about one thousand times lighter than water.

Each bucket on the rising side adds to that upward force and consequently, the chains **30** need considerable strength. The weight of the buckets on each side of the chain match and so the main advantage of light buckets is to lower the inertial mass of the moving parts. Movement through the water is relatively slow but this is offset by gearing between the output drive shaft and the generator's input shaft. The power of the system can be increased by adding more buckets in the vertical chain, increasing the water depth accordingly. Other ways of increasing the power include increasing the volume inside each bucket and/or increasing the flow rate produced by the air pump or pumps used. Another simple method is shown in **Fig.3** and discussed below. An alternative to air pumps is to use tanks of a compressed, non-polluting gas, possibly air.

The buckets shown in the various Figures are rigid, very simple shapes, possibly made by a plastic moulding process in order to be cheap, strong, lightweight and permanently water-resistant. There are, of course, many possible variations on this including using rigid hinged plates sealed with a strong flexible membrane, allowing the buckets to fold and become streamlined on their downward path, and opening as soon as they turn to start their upward movement. There are many mechanisms which can provide this movement, but it is a matter of opinion as to whether or not the extreme simplicity of rigid buckets is worth sacrificing

Fig.2 shows a schematic layout of the generator when seen from the side. The same numbers apply to the components already seen in **Fig.1**. The arrangement seen in **Fig.2** is the most simple, basic, single bucket set. The near-side rising buckets **8** obscure the view of the far-side falling buckets **9** and only the lowest part of the falling buckets **9** can be seen in this view. **Fig.1** shows buckets which are some two and a half times longer than they are wide, but this, of course, is just one option among literally thousands of possible proportions. The size and shape of buckets is related to the performance and number of air pumps being used for any one set of buckets and that choice depends on what is available locally at a reasonable price. It would not be unusual for two or three air pumps to be used side by side along the length of the bucket **8** although **Fig.2** only shows a single pump.

Fig.2 also shows a simple method for power take off where a large diameter sprocket wheel **16** is mounted on the upper axle **4**, and driving a much smaller diameter sprocket wheel **18** which is mounted on the drive shaft of the electricity generator **19** which is mounted on plate **20** which is attached securely to the top of tank **1**.

Fig.3 shows one of the possible arrangements for increasing the system power without increasing the depth of water used. Here, the axles **4** and **5** extend far enough to allow another set of buckets to drive them, increasing the torque very substantially. While **Fig.3** shows one extra set of buckets, there is, of course, no reason why there should not be three or more sets of buckets side by side. It should be noted however, that the partitions shown between the bucket sets are not there just to reduce the water swirling but are needed to support the bearings which are essential for the extended axles, since without those, the diameter of the bars used for the axles would have to increase very markedly to avoid unwanted flexing along their length. While the second set of buckets has been shown aligned exactly with the first set, there is an advantage in offsetting them relative to each other so that the output torque is more even with buckets emptying and filling at different points in the bucket cycle.

Fig.4. shows a method for further simplification, where the air is pumped from above the water surface. It is a matter of concern to most people, that the pressure of the head of water above the air pump is a major obstacle to overcome and will be a continuous opposing force during operation of the generator. If air is being injected from underneath the tank, then initially, that pressure head has to be overcome. However, once the air flow is established, a vertical cigar-shaped area of water vortex is established by the rising air stream. This three-dimensional annular vortex negates the water head in the small area immediately above the air nozzle, and almost sucks the air out of the pump, after the initial introduction of the air has been accomplished.

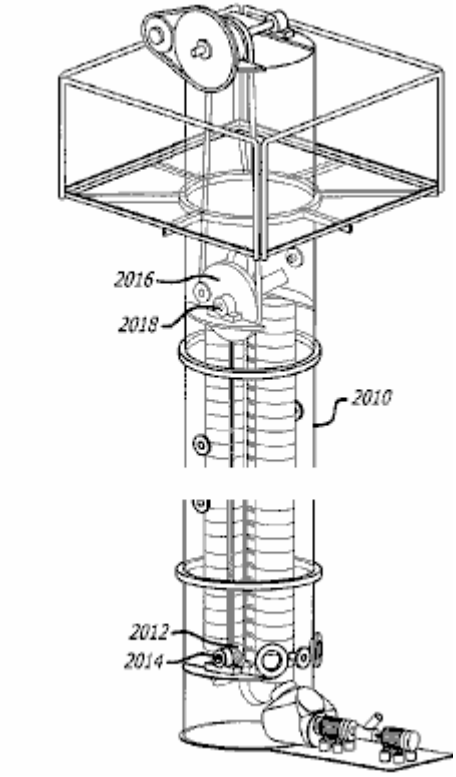
There is another way of achieving this desirable effect without ever having to pump against the total head of water, and that is to use a mobile air pipe as shown in **Fig.4**. Initially, the air pump is started and lowered a short distance into the water. The opposing head of water is not large and the water vortex can be established quite easily. The pipe is then lowered very slowly, so as to maintain the vortex at a progressively lower depth, where, in spite of the increased head of water, the pump does not have to overcome that head. When the pipe outlet reaches the operational depth, it is then rotated to bring it under the set of rising buckets. The major advantage of this arrangement is that the tank is as simple as possible, with no possibility of leaking, and so abandoned wells can be modified to become energy generators. Alternatively, an earth bank can be erected to form an above-ground tank, possibly sealed with a plastic membrane. This method also avoids needing to support the weight of tank and water above a work-area where the air pump or compressed-air cylinders are located and maintained. The creation of the water vortex can be assisted by the addition of a cowl around the pipe exit as shown in this figure, but that is an optional feature.

The Ribero Buoyancy Patent.

While internal combustion engine demonstrate that considerable power can be had from motion which moves backwards and forwards continuously, that sort of action is not very efficient as there is continuous reversal of the oscillating drive components. The floats in the (very successful) 'Hidro' design shown above. A different design is shown in the 2011 patent of Renato Bastos Ribero of Brazil. Here is an excerpt from that patent:

US 7,958,726 **14th June 2011** **Inventor: Renato Bastos Ribero**

Apparatus and associated methods to generate useable energy



Abstract:

The present disclosure relates to an apparatus and associated methods for generating energy by capturing and taking benefit of the energy generated by any quantity of air surfacing inside water. In exemplary embodiments, the apparatus comprises compressing a lower density gas in a liquid medium, allowing the gas to naturally rise to the surface of the liquid medium and then capturing the energy generated by the surfacing gas.

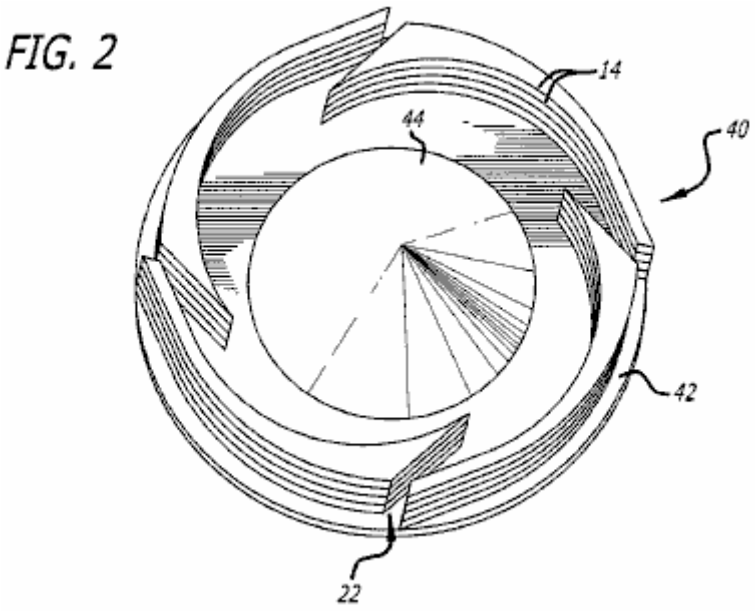


Fig.2 is a perspective upper view of a rotor disc for compressing a gas into a liquid medium. This disclosure is in two stages which, in this case, work together. The first stage consists of the creation of energy with the introduction of air at the bottom part of a water column. Once introduced, the air creates energy when moving towards the surface. The introduction of air into the water is the main point of this first part of the disclosure. A method was created in order to use a very small quantity of energy when doing this.

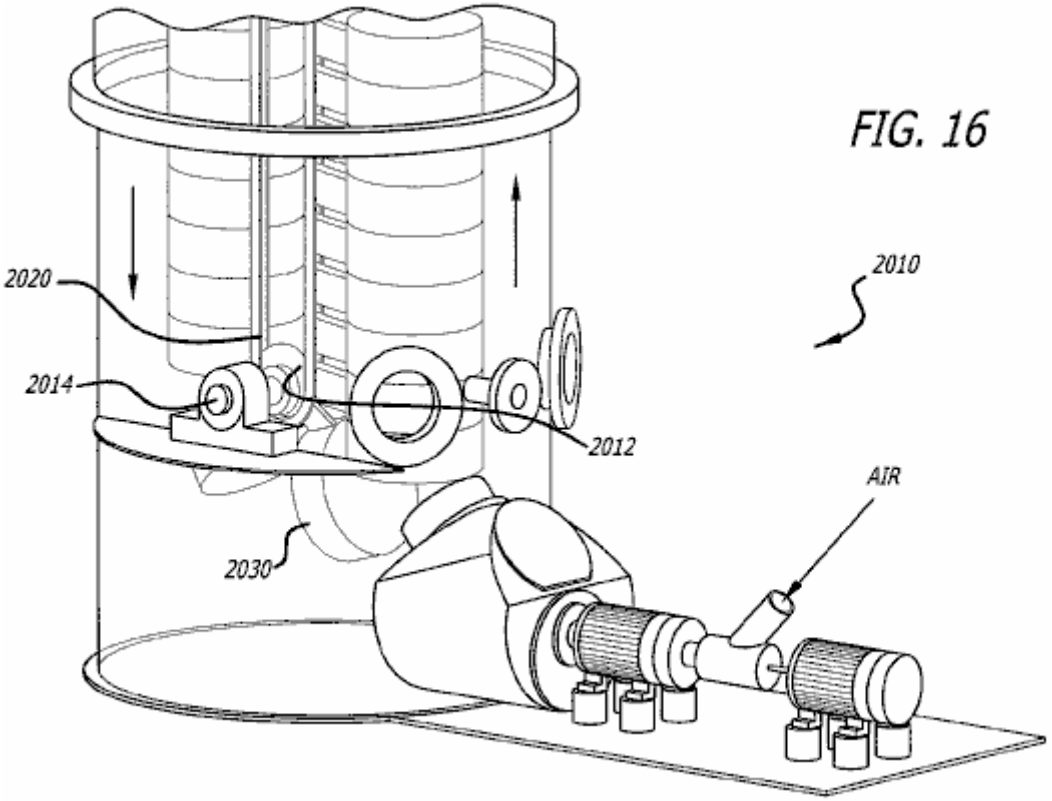
The teeth on the disc, when rotated in water, water to flow away from the area between the teeth, lowering the pressure there and allowing the easy introduction of air in that area. Without air introduction, water would not move away and the pressure would not be reduced. The purpose of the cone is to spread the incoming air.

The second section of the present disclosure refers to a system with the objective of capturing the air which is inserted at the bottom of a water column or tank, while moving towards the water surface.



As shown in **Fig.16**, buckets **2030** descend on a continuous chain **2020** which passes around a lower and an upper wheel or pulley. On reaching the lower pulley, the buckets turn around the bottom pulley **2014** and line up again on the ascending side of the chain. Immediately after turning around the bottom pulley, each bucket receives the rising airflow.

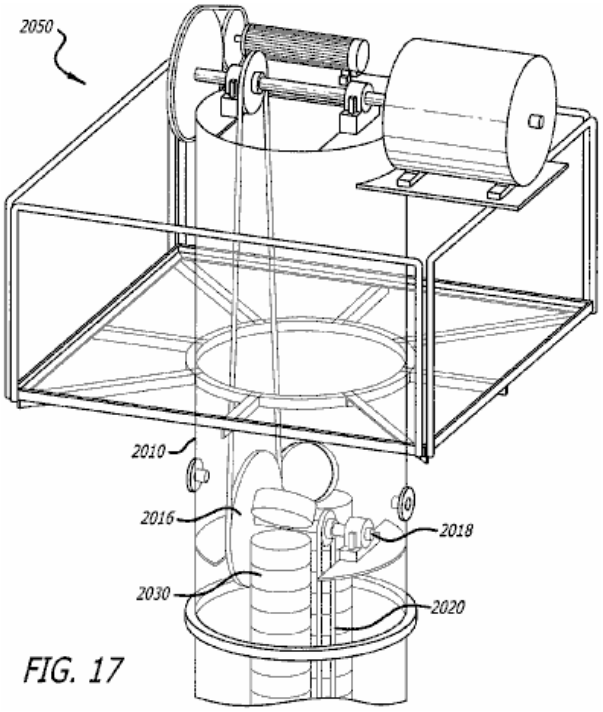


Fig.17 shows the arrangement at the top of the water tank **2010**. Buckets **2030** rising due to being filled with air, turn over as they pass around the top pulley **2018**, releasing the air inside them and start descending again towards the bottom pulley. The upper axle **2018** has an estimated rotational speed of 120 rpm.

In Fig.17 I (Ribero) am showing the transmission of this energy to an axle at the top of the water column where we have a generator **2050** requiring a rotation of 300 rpm plus an engine connected to another generator with rotation of 600 rpm. This part of Fig.17 is only illustrative to show that we shall generate energy at the primary axle at 120 rpm, or use any kind of transmission to more convenient rotational speeds.

***

I think that the words marked in red indicate that although this patent has been granted, the generator has never been built and is only an idea. Personally, I am highly dubious about the mechanisms which are supposed to give reduced water pressure at the air intake, as I don't think that they would work, or if they do, certainly not for the reasons stated. What he wants to do can certainly be done, but not in the way that he suggests. If the axles are rotating at the 120 rpm which he suggests, then that would allow less than one eighth of a second to fill each bucket and while the notion of reduced water turbulence through the buckets touching each other is attractive, I don't think that the method described is feasible.

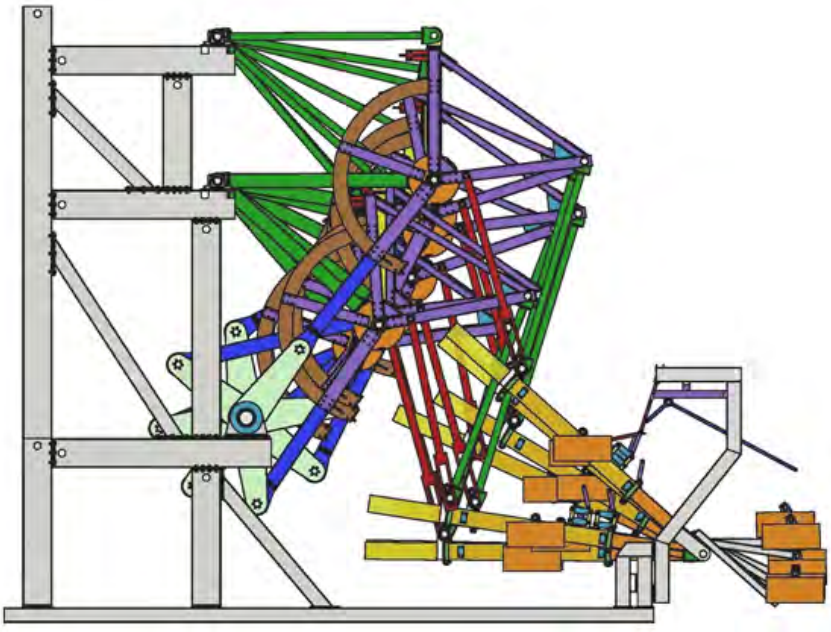
So, while we can be sure that buoyancy methods are perfectly capable of generating serious power, we need a better design than either of the two shown here as the Hidro appears to be very expensive to build.

The Thirty Kilowatt Motor

The recent website http://www.rarenergia.com.br/ shows a gravity-powered motor which is capable of driving a 30-kilowatt electrical generator.

This is certainly not a home-build project and the cost of construction and day-to-day maintenance cost makes this appear to be a very uneconomic project. However, one enormous advantage of the building of these two generators is that they show very clearly that free-energy is available and perfectly viable. The people building these two constructions point out very clearly that these are gravity-powered motors rather than just electrical generators. While these motors can drive electrical generators, it is emphasised that they

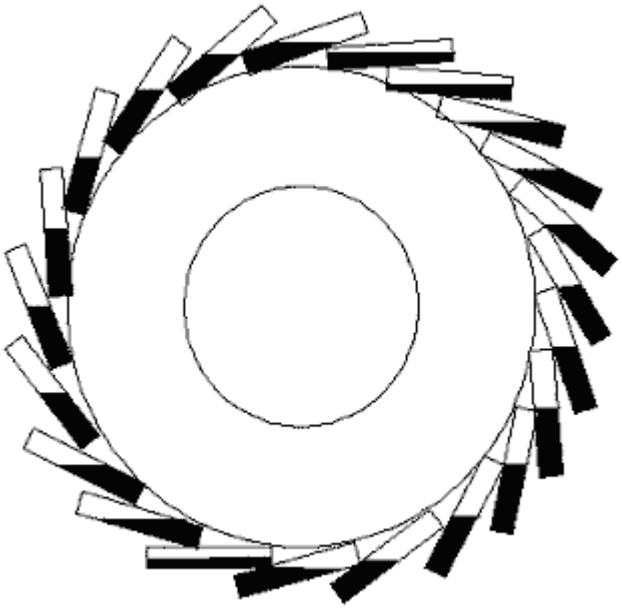
can also perform any task which needs a motor, such as pumping, drilling, etc. The size of these motors is substantial as can be seen from the following pictures:



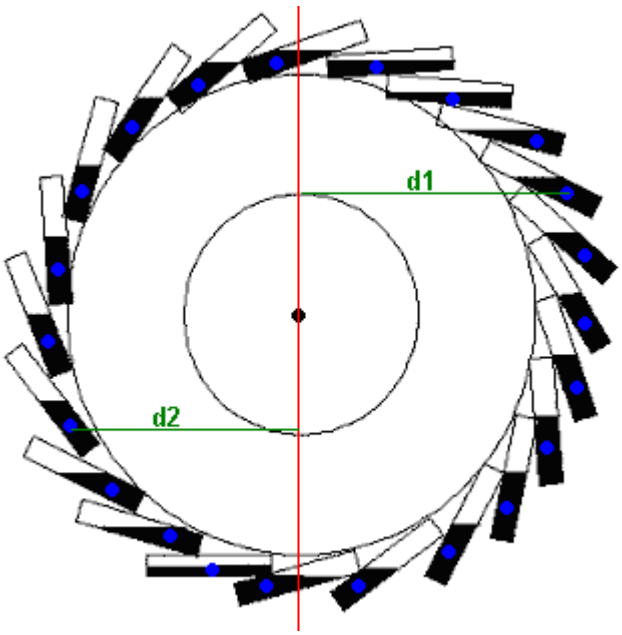
Bhaskara's Gravity Wheel

I have recently been made aware of the Baskara gravity wheel invented in 1150 in India. This is a most interesting idea which appears to have considerable potential. There is what appears to be a marginal replication at http://www.dailymotion.com/video/xygxsy_bhaskara-wheel-overbalanced-chain_tech. Any gravity-powered device needs to be large and heavy if it is to produce serious usable power. The tiny device

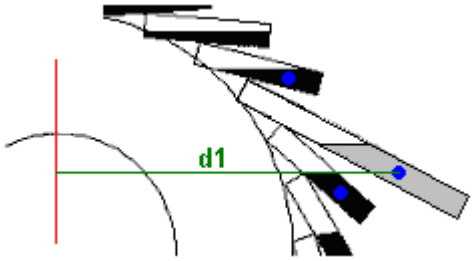
shown in the video is shown stationary which shows that the bearing friction is far too great for the weight of liquid involved. Properly built, it would be impossible to have the wheel stationary unless it were locked in place as the weight imbalance would start it rotating from any stationary position. The overall design of the wheel is generally shown like this:



The idea is that the liquid on the right has its Centre of Gravity further from the axle of the wheel, than that on the left. The “Centre of Gravity” of any object is the point at which all the weight of the object is considered to act. It is usually at the centre of an object which has a regular shape. In this case, the turning effect is created by very small differences in lever arm lengths:

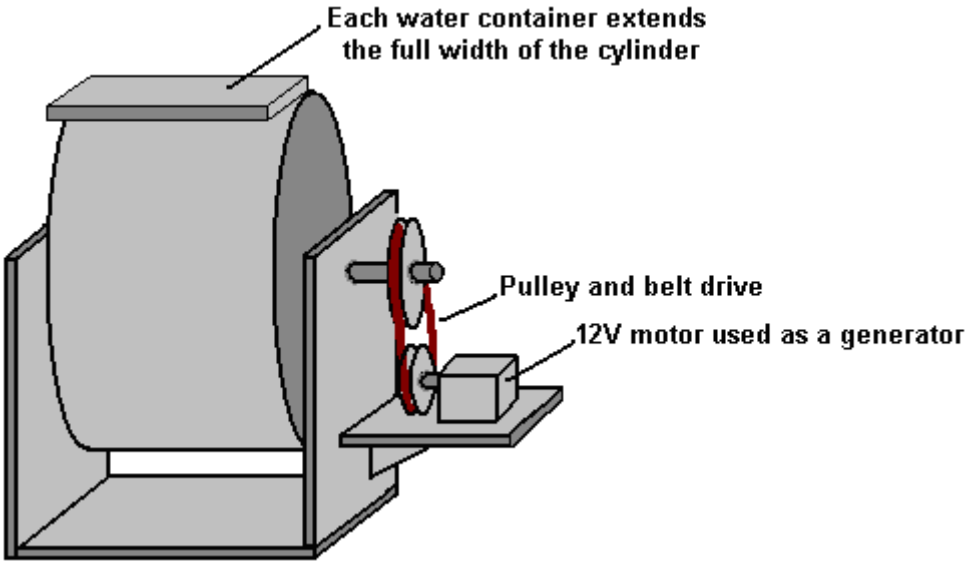


Here, the Centre of Gravity of each body of liquid is marked with a blue dot. The lever arms “d1” and “d2” show the distances for two tubes on opposite side of the axle. Although it is not obvious in this illustration, the length “d1” is actually longer than the length “d2”. The tubes are fixed in position and do not move relative to the wheel and so, the only moving part is the liquid and the rotating wheel. As shown here, the mechanism is not efficient as much of the potential power is not being accessed. The turning force of the liquid is created by the liquid flowing outwards, away from the axle. That flow is being severely limited by the short tube lengths. It would be much more realistic to use a much longer tube like this:



Just by lengthening the tube, there is a major increase in the movement of the liquid away from the axle. The increased tube length has no noticeable effect on the rising side of the wheel.

Most people think of the wheel as being small with a few small tubes attached to it. If actual power extraction is the objective, then the wheel becomes a cylinder and the “tubes” extend all the way across the cylinder. I would suggest that the cylinder diameter is made about one meter and the cylinder length about half a metre if you are going to carry it through a doorway, and much longer if not. In this arrangement, the “tubes” become shallow, flat containers, making the arrangement something like this:



If the liquid containers are made of, say, 3 mm MDF, then I would suggest that the sides are made using MDF of 6 mm thickness to make the container rigid as the weight of liquid will be quite high. The inside of the container is sealed if the construction material is not waterproof, then a coating of varnish, paint or one of the waterproofing sprays will prevent water absorption. The liquid is added before the top of the container is glued in place. Exactly the same amount of liquid should be poured into each container before sealing and a measuring jug should be used to make sure that each half-filled container matches the weight of each of the other containers.

A twelve volt DC motor can be used as a generator, driven by a belt and two pulleys, in order to get some useful electrical output from the device. Materials other than a liquid have been suggested as the heavier the material is, the more powerful the generator becomes. Mercury would be very good as it is very heavy, but as it is so poisonous, (not to mention expensive), it is not a realistic choice. Lead shot or steel ball bearings have been suggested but they would probably not flow across the containers well enough to be a good choice, and so a liquid is perhaps the best thing to use, water being an obvious choice.

The Torque Generator of William F. Skinner

In 1939, William Skinner of Miami in Florida, demonstrated his fifth generation generator powered by spinning weights. His demonstration can still be seen at http://www.britishpathe.com/video/gravity-power where he shows his design powering a twelve-foot lathe, a drill press and a power hacksaw, all simultaneously. The newsreel commentator states that the output power was “1200% of the input power” which is COP=12 but it is highly likely that he should have said “1200 times” rather than “1200%” because

he continues to state that using the design would allow a one-horsepower (746 watts) input power to power 3,500 homes. If it were COP=12 then each of those 3,500 homes would receive less than 2.6 watts, which is clearly wrong. At the much more likely COP=1200, each household would receive on average, 255 watts, which might be just possible in 1939 when few appliances were electric. Anyway, Skinner's impressive equipment could be driven by a single cotton thread drive band while powering his whole workshop. It looked like this:

This design has four nearly vertical shafts, each braced to give additional rigidity. These rotating shafts pass their rotating power to the mechanical output drive belt seen on the left. Each of these rotating shafts has a heavy weight in the form of a thick, short cylinder mounted high up near the top of the shaft and what is probably an even heavier weight in the form of a long narrower cylinder attached near the bottom of the shaft as seen just to the right of the output drive belt. These four identical sets of shafts with their pairs of weights spin two or three times per second and produce the whole of the output power.

As far as I am aware, Skinner never patented his design or disclosed how it worked. However, the operating principle is very simple indeed although it may take you a while to grasp how it works. You can check this out quite easily for yourself if you have access to an old-fashioned chair with four rigid legs like this:

Tilt the chair over so that it is balanced on one leg. You will notice that almost no effort is involved in keeping it in that position as all of the weight is supported by the floor through just one of the legs. Now, move the top of the chair by a very small amount and keep the top of the chair in that position. You will notice two things: first, very little effort was needed to move the top of the chair and second, the chair now swings around and becomes stationary on the same side that the top of the chair was moved.

Notice two other things: the chair swung around because of your moving the top slightly and **you** did not swing it around, and if the chair is heavy, the amount of energy in the swinging chair is very much greater that the amount of energy which you applied to the top of the chair.

If you were to keep moving the top of the chair in a tiny circle, then the chair will spin around continuously for however long that you choose to wobble the top of the chair. The amount of energy in the spinning chair is very much greater than the energy which you are expending to make the chair spin. So from where is that extra energy coming?

What is happening is that the chair swings round under gravity to reach the lowest possible point for it with the new position of the top of the chair. But, before it can get there, you move the top of the chair further around and so the chair has to swing further in order the reach the lowest point. But before it can get there, you move the top again ….. The chair keeps swinging round and round, pulled by gravity, for as long as you choose to keep moving the top. But, no matter how heavy the chair, very little effort is needed from you to cause the spinning.

Skinner had a mechanism at the top of each vertical drive shaft, and that mechanism kept moving the top of the shaft in a small circle while allowing the shaft to rotate freely at all times. That caused the very heavy weights attached to the shaft to keep spinning around, and he used that power of the heavy spinning weights to power his whole workshop. Moving the top of the shafts required so little power that he used a 93-watt electric motor and to show that he was not even using all the power of that small motor, he used a single cotton thread as a drive band to move the tops of the four power output shafts.

His mechanism looks complicated. This is partly due to the fact that there are four identical power shafts with their weights, mounted in the one compact frame and that makes the device look more complicated than it really is. It is also due to the fact that the system shown in the newsreel is William's fifth version of the device. It is likely that his earlier, much more simple versions worked well and encouraged him to build even fancier versions.

There are two forums where members of those forums are trying to work out exactly how his final version machine worked and then replicate the design for current day use as it is a neat system for accessing additional usable power. Those forums are at:

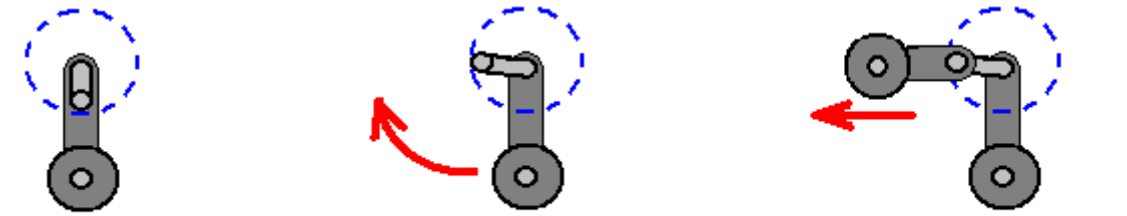
http://www.overunity.com/14655/1939-gravity-power-multiply-power-by-1200/#.U5y0gXaqmJA and

http://www.energeticforum.com/renewable-energy/17195-william-f-skinner-1939-gravity-power.html

It needs to be remembered however, that it is not actually necessary to replicate William's fifth version, but instead it would be quite enough to use the principle of the spinning chair to produce a simple mechanism where the input power is far less than the output power.

If we consider what is happening, then perhaps we can understand Skinner's complicated-looking arrangement. We can consider just one of the four axle shafts The large weight is spinning around in a circle and that motion is then used to power the output shaft. In order to reduce the effort needed to spin the weight, the axle shaft has been made thinner and four bracing rods have been used to brace the shaft in exactly the same way that sailing yacht masts are usually braced with "spreaders" to hold the bracing out from the mast and so give greater overall stiffness. So we can ignore those bracing bars as they have nothing to do with the actual operation of his design, but are merely his choice out of many different construction options.

Remember the spinning chair and consider what has to be done to spin Skinner's heavy weight. The top of the shaft has to be moved in a small circle. Looking down from the top the situation is like this:

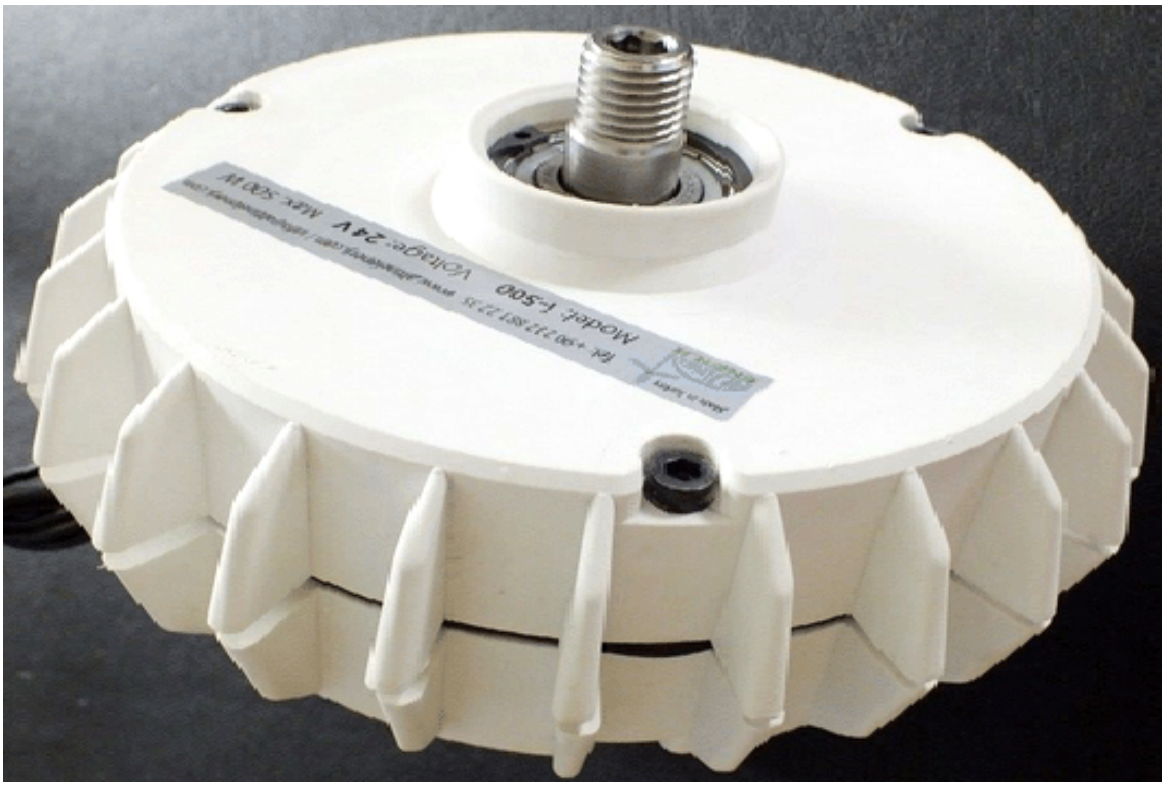


When the system is switched off, the weight attached to the bottom of the shaft comes to rest directly underneath the top of the shaft. When the system is started again, the first move is to shift the top of the axle shaft ninety degrees around. This is the start of the rotary movement and initially, the movement is slow as it takes the heavy weight some time to get moving. To reduce the effort of moving the top of the shaft ninety degrees ahead of the big lower weight, Skinner has added a weight at the top to assist the movement in that direction.

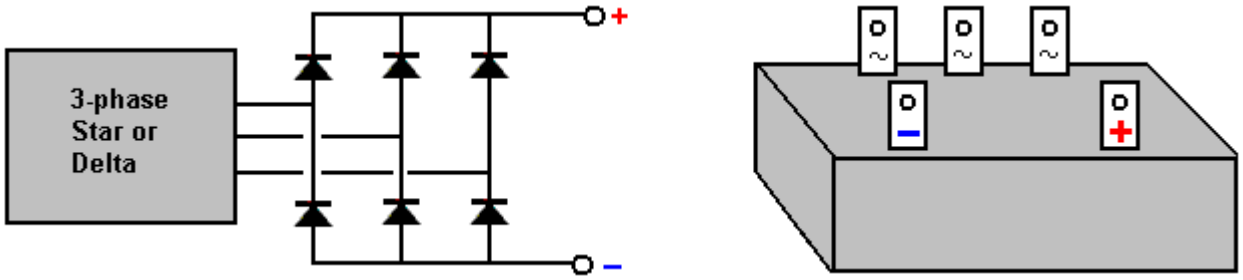
Skinner also took advantage of his very large workshop to use a belt-driven mechanism above the top of the shaft, in order to reduce the effort of moving the top of the axle shaft even further (to the level where it could be driven by a cotton thread). He used four separate identical shafts in his construction for two reasons: first, the overall output power is increased and second, any sideways forces stressing the mounting frame are matched on every side, which is helpful when you have heavy weights on a rotating arm as Skinner did.

As the output shafts appear to be rotating at about 150 rpm, Skinner opted to use a straight mechanical drive. Back in 1939, electrically-driven equipment was not as widespread as it is today, but nowadays we would probably prefer to have an electrical output rather than a mechanical drive although that mechanical drive could be used for driving pumps and other low-speed devices. So, we are faced with introducing some form of gearing which can raise that 150 rpm to the much higher level preferred by most alternators.

While it would be possible to use an ordinary 12-volt motor as a generator and produce a 12-volt electrical output, it is likely to be more convenient to use an off-the-shelf electrical generator, perhaps a very low-friction one like this which has been designed for wind-power operation and which has a 12V or 24V 3-phase output:

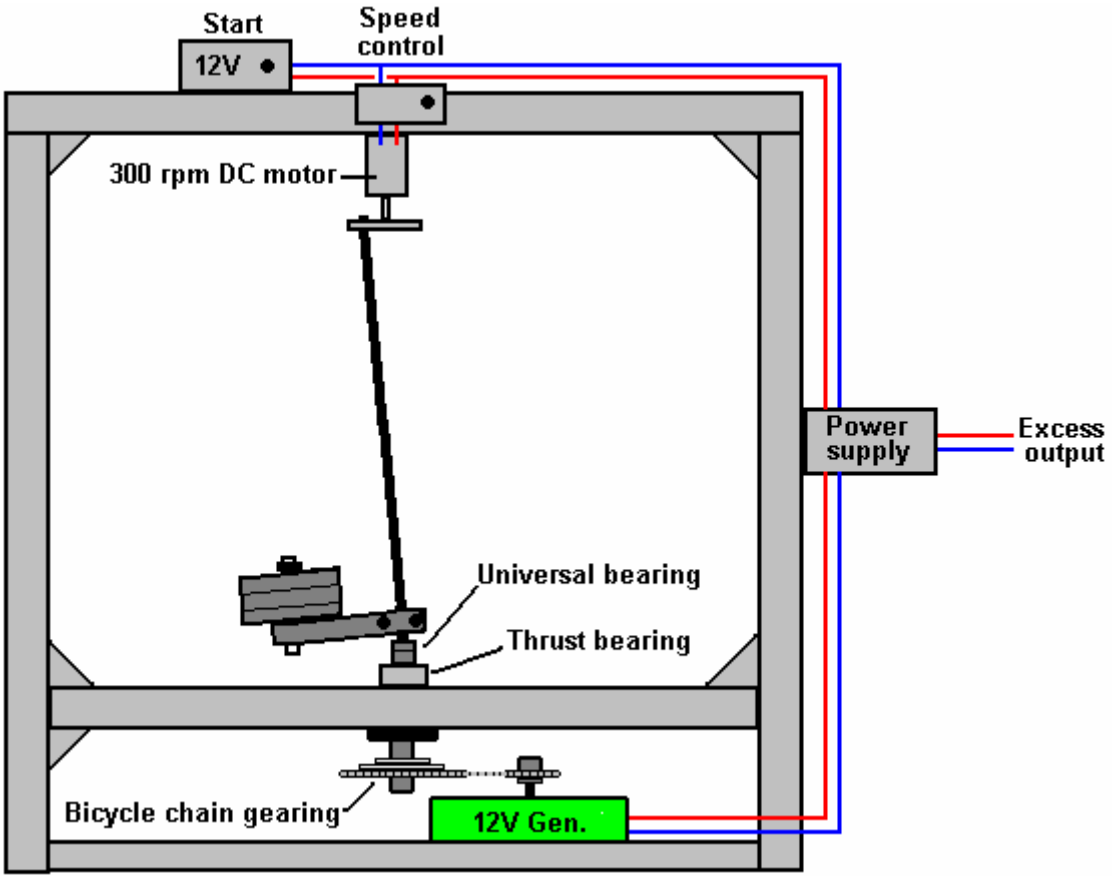


The fact that the output is 3-phase can sound a little daunting, but the conversion to DC is quite straightforward:

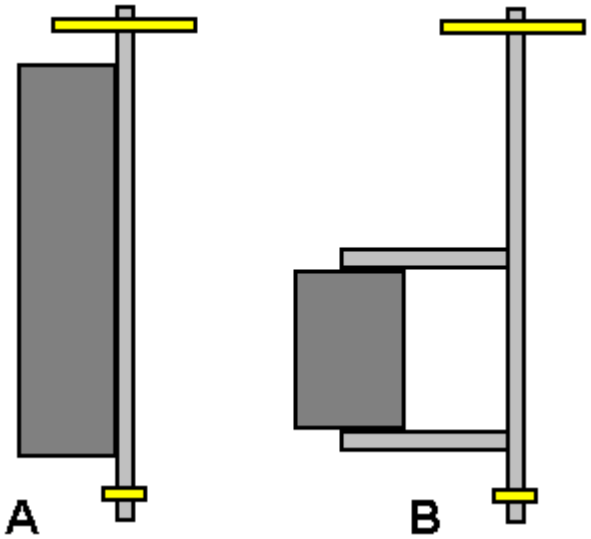


The output can be converted to DC with six ordinary diodes or a integrated diode arrangement can be used where there is a connecting tag for each of the three outputs and a separate tag for the DC Plus and for the DC Minus. The currents involved are quite high as 400 watts at 12-volts represents more than 33 amps and the peak output of 500 watts is a current of about 42 amps. For that reason, the 3-phase rectifier blocks are rated at 50 amps which sounds very high until you do the calculations and discover what the current is likely to be. It should also be borne in mind that the DC output wire has to carry that level of current on a continuous basis and so fairly robust wire is needed. If the voltage were 220V then the wire would be carrying more than 9 kilowatts at that current flow, and so the normal 13-amp mains wire is just not sufficient and instead, we need to use thick wire or more than one strand of wire for both the Plus and the Minus connections.

This particular generator is not expensive and can output 400 watts of electricity (33 amps) continuously. As the Skinner type appears to be spinning at 150 Hz, a gearing up of the output speed would allow greater output, so perhaps for a home-builder, the physical arrangement might be like this:



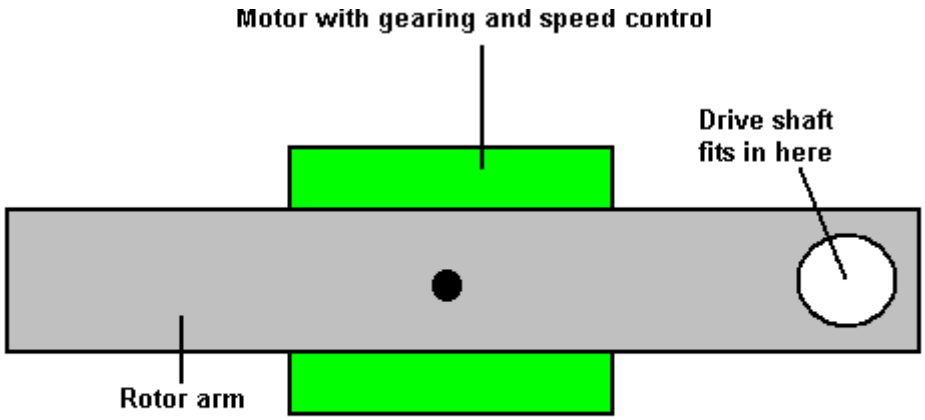
There are, of course, many different forms of construction which might be used, but with each of them, the question is, “how do you make the angled shaft rotate powerfully?”. If you can work out the complexities of Skinner’s fifth version shown in the newsreel, then that would certainly do the job. However, we would prefer a much more simple design and so we do not necessarily have to copy what Skinner did but instead we can just apply the principle which he demonstrated. One possible arrangement might be to imitate the chair experiment using a strong shaft with a weight attached to one side of it, perhaps like this:



Version “A” uses the weight to stiffen the shaft but doing that raises the centre of gravity of the combined shaft and weight which may not be convenient. Version “B” increases the torque for any given weight by moving the centre of gravity of the weight away from the centreline of the shaft by means of extension arms. As the shaft rotates at a constant rate, the load on the shaft will be essentially constant and there should not be any significant flexing of the shaft although it might bend and remain with that same bend during all of the time when it is spinning if the weight is very high relative to the stiffness of the shaft.

We do have to input some power to rotate the top of the drive shaft, but if we arrange things in any one of the hundreds of viable configurations, then the output power will be massively greater than our input power. An alternative arrangement which allows speed control (and so, output power control) is to take some of the generated output of electricity and use that to power an electrical drive which positions the top of the drive shaft.

There will be many different ways of achieving that movement. One method for doing this might be:



SEEN FROM UNDERNEATH

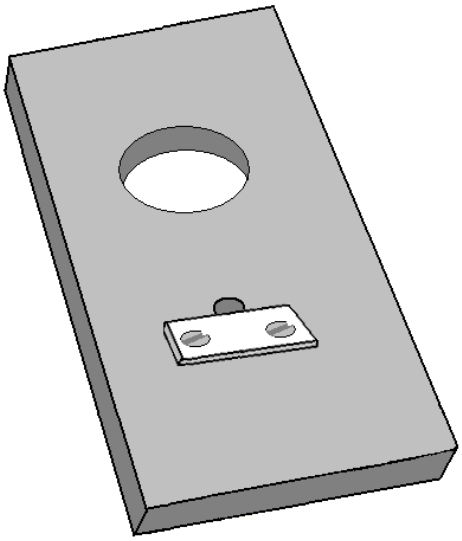
Here, the small electric motor shown in green is geared down and used to move the top of the drive shaft at whatever rate of revolution that we consider to be satisfactory, using a standard DC motor speed controller.

It should be noted that no matter what angle is chosen for the axle shaft, that is always a constant relative to the motor arm moving it round in the circle at the top of the shaft. This means that no roller bearing is needed as there is no relative movement and the shaft will automatically take up that fixed angle. The drive motor arm moving the top of the shaft will probably not be long, as Skinner appeared to be moving the top of his shafts by about 40 mm away from the centreline of the bottom pivot, making only one degree or so for the angle of the shaft on every side of the vertical.

It is, of course, not essential to convert the output power to electricity and instead it could be used in the same way that Skinner did, driving mechanical equipment such as water pumps for irrigation or extracting water from wells, milling operations for processing grain or for operating any form of workshop equipment. It is also not necessary to build the device anywhere near as large as Skinner did, and small versions could be used to power lighting systems, operate fans or cooling systems or for any other minor household requirements.

The power output from the machine can be increased by increasing the weight attached to the output shaft, or by increasing the length of the arm holding the weight, or by tilting the output shaft through a greater angle (which increases the input power needed, but probably not by much), or perhaps by scaling the whole thing up so that it is physically bigger. Skinner's design uses stiffening bracing on the output shaft, which suggests that the lighter the shaft is, the better the performance. Because of this, a prototype build might use a timber shaft of perhaps, 33 mm square as that is both light and very strong and rigid and it is a good shape for ensuring that there is no slipping of the arm which supports the weights. The top of the shaft is reduced slightly so that it has a circular cross-section. A 300 rpm motor rotates at a maximum of 5 turns per second and so is suitable for rotating the axle shaft. A suitable, low-cost motor of that type, looks like this:

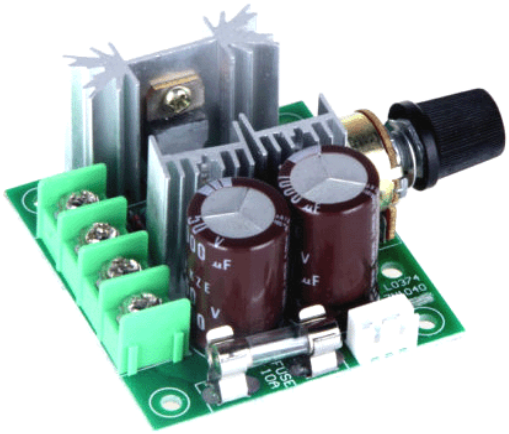
The motor needs to be linked to the shaft in a simple way which ensures that there will be no shaft slippage:



Perhaps cutting a suitable sized hole through a strip of material and using a strip of metal pressed into the flat face of the motor drive shaft (in addition to the hole being a tight push fit) would be adequate for this. A screwed collar or layer of epoxy resin holds the plate firmly to the motor as the plate is positioned below the motor and so gravity tends to pull the plate off the motor shaft at all times.

It would initially be assumed that a ball bearing or roller bearing would be needed in this motor arm, but that is not the case as the axle shaft does not rotate relative to the motor arm and while the axle shaft can be a loose fit in the hole, there is certainly no need for a bearing.

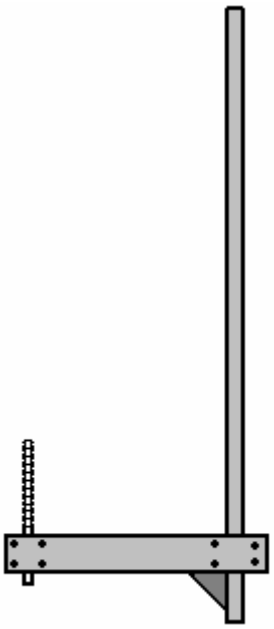
A commercial DC Motor Speed Controller can be used to bring the shaft rotation speed gradually up from a stationary start to the chosen rate of revolution:



Using a commercial module like this means that no electronics knowledge is needed to build a working generator of this type.

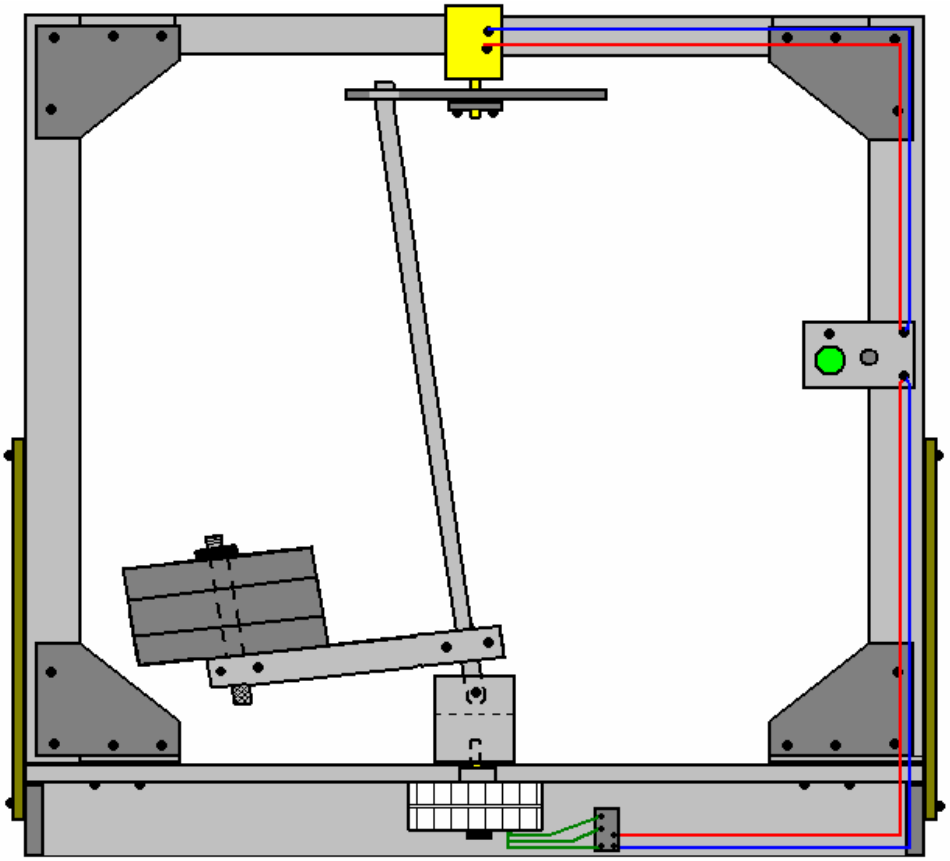
There are many options for providing the necessary weight which drives the generator. One possibility is to use a barbell shaft with as many weights as are required, that being a very simple alteration:

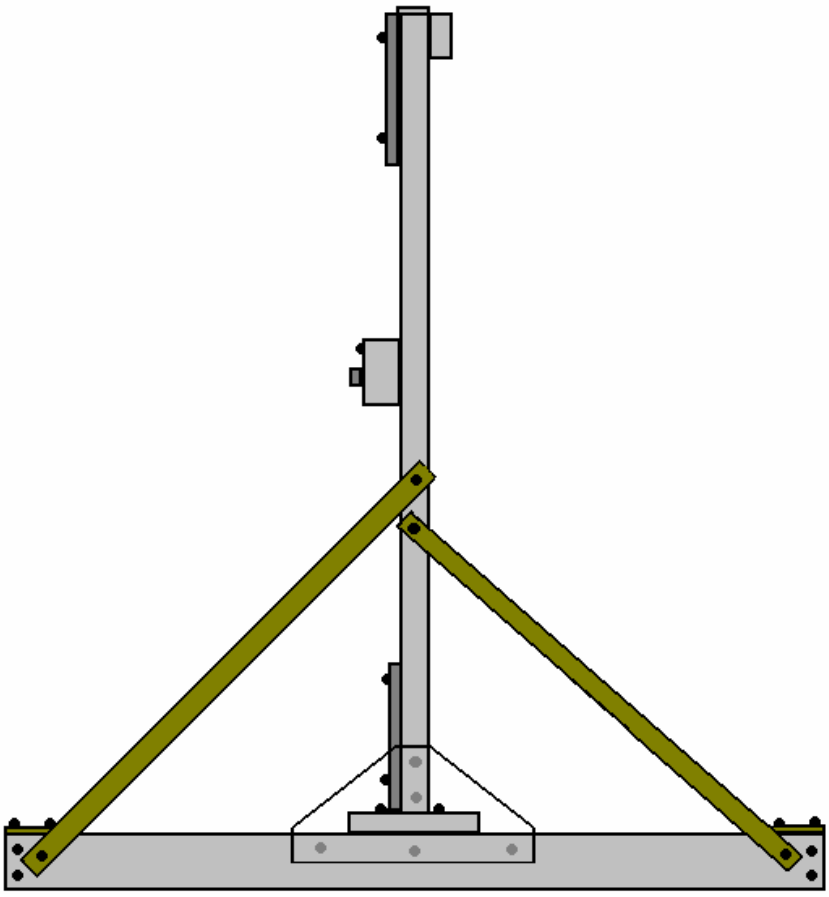
One of the hand grips can be cut and used directly as part of the mounting, perhaps like this:



This simple arrangement allows the weight discs to be added and secured in any combination desired. As dumbbells are supplied in pairs, there are four discs of each side which allows a wide range of weight options going up in jumps of just 1 Kg which is very convenient. If the axle shaft has a square cross section, there is no tendency for the lever arm to slide around the shaft

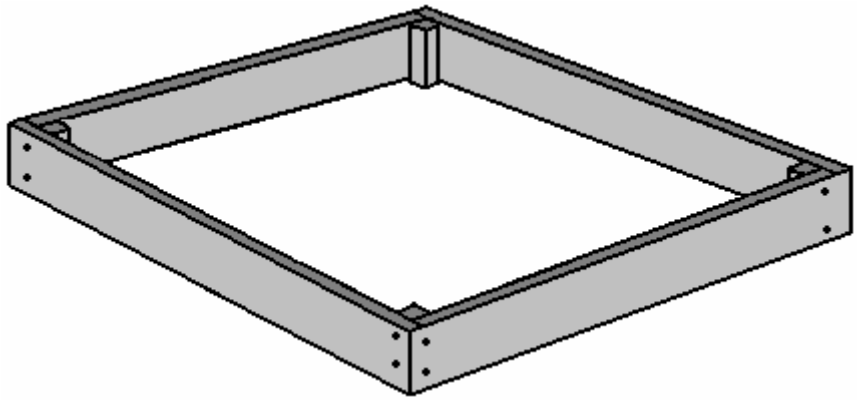
The following sketches are not to scale, but one form of construction might be:



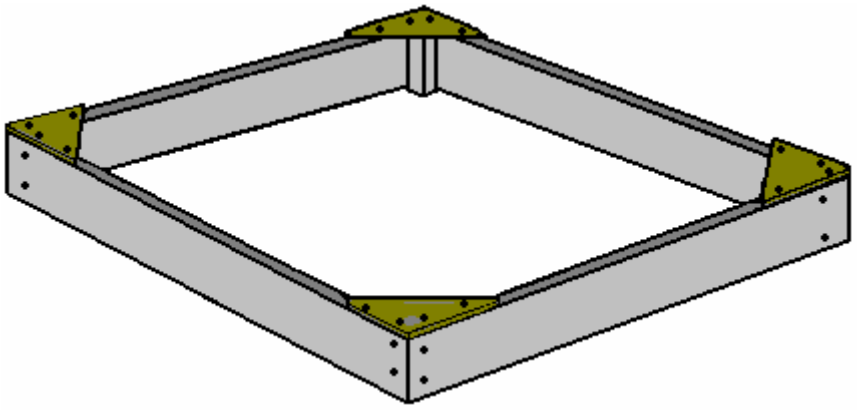


For this style of construction, four pieces of, perhaps, 70 x 18 mm Planed Square Edge timber are cut to perhaps 1050 mm and two 33 x 33 x 65 mm pieces epoxied and screwed to two of the pieces, 18 mm in from the ends:

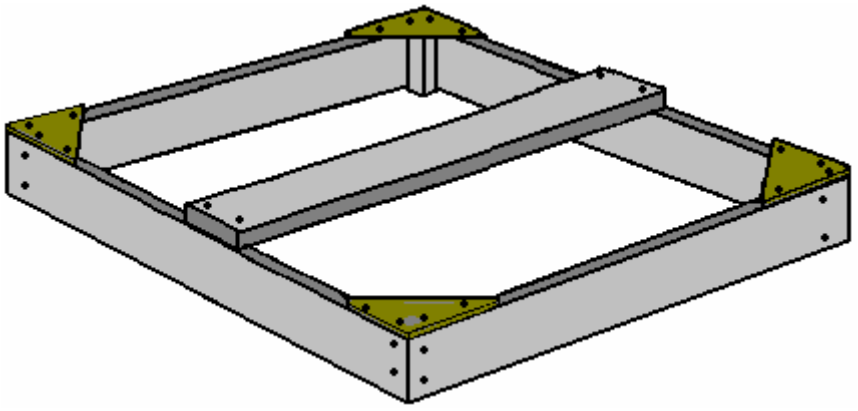
Then the four pieces are screwed together while resting on a flat surface:



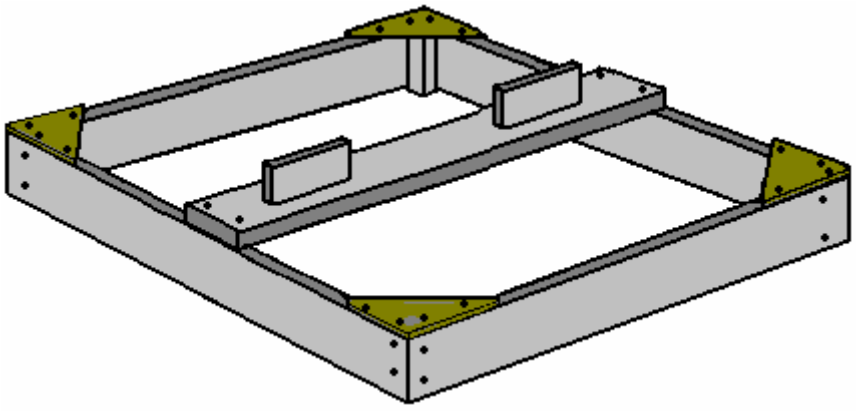
Then corner bracing triangles of MDF are screwed in place:



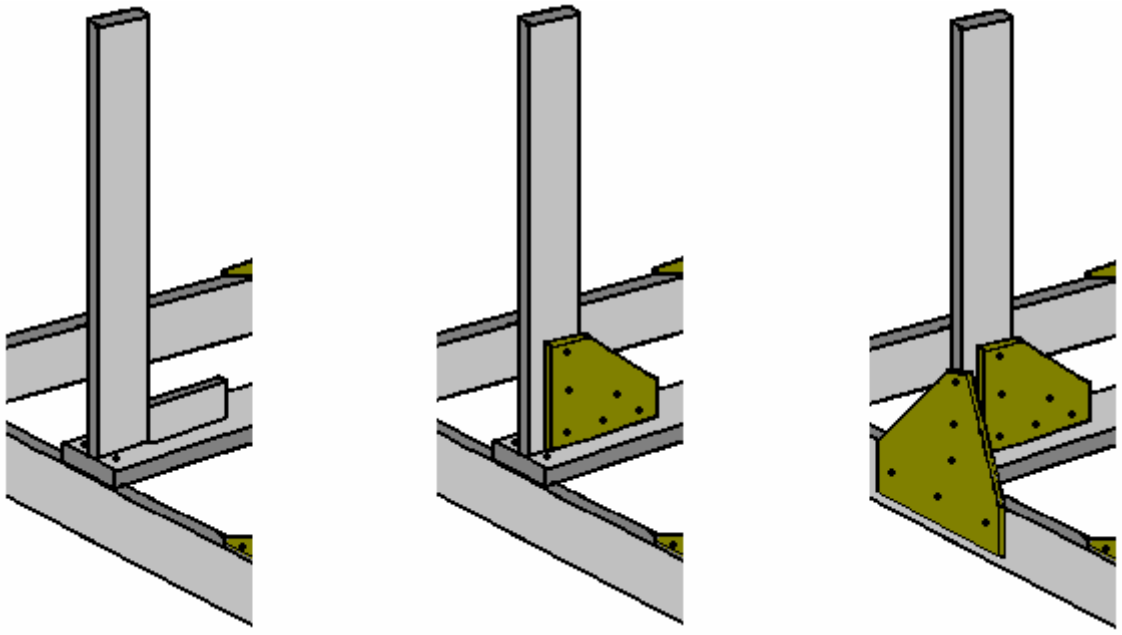
Then a 130 x 25 mm thick plank is attached across the width at the centre point and screwed in place:



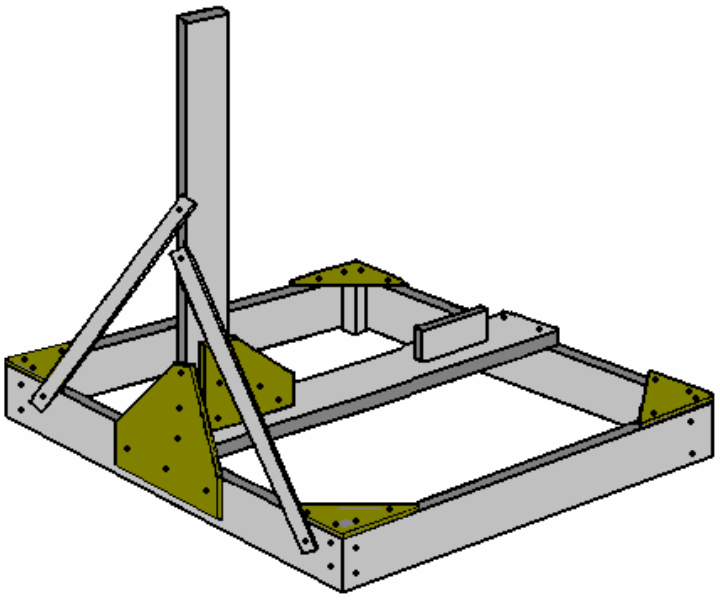
Next, two lengths of the 18 mm thick timbers about 180 mm long are epoxied and screwed to the centre of the 25 mm thick plank, leaving 70 mm clearance to the end of the plank:



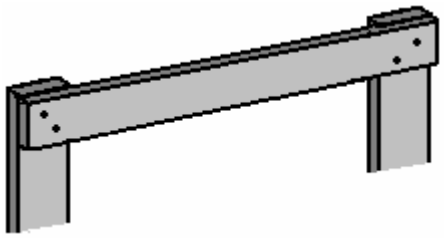
Two timber strips 1350 mm long, are cut and erected vertically, being attached by screws coming upwards through the 25 mm thick plank, and by MDF bracing triangles on one side and across the lower end of the verticals. If a spirit level is used to ensure that the vertical timber is actually vertical, then first, the four corners of the floor frame need to be weighted down to overcome any twisting and the floor frame confirmed to be actually horizontal before attaching the vertical timbers:



Each vertical needs to be braced on both sides with diagonal strip, either metal or timber:

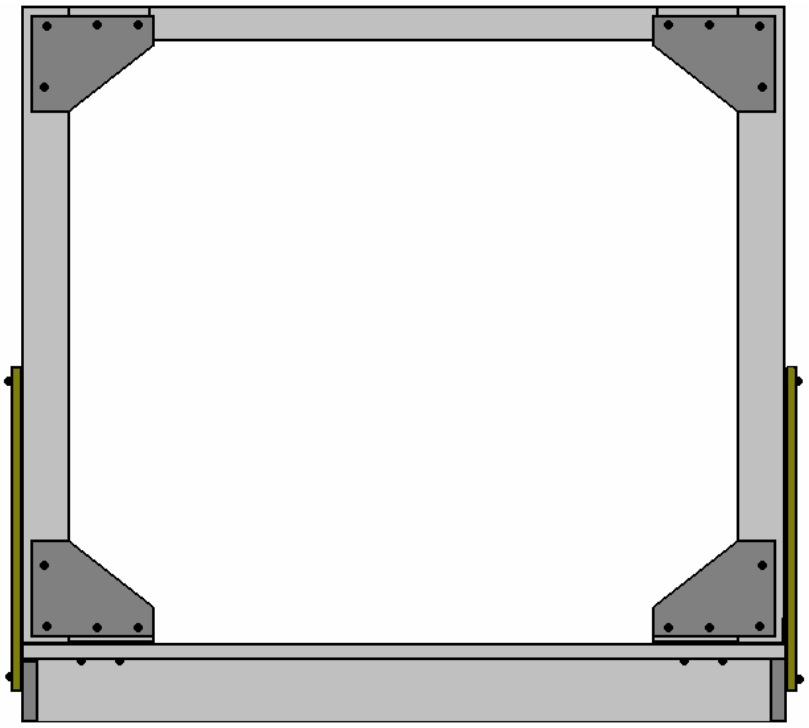


An 18 mm thick timber strip is screwed to the tops of the verticals. This deliberately positions the timber 18 mm off centre as the motor which rotates the top of the axle shaft has to be attached to the middle of this newest timber and that places the motor shaft very close to the central point of the base:

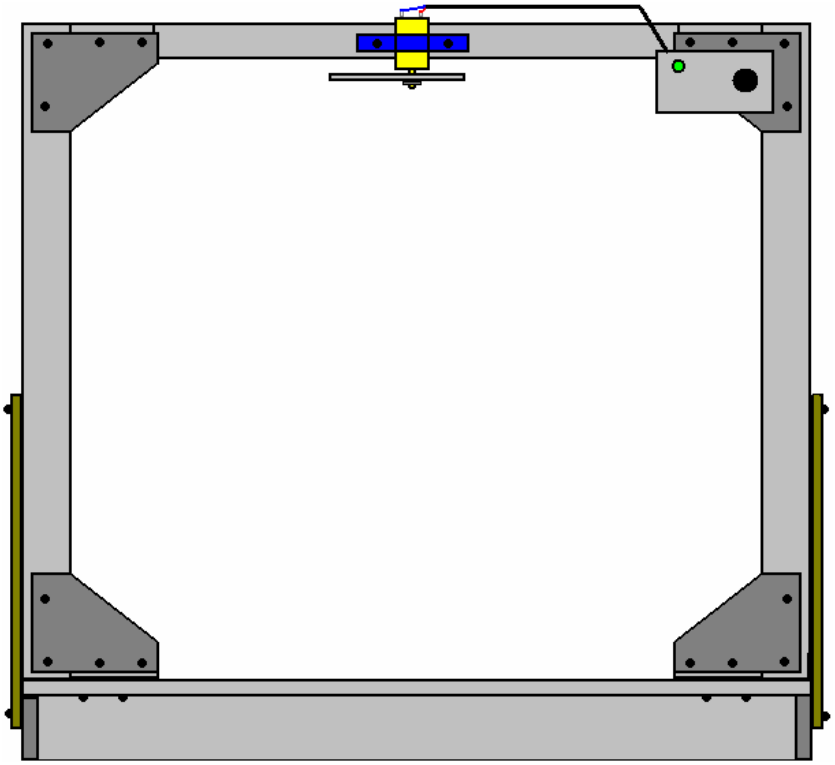


One slight disadvantage is that a packing piece is needed for the triangular MDF bracing pieces which increase the frame rigidity at the top:

At this stage, the construction will look like this:



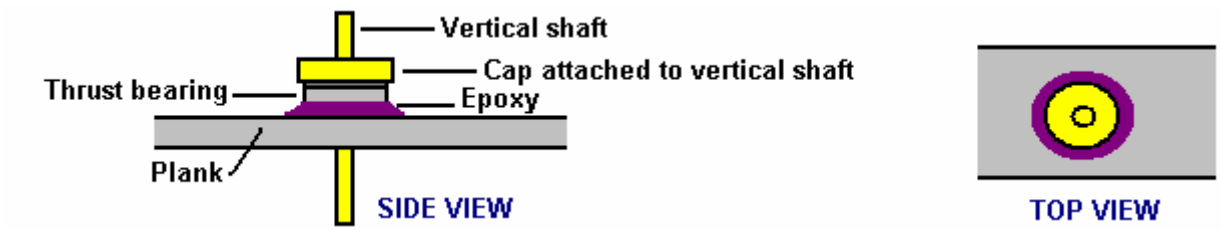
At this point, the 300 rpm motor with it's actuator arm and the speed-control box can be fitted. The motor is located centrally, and the control box can be positioned anywhere convenient. The control box is merely a 12-volt battery pack of 1.2V NiMh AA-size batteries connected through a push-to-make press button switch and the commercial DC Motor Speed Controller, to the 300 rpm motor. With this arrangement, the motor can be powered up by pressing the button and adjusting the speed slowly up from stationary, getting the rotor weight moving gradually faster and faster until its best operating speed is reached. When everything is in place, then the rectified output of the alternator is fed into the control box, so that the Start button can be released and the device becomes self-powered from part of the output power. The initial step looks like this:



It should be explained that, with the exception of the 25 mm thick plank, all of this construction is only loaded very lightly as rotating the top of the axle shaft does not take much power or effort at all. Almost all of the rotating weight is located at the bottom of the axle shaft and that weight rests on some form of bearing which rests in the middle of the 25 mm plank.

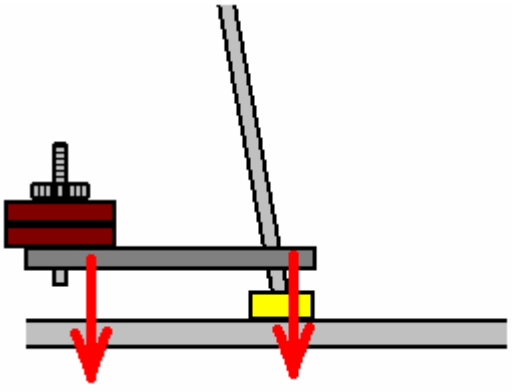
For a small version of the generator, such as this one, the rotating weight does not need to be all that great and so, the forces generated by the weight and its rotation about the bearing need not be a major thing. However, in spite of the fact that we are only dealing with limited forces which can be handled by simple components, people may be inclined to use a thrust bearing instead of allowing the weight to rest on the shaft of the alternator. A bearing of that kind may look like this:

Here, the base and inner ring do not move while the top outer ring revolves freely and can support a major load while it rotates. If we choose to use one of these, then an arrangement like this could be used:

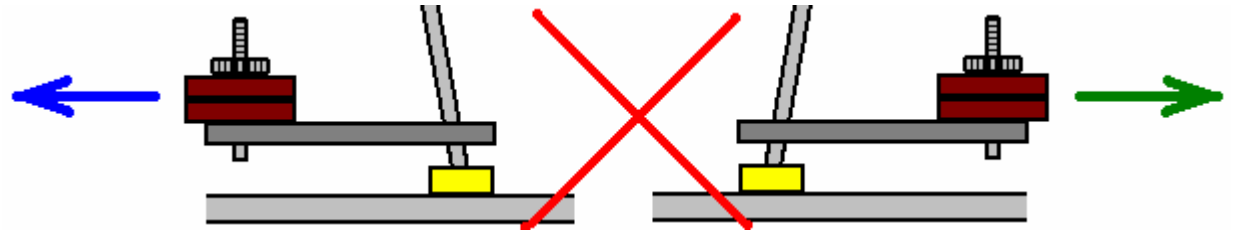


This combination has a cap (shown in yellow) with a central vertical shaft (yellow) attached to it, tightly encasing the upper ring of the bearing whose lower ring is securely attached to the 25 mm thick plank (grey) perhaps using epoxy resin (purple). This allows free rotation of the upper ring and vertical shaft while carrying significant loading. The power take-off in the arrangement shown is from the shaft projecting beneath the plank. Generally speaking, the electrical power output increases with increased speed of rotation, so gearing the alternator up so that it rotates much faster than the axle shaft is desirable and this arrangement may be convenient for that. If it is important to have the power take-off above the plank, then a strong bracket can be used to raise the bearing high enough above the plank to accomplish that.

There are two separate forces acting on the bearing. One is always downwards as the bearing supports the rotating weight:

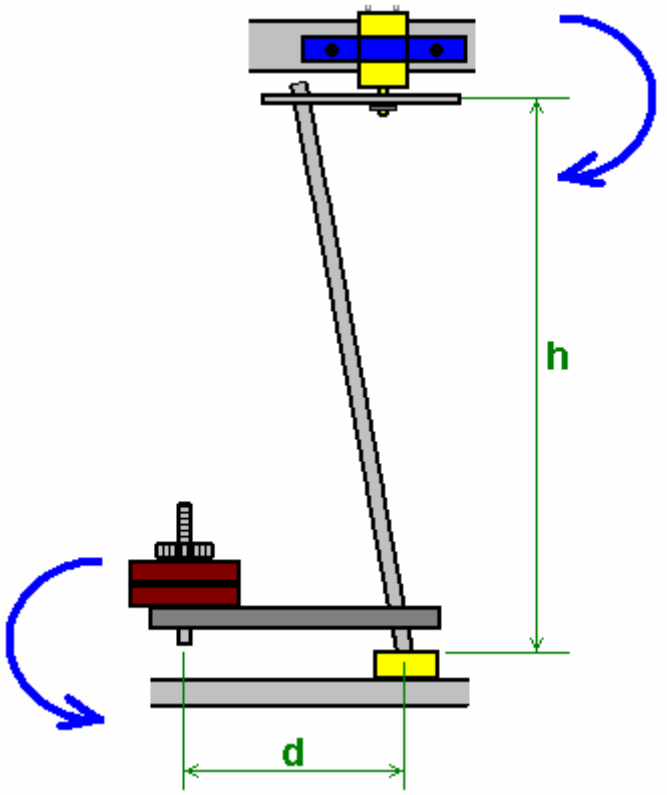


Then there is the sideways forces caused by the rotation of the (unbalanced) weight:



This sideways force is normally considered to be a major problem, however, in this instance, the weight is not being whirled around and trying to escape from the shaft in a horizontal direction, but instead, the weight is turning under gravity powered by its own weight, and the forces generated are quite different and in a different direction. Also, the rate of rotation is very small compared to the speeds which we automatically think about when considering an orbiting weight, typically, this rotation only being between 150 and 300 rpm.

As far as the loading on the axle drive motor is concerned, the situation is like this:

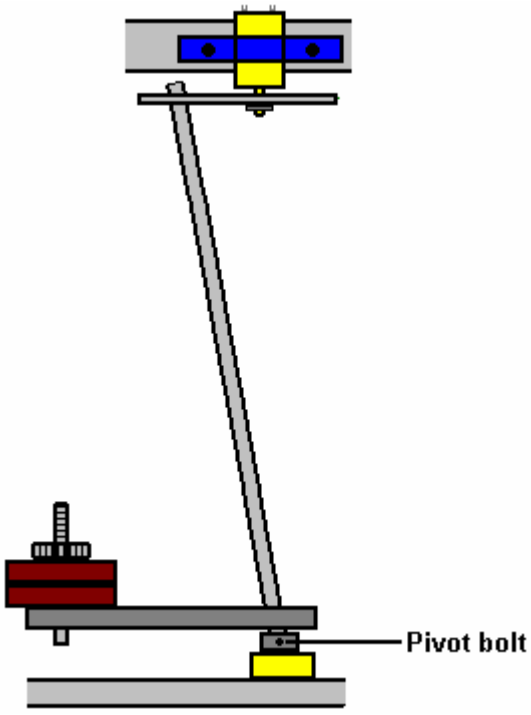


This is the position when at rest. The pull on the motor shaft at the top of the axle shaft is **W x d / h** where **W** is the weight at the end of arm **d**. The situation changes immediately the top of the axle shaft is rotated and the weight **W** starts to swing under the influence of gravity.

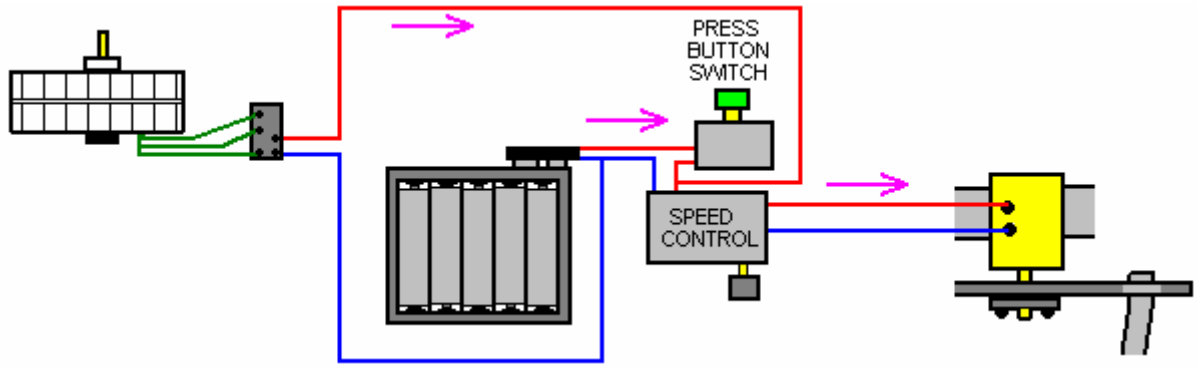
I am told that the axle shaft needs to be light. With small weights, a rigid wooden shaft is adequate and it does not flex under the loading. I am assured that the bottom of the axle shaft needs a universal joint and a major version of this generator where the weights are very high, that is certainly true as the shaft will flex if designed to its minimum specification, but under these much less stressed conditions, there will be no flexing of the shaft when it is pulled sideways and as the shaft angle is a constant, I do not believe that any such joint is necessary. However, many people will wish to include one. These bearings come in different forms, and one of them looks like this:

It must be remembered that if a joint like this is fitted, then it will not be in constant motion, that is, the joints will take up one particular position and will maintain that position during the whole of the time that the generator is in operation.

A compromise would be to provide a hinged movement in one plane by pivoting the axle shaft joint just above the thrust bearing:



The electrical connections are quite straightforward:



The 12-volt battery pack of 1.2V AA-size batteries is connected to the motor speed controller when the button of the press-button switch is held down. This powers the motor, and as the axle shaft speeds up progressively, the generator starts producing power which is always fed to the speed controller box. As soon as the generator gets up to speed the press button switch can be released and the system runs on power produced by the generator. Excess power will be drawn from the generator output, but those links are not shown in the diagram.

Chapter 5: Energy-Tapping Pulsed Systems

Note: If you are not at all familiar with basic electronics, you might find it easier to understand this chapter if you read chapter 12 first.

One very interesting feature of free-energy devices is that although various devices which appear to be completely different and have different apparent applications, the background operation is often the same. It is clear that a sharp positive going DC electric pulse interacts with the surrounding energy field, making large quantities of free-energy available for anyone who has the knowledge of how to gather and use that extra energy.

Let me stress again that "over-unity" is an impossibility. Over-unity suggests that more energy can be taken out of a system than the total energy which goes into the system. This is not possible as you can't have more than 100% of anything. However, there is another perfectly valid way of looking at the operation of any system, and that is to rate the output of the system relative to the amount of energy that the user has to put in to make it work. This is called the "Coefficient Of Performance" or "COP" for short. A COP = 1 is when all of the energy put in by the user is returned as useful output. A COP>1 is where more useful energy comes out of the device than the user has to put in. For example, a sailing boat in a good breeze transports people along without the need for the energy of movement to be supplied by the crew. The energy comes from the local environment and while the efficiency is low, the COP is greater than 1. What we are looking for here is not something to tap wind energy, wave energy, sunlight energy, river energy, thermal energy or whatever but instead we want something which can tap the invisible energy field which surrounds us all, namely the "zero-point energy" field or the "ambient background".

For this, let us look at pulsing circuits used by a wide range of people in a number of apparently quite different devices. An electrical "pulse" is a sudden voltage rise and fall with very sharply rising and falling voltages. However, pulses are seldom generated as isolated events when working with practical devices, so it is probably better to think of a train of pulses, or a "waveform" with very sharp rising and falling edges. These can be called oscillators or signal generators and are so commonplace that we tend not to give them a second thought, but the really important factors for using an oscillator for zero-point energy pick-up is the quality of the signal. Ideally, what is needed can be a perfect square wave with no overshoot, and the voltage level never going below zero volts, or a complex waveform, also with very sharp attack and decay times. These waveforms are a good deal more difficult to generate than you might imagine.

Even in these days of sophisticated solid-state electronic devices, the best method of creating a really sharp voltage pulse is still considered to be a spark gap, especially one which has the spark chopped off suddenly by the use of a strong magnetic field at right angles to the spark gap. For an example of this style of operation, consider the following device.

Frank Prentice's COP=6 Pulsed Aerial System.

Electrical Engineer Frank Wyatt Prentice of the USA invented what he described as an 'Electrical Power Accumulator' with an output power six times greater than the input power (COP = 6). He was granted a patent in 1923 which says:

My invention relates to improvements in ELECTRICAL POWER ACCUMULATORS and the like, wherein the earth, acting as rotor and the surrounding air as a stator, collects the energy thus generated by the earth rotating on it's axis, utilises it for power and other purposes.

In the development of my WIRELESS TRAIN CONTROL SYSTEM for railways, covered by my United States Letters Patent Number 843,550, I discovered that with an antenna consisting of one wire of suitable diameter supported on insulators, three to six inches above the ground and extending one half mile, more or less in length, the antenna being grounded at one end through a spark gap, and energised at the other end by a high frequency generator of 500 watts input and having a secondary frequency of 500,000 Hz, would produce in the antenna, an oscillatory frequency the same as that of the earth currents and thus electrical power from the surrounding media was accumulated along the length of the transmission antenna and with a closed oscillatory loop antenna 18 feet in length run parallel with the transmission antenna at a distance of approximately 20 feet, it was possible to obtain by tuning the loop antenna, sufficient power to light to full candle power a series bank of 50 sixty-watt carbon lamps. Lowering or raising the frequency of 500,000 Hz resulted in a diminishing of the amount of power received through the 18 foot antenna.

Likewise, raising the transmission antenna resulted in a proportionate decrease of power picked up on the receiving antennae and at 6 feet above the earth no power whatsoever was obtainable without a

change of voltage and frequency.

It is the objective of my generic invention to utilise the power generated by the earth, by the means described here and illustrated in the drawings. The two drawings show simple and preferred forms of this invention, but I wish it to be understood that no limitation is necessarily made as to the exact and precise circuits, shapes, positions and structural details shown here, and that changes, alterations and modifications may be made when desired within the scope of my invention and as specifically pointed out in the claims.

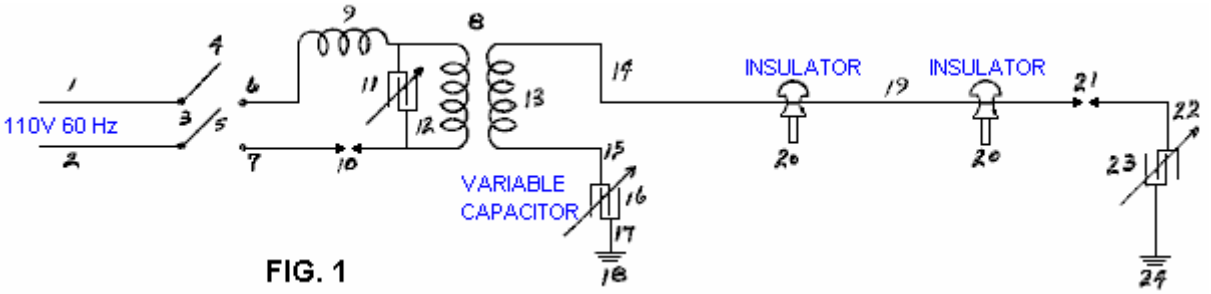

FIG. 1

Referring particularly to **Fig.1**, **1** and **2** are alternating current feed wires supplying 110 volts 60 cycles per second to a high-frequency generator. **3** is a switch with poles **4** and **5**, while **6** and **7** are the connections to the high-frequency transformer **8**, which is used to step-up the frequency to 500 kHz and the voltage to, say, 100 kV. **9** is an inductor, **10** is a spark gap, **11** is a variable capacitor, **12** is the primary winding and **13** the secondary winding of transformer **8**. The secondary winding is connected to ground through variable capacitor **16**, and wire **17**. Wire **14** connects transformer **8** to the main transmission antenna **19** which is supported along it's length on insulators **20**. Spark gap **21** is positioned between the main transmission antenna **19** and the ground **24**, passing through connecting wire **22** and variable capacitor **23**. The main transmission antenna **19**, can be any desired length.

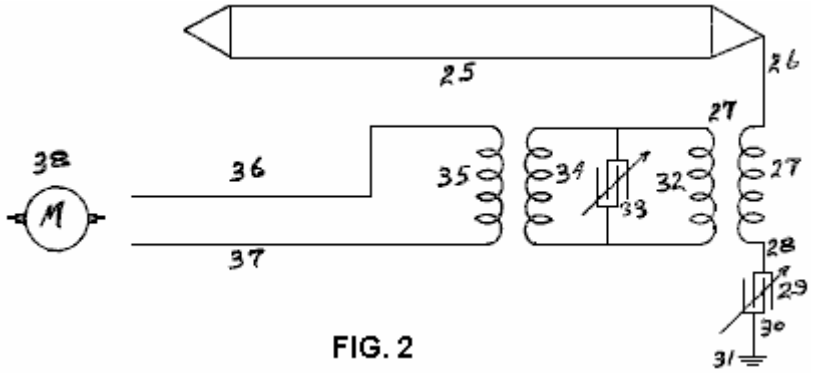

FIG. 2

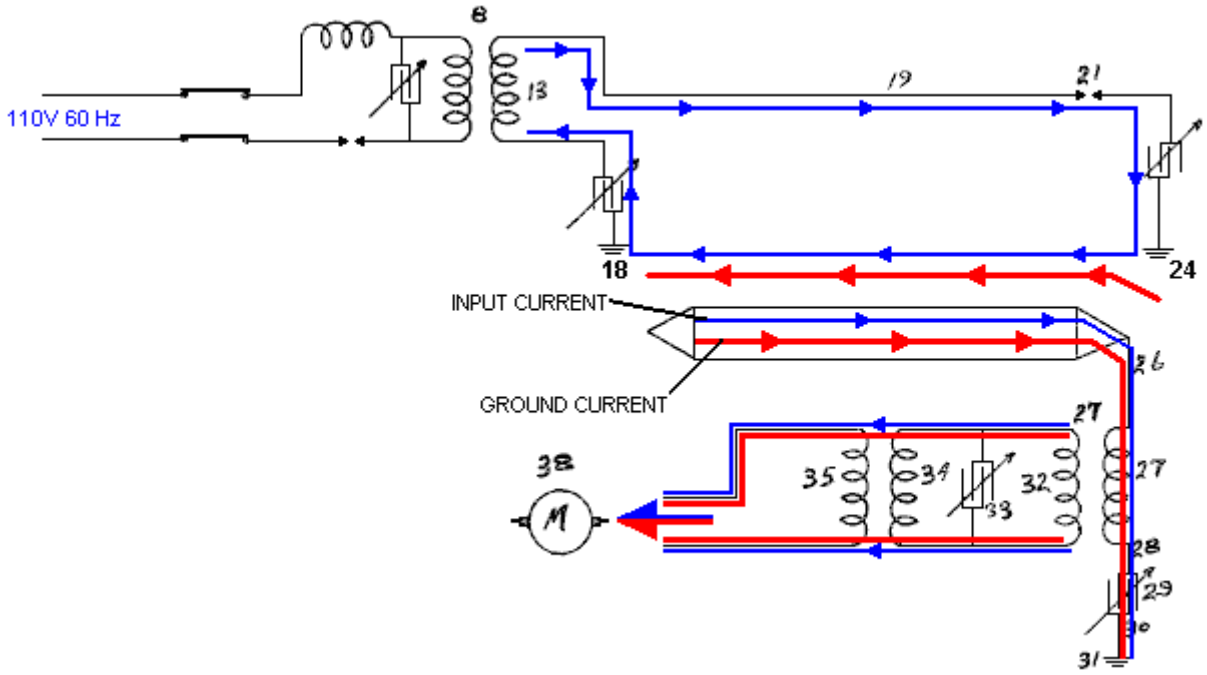
In **Fig.2**, **25** is a closed oscillating loop antenna of any desired length. For greatest efficiency, it is run parallel with the main transmission antenna **19** of **Fig.1**. Wire **26** is connected to the secondary winding **27** of a step-down transformer which winding then goes to ground **31** through variable capacitor **29**. The primary winding **32** of the step-down transformer has variable capacitor **33** connected across it and it feeds directly into winding(s) **34** of frequency transformer(s) which supply current through winding(s) **35** to a motor "**M**" or other electrical load(s).

Having described the drawings, I will now describe the operation of my invention. Operate switch **3** to connect the input power. Adjust spark gap **10** and variable capacitor **11** so that 100,000 volts at a frequency of 500,000 cycles per second is delivered to step-up transformer **8** of **Fig.1**. Next, adjust spark gap **21** of the transmission antenna **19** so that all (voltage) peaks and nodes are eliminated in the transmission of the 100,000 volts along the antenna by the current surges across spark gap **21**. The high-frequency alternating current flowing through spark gap **21** passes through variable capacitor **23** to ground **24** and from there, back through the ground to earthing point **18**, through variable capacitor **16** and back to winding **13** of transformer **8**. As the 500,000 Hz

current is the same as the earth-generated currents and in tune with it, it naturally follows that accumulation of earth currents will amalgamate with those for transformer **8**, providing a reservoir of high-frequency currents to be drawn upon by a tuned circuit of that same 500 kHz frequency, such as that shown in **Fig.2**, where the antenna **25** is turned to receive a frequency of 500 kHz, which current then passes through transformer **27**, any frequency-adjusting transformer(s), and on to power the load(s) **38**.



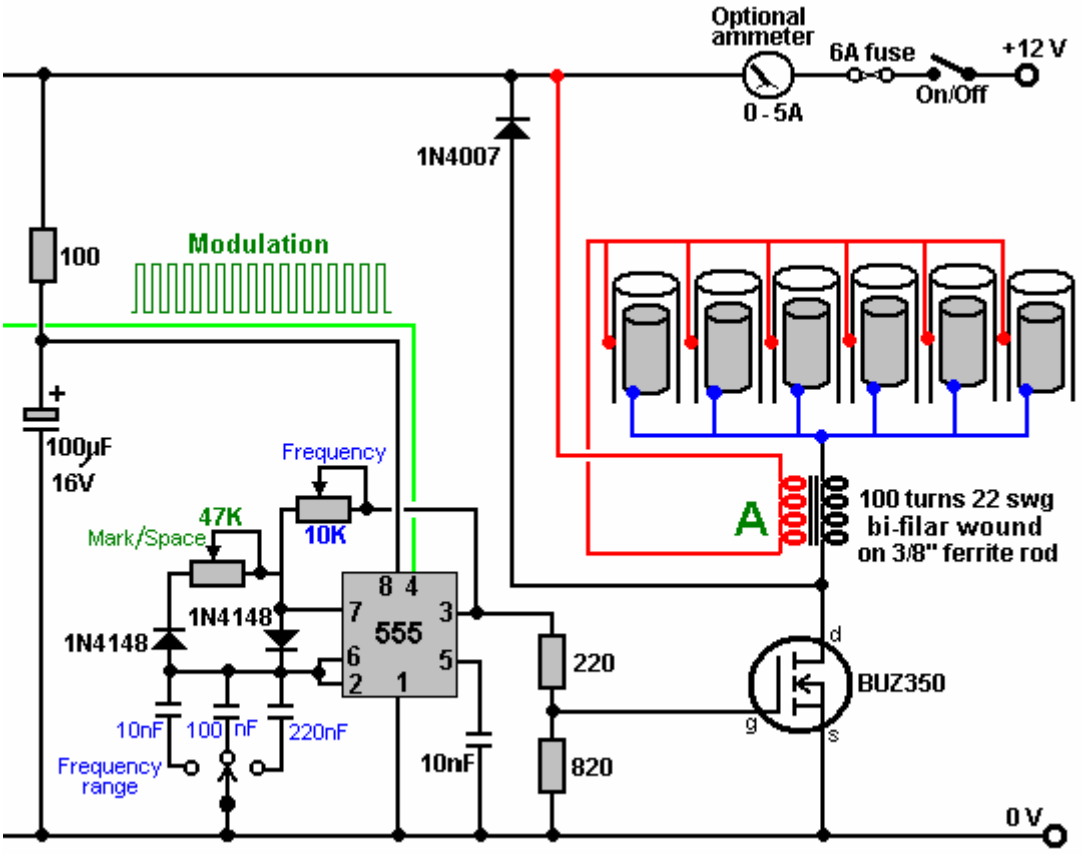
The return of current through the earth from transmission antenna **19**, is preferable to return through a wire as the ground return current picks up more earth currents than a wire does. I also prefer under certain conditions, to use a single antenna wire in place of the closed loop antenna shown in **Fig.2**. Under certain operational requirements, I have had improved performance by having the transmission antenna elevated and carried on poles many feet above the earth, and with that arrangement it is necessary to use a different voltage and frequency in order to accumulate earth currents.

This system of Frank's effectively applies very sharply pulsed DC pulses to a long length of wire supported in a horizontal position not far above the ground. The pulses are sharp due to both the spark gap on the primary side of the transformer, along with the spark-gap on the secondary (high voltage) side of the transformer. An input power of 500 watts gives a 3 kW power output from what appears to be an incredibly simple piece of equipment.

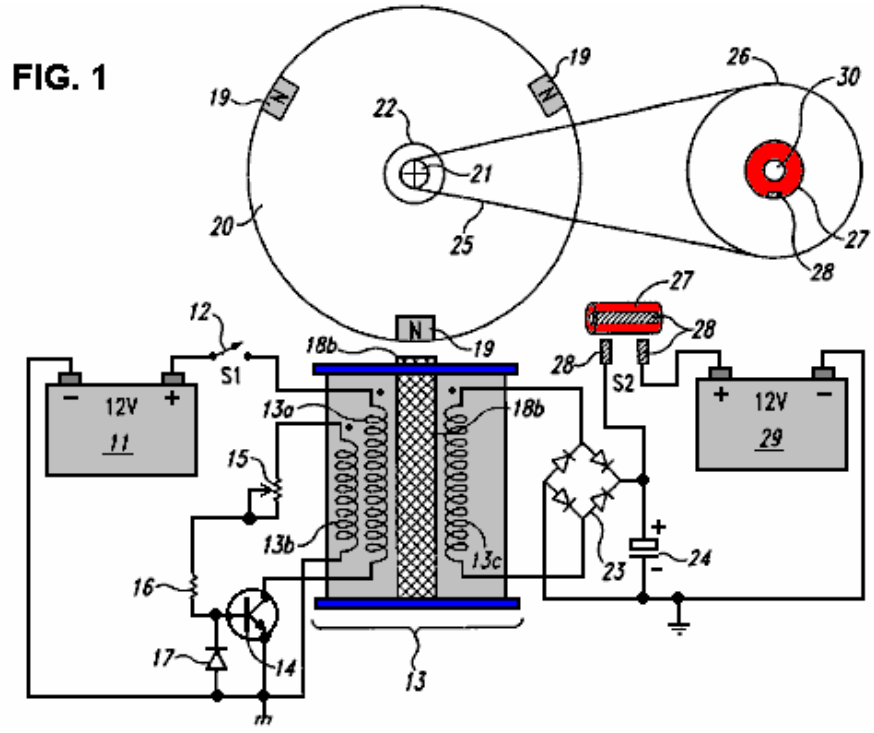
Dave Lawton's Solid-State Circuit.

A solid-state semiconductor circuit which has proved successful in producing pulses like this is shown as part of Dave Lawton's replication of Stan Meyer's Water Fuel Cell. Here, an ordinary NE555 timer chip generates a square wave which feeds a carefully chosen **F**ield-**E**ffect **T**ransistor the BUZ350 which drives a water-splitter cell via a combined pair of choke coils at point "A" in the diagram below.

Stan Meyer used a toroidal ferrite ring when he was winding these choke coils while Dave Lawton uses two straight ferrite bars, bridged top and bottom with thick iron strips. Chokes wound on straight ferrite rods have been found to work very well also. The effects are the same in all cases, with the waveform applied to the pipe electrodes being converted into very sharp, very short, high-voltage spikes. These spikes unbalance the local quantum environment causing vast flows of energy, a tiny percentage of which happens to flow into the circuit as additional power. The cell runs cold, and at low input current, quite unlike an ordinary electrolysis cell where the temperature rises noticeably and the input current needed is much higher.

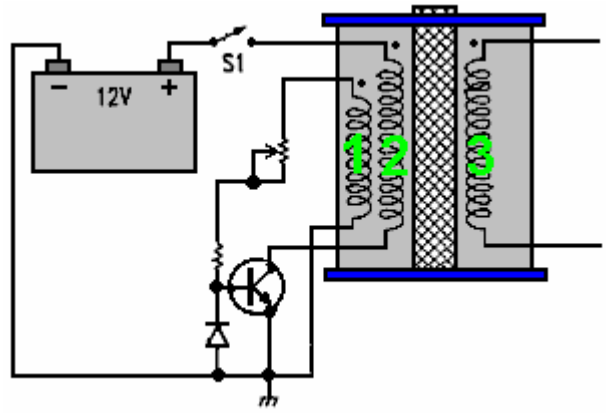


John Bedini's Battery-Charging Circuit.
John Bedini uses this same pulsing of a bi-filar wound coil to produce the same very short, very sharp voltage spikes which unbalance the local energy field, causing major flows of additional energy. The figure shown here is from his US patent 6,545,444.



John has produced and generously shared, many designs, all of which are basically similar and all using a 1:1 ratio bi-filar wound transformer. This one uses a free-running rotor with permanent magnets embedded in it's rim, to trigger sharp induced currents in the windings of the coil unit marked "**13b**" which switches the transistor on, powering winding "**13a**" which powers the rotor on its way. The pick-up coil "**13c**" collects additional energy from

the local environment, and in this particular circuit, feeds it into the capacitor. After a few turns of the rotor (dictated by the gear-down ratio to the second rotor), the charge in the capacitor is fed into a second "on-charge" battery.



The rotor is desirable but not essential as the coils marked **1** and **2** can self-oscillate, and there can be any number of windings shown as **3** in the diagram. Winding **3** produces very short, sharp, high-voltage spikes, which is the essential part of the design. If those sharp pulses are fed to a lead-acid battery (instead of to a capacitor as shown above), then an unusual effect is created which triggers a link between the battery and the immediate environment, causing the environment to charge the battery. This is an amazing discovery and because the voltage pulses are high-voltage courtesy of the 1:1 choke coils, the battery bank being charged can have any number of batteries and can be stacked as a 24-volt bank even though the driving battery is only 12 volts. Even more interesting is the fact that charging can continue for more than half an hour after the pulsing circuit is switched off.

It can be tricky to get one of these circuits tuned properly to work at peak performance, but when they are, they can have performances of COP>10. The major snag is that the charging mechanism does not allow a load to be driven from the battery bank while it is being charged. This means that for any continuous use, there has to be two battery banks, one on charge and one being used. A further major problem is that battery banks are just not suitable for serious household use. A washing machine draws up to 2.2 kilowatts and a wash cycle might be an hour long (two hours long if a "whites" wash and a "coloureds" wash are done one after the other which is not uncommon). During the winter, heating needs to be run at the same time as the washing machine, which could well double the load.

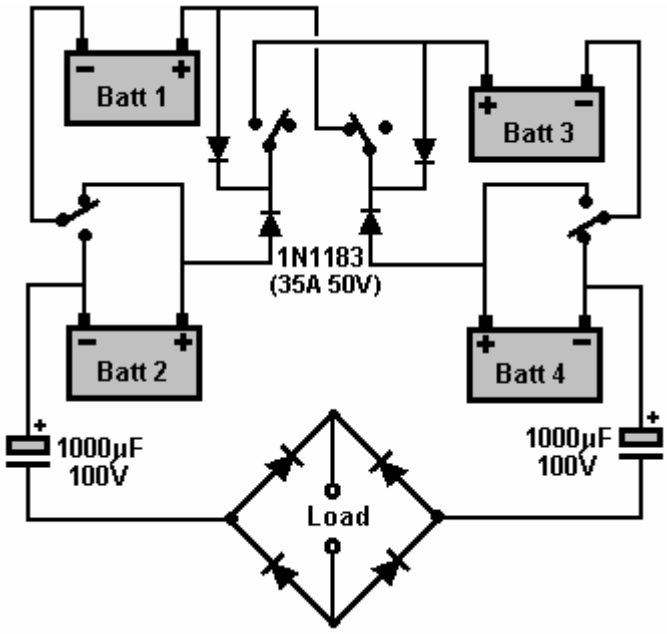
It is recommended that batteries are not loaded much beyond their "C20" rate, that is, one twentieth of their Amp-Hour nominal rating. Say that 85 Amp-Hour deep-cycle leisure batteries are being used, then the recommended draw rate from them is 85 Amps divided by 20, which is 4.25 amps. Let's push it and say we will risk drawing double that, and make it 8.5 amps. So, how many batteries would we need to supply our washing machine assuming that our inverter was 100% efficient? Well, 2,200 watts on a 12-volts system is 2,200 / 12 = 183 amps, so with each battery contributing 8.5 amps, we would need 183 / 8.5 = 22 large, heavy batteries. We would need twice that number if we were to treat them right, plus twice that again for household heating, say 110 batteries for an anyway realistic system. That sheer size of battery banks is not realistic for your average householder or person living in an apartment. Consequently, it appears that the Bedini pulse-charging systems are not practical for anything other than minor items of equipment.

However, the really important point here is the way that when these short pulses are applied to a lead-acid battery, a link is formed with the environment which causes large amounts of energy to flow into the circuit from outside. This is extra "free-energy". Interestingly, it is highly likely that if the pulses generated by Dave Lawton's water-splitter circuit shown above, were fed to a lead-acid battery, then the same battery-charging mechanism is likely to occur. Also, if a Bedini pulse-charging circuit were connected to a water-splitting cell like the Lawton cell, then it is highly probable that it would also drive that cell satisfactorily. Two apparently different applications, two apparently different circuits, but both producing sharp high-voltage pulses which draw extra free-energy from the immediate environment.

The Tesla Switch.

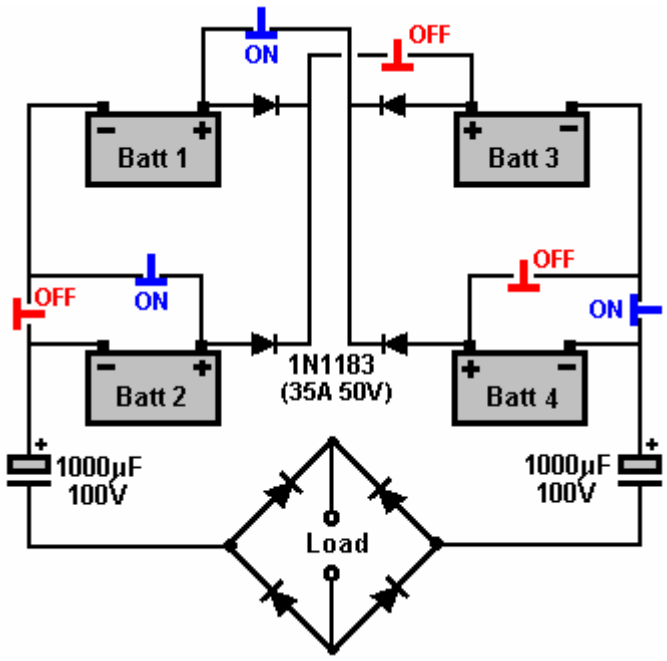
It doesn't stop there. Nikola Tesla introduced the world to Alternating Current ("AC") but later on he moved from AC to very short, sharp pulses of Direct Current ("DC"). He found that by adjusting the frequency and duration of these high-voltage pulses, that he could produce a whole range of effects drawn from the environment - heating, cooling, lighting, etc. The important point to note is that the pulses were drawing energy directly from the local environment. Leaving aside the advanced equipment which Tesla was using during those experiments and moving to Tesla's simple-looking 4-battery switch, we discover the same background operation of sharp voltage pulses drawing free-energy from the environment.

Consider the Electrodyne Corp. circuit (shown in "The Manual of Free-Energy Devices and Systems", 1986) tested by them for a period of three years:



Please note that when I shared this circuit diagram several years ago, someone persuaded me that the diodes were shown the wrong way round, and because of that, I have shown these diodes incorrectly. The diagram above is the one shown by the Electrodyne Corp. staff, and is correct.

As the switching used by this device was a mechanical device which has six switches where three are **ON** and three are **OFF** at any moment, the Electrodyne Corp. staff present the circuit diagram like this:



With switching like this:

It is recommended that this simple-looking circuit has an inductive load, preferably a motor, but consider the results of that very extended period of testing. If the switching rate and switching quality were of a sufficiently high standard, then the load could be powered indefinitely. The batteries used were ordinary lead-acid batteries, and after the three years of tests, the batteries appeared to be in perfect condition. Their tests revealed a number of very interesting things. If the circuit was switched off and the batteries discharged to a low level, then when the circuit was switched on again, the batteries returned to full charge in under one minute. No heating occurred in the batteries in spite of the massive charging rate. If the circuit was switched off and heavy current drawn from the batteries, then heat would be produced which is quite normal for battery discharging. The system operated lights, heaters, television sets, small motors and a 30-horsepower electric motor. If left undisturbed, with the circuit running, then each battery would charge up to nearly 36 volts with no apparent ill effects. Control circuitry was developed to prevent this over-charging. This, of course, is easy to do as all that is required is to place a relay across one battery and have it disconnect the circuit when the battery voltage reaches whatever voltage is considered to be a satisfactory maximum voltage.

These test results show spectacular battery charging and battery performance, quite outside the normal range associated with these ordinary lead-acid batteries. Are they being fed very short, very sharp pulses, like the previous two systems? It would look as if they were not, but one other very interesting piece of information coming from Electrodyne is that the circuit did not operate correctly if the switching rate was less than 100 Hz (that is 100 switchings in one second). The Electrodyne switching was done mechanically via three discs mounted on the shaft of a small motor.

One other detail reported by the Electrodyne testers, is that if the switching speed exceeded 800 times per second, that it was “dangerous” but unfortunately, they didn’t say why or how it was dangerous. It clearly was not a major problem with the batteries as they were reported to be in good shape after three years of testing, so definitely no exploding batteries there. It could well be as simple a thing that the voltage on each battery rose so high that it exceeded the voltage specifications of the circuit components, or the loads being powered, which is a distinct possibility. It is possible that at more than 800 pulses per second, the charging produced excessive cooling which was not good for the batteries.

It is generally accepted that for a circuit of this nature to work properly, the switching has to be very sudden and very effective. Most people have an immediate urge to use solid-state switching rather than the mechanical switching used by Electrodyne. A 'thyristor' or 'SCR' might be suitable for this, but the sharp switching of a PCP116 opto-isolator driving an IRF540 FET is impressive and a TC4420 FET-driver could substitute for the opto-isolator if preferred. It is possible that having a slight delay after the switches have turned On and Off, can prove very effective.

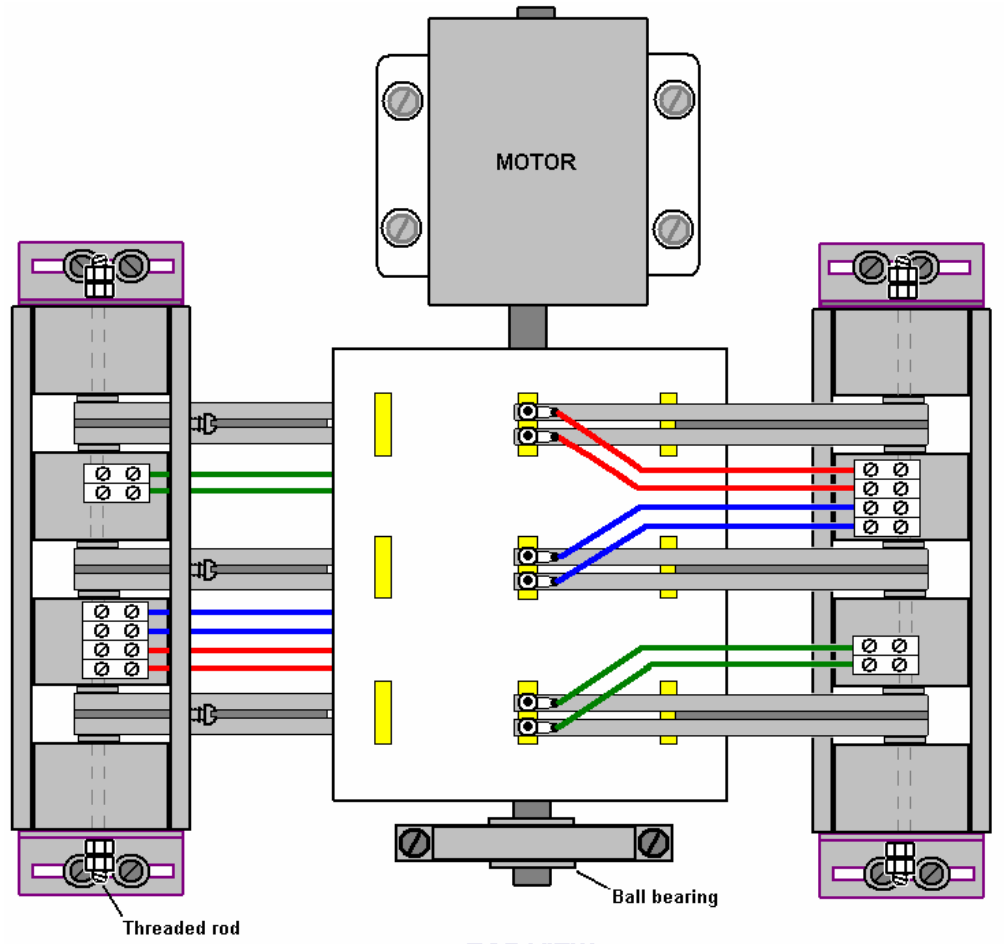
The Electrodyne Corp. staff used three identical discs mounted on the shaft of a motor as shown above. This allows the contact "brushes" to be located on opposite sides of the discs. There are, of course, many possible alternative constructions and I have been asked to show how I would choose to build this type of mechanical switching. The common idea of using mechanical relays is not very practical. Firstly, relays have trouble switching at the speeds suggested for this circuit. Secondly, with a contact life of say, two million and a switching speed of just 100 times per second, the relays would reach their projected lifespan after two weeks of operation, which is not a very practical option.

The objective is to have a simple construction which produces several switchings for each revolution of the motor, easy adjustment of the timing of two separate sets of three switches (one set being OFF when the other set is ON), a construction which can be taken apart and then assembled again without altering the timing, and an electrical connection method which is straightforward. Obviously, the construction needs to use components which are readily available locally, and ideally, only require simple hand tools for the construction.

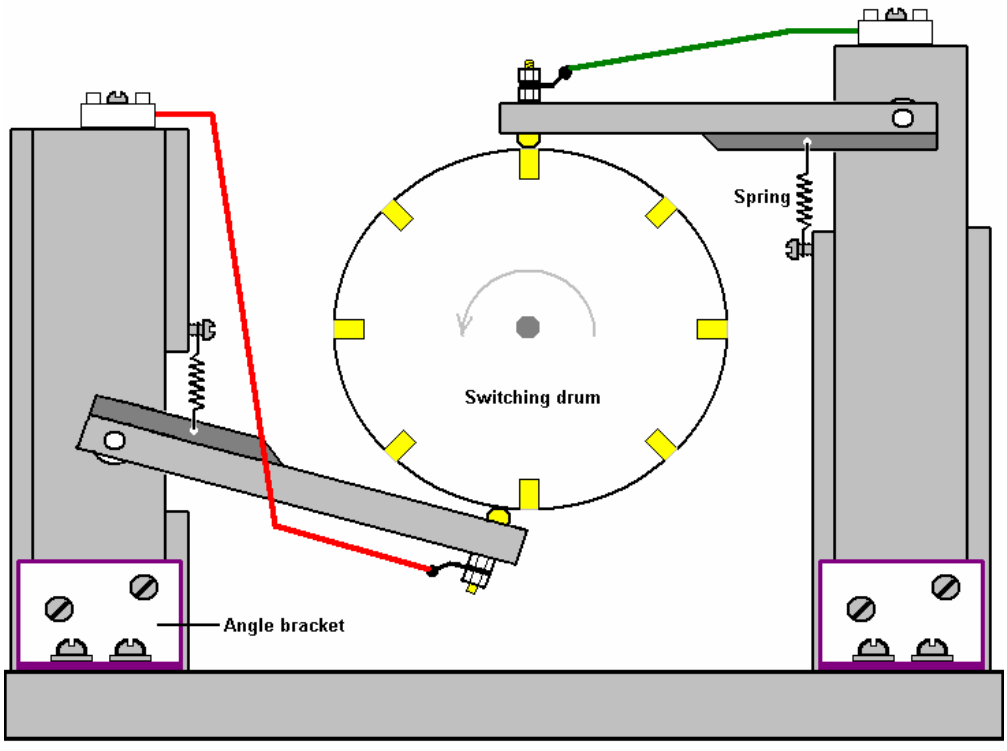
This suggested construction allows adjustment of the timing for both the start of the first set of switches and the start of the second set of switches. It should also be possible to introduce a short gap between the operation of these two sets of switches. This particular design is assuming a gap between each switching operation as that may be beneficial.

The switch contacts are rigid arms, pulled against the rotating drum by springs. The contacts touching the drum can be of various types and the ones shown are brass or copper cheese-head screws or bolts which are particularly convenient as they allow standard solder tags to be used to make the connections to the switch wires which then run across to ordinary electrical screw connectors, all of which can be accessed from above. I would suggest that four screw connectors should be used as a block as that allows them to be fastened in position with two screws which then stops them rotating when the wires are being tightened. There should not be any need for the conducting inserts in the switching cylinder to be particularly wide in the direction of rotation.

A practical construction method might be:



TOP VIEW



SIDE VIEW

The contact arms are shown as attached to each other in pairs. A lower level of construction accuracy can be allowed if they are all kept separate and a spring used for each arm rather than one spring for two arms as shown

in the drawing. I strongly recommend that the switching drum be solid and the brass or copper insets be a fair thickness and keyed securely into the drum. The surface of the inserts should be very gently eased into exact alignment with the surface of the drum, possibly by the very careful use of a small file or lathe if you are lucky enough to have access to one.

The pivots for all of the switching arms can be a length of threaded rod with lock nuts at each end. There should be almost no movement of the switching arms when the drum is spinning, so no enormous precision is needed for the holes in the switching arms, through which the threaded rod runs. Having said that, it must be understood that each switch in the set of three, must turn On and OFF at the same time, so the contacts on the spring-loaded arms must slide on to and off the conducting strips in the switching cylinder, at exactly the same time.

The drawing shows three conducting inserts at each of eight evenly-spaced positions around the circumference of the drum. The number around the drum is not critical although this suggestion gives eight switchings per revolution. If you choose to use a different number, you need to remember that the positioning of the arms underneath the drum will be different. You need to arrange it so that just after one set runs off its conducting strips that the other set slides on to it's conducting strips. Both sets of switches must not be ON at the same time as that short-circuits the batteries, which is probably not a good idea.

The timing adjustment is achieved by moving the supporting block slightly, by easing the four clamping screws, sliding the block and tightening the screws again. This, of course, is done when the drum is not rotating.

Each set of six switching arms needs to have all of the arms exactly the same length between the sliding contact (shown as a bolt head) and the pivot hole. Each of the conducting strips inset into the drum, need to be aligned exactly and be exactly the same width, otherwise the switching action will be ragged and not properly synchronised.

The supports for the switching arms can be either a single block with slots cut in it or the easier construction shown, where it is fabricated from several standard rectangular pieces and glued and/or screwed together.

The unequal amount of conducting strip compared to the non-conducting part means that there will be a timing gap between each pair of On/Off switchings. In spite of that, the battery switching will be a 50% Duty cycle as required. The switching sequence will then be: On / Off / Pause, On / Off / Pause, On / Off / Pause ….. and that may well be a desirable arrangement as having an inter-pulse delay can be very good for battery charging.

However, please don't imagine that the Tesla Switch described here is a 'plug-and-play' device which you can switch on and it will give you the sort of outputs mentioned above, as that is very much not the case. You need to see the Tesla Switch as being a long-term development project with high potential.

If you use the Tesla Switch circuit with manual switches and run each phase for many minutes before altering the switching, it can give up to four times better performance than running the load off the four batteries in parallel. That is not what the Tesla Switch is all about.

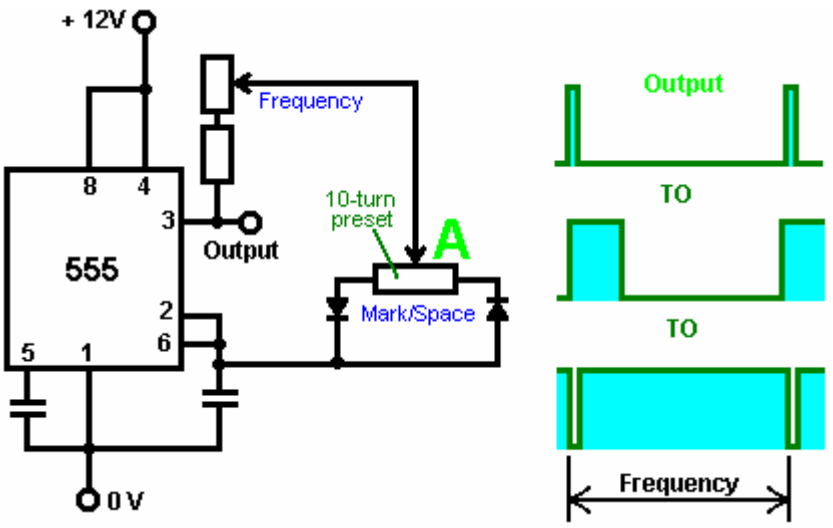
The Tesla Switch is one of the more difficult devices to get operational, in spite of the fact that it appeals to a large number of people. There are three possible modes of operation. If the diodes are turned the wrong way round so that they can feed current from each battery, then the operation will definitely be COP<1 but it will be a good deal better than operating without the switch circuit in place.

The second way has only been achieved by John Bedini as far as I am aware. This is where the circuitry is the same but the circuit components and connecting wires are adjusted very carefully to produce circuit resonance. When that happens, the circuit becomes self-powering although there is little or no extra power for other devices.
The third way was developed and tested over three years by staff of the Electrodyne Corporation in America. In this version, the diodes are reversed and they only feed sharp voltage spikes back to the batteries, through the diodes which supposedly don't allow current to flow in that direction. This is a very different form of operation where the operating power flows into the circuit from the local environment. The batteries need to be 'conditioned' through long periods of being operated this way as the 'cold electricity' used in the circuit is the opposite of the 'hot electricity' which the batteries have been using up to now. This long conditioning period is generally enough to make the average builder give up and believe that the circuit just doesn't work. Dave Lawton was faced with exactly the same type of problem when he attempted to replicate Stan Meyer's "Water Fuel Cell". It appeared 'dead' and produced nothing during a whole month of testing, and then it suddenly burst into life, producing large amounts of HHO gas mix for almost no electrical input. Without his exceptional patience, Dave would never have succeeded. I believe that the same applies to the Tesla Switch when wired correctly with the diodes blocking current flow from the batteries – it is likely to take long-term and patient testing before the system swings into life.

One experimenter who did not believe the diodes could possibly work that way round, tested the arrangement and discovered that in spite of the theory, in practice, the reverse-biased diodes actually pass very sharp voltage

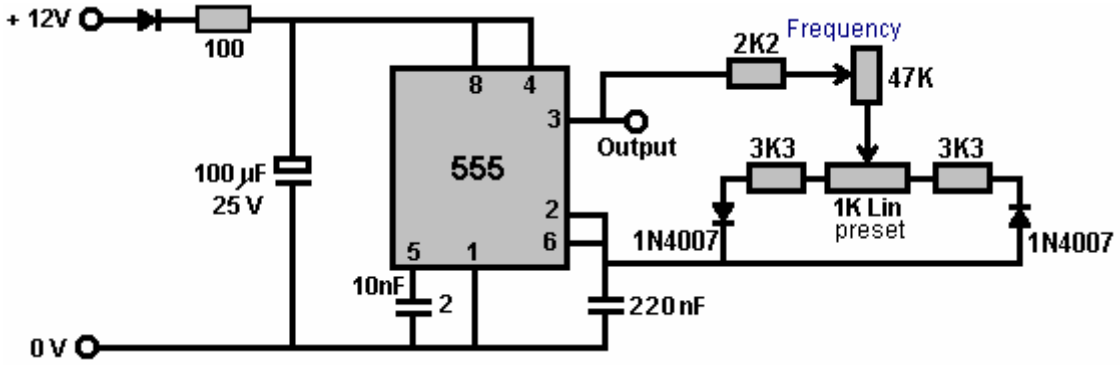
spikes to the batteries, so the effect may well be like a slick version of the various battery pulsing circuits shown in chapter 6.

Mechanical switching appears to work very well indeed, but if we decide to try using electronic circuitry, then we need to get an exact 50% Mark/Space ratio using a switching circuit, and so the following style of circuit might be used with a multi-turn preset resistor in position “A”:



Here, the frequency is not noticeably affected by adjustment through a very wide range of Mark/Space settings. The output from Pin 3 needs to drive a very sharp switching combination such as a TC4420 FET driver connected to IRF540 FETs.

Perhaps the circuit might be something like this:



This circuit allows the Mark-Space ratio to be adjusted without altering the frequency, and the frequency can be adjusted without affecting the Mark-Space setting in any way. In the Tesla Switch circuit, three switches need to be in their On position and the other three switches in their Off position, so we will arrange this by using the ordinary NE555 timer circuit shown above, with it's adjustable Mark-Space ratio (that is, variable On-to-Off ratio). We will use this circuit to drive six opto-isolators which will turn the six transistors On and Off in groups of three as required. To get the very high switching speed needed, PCP116 opto isolators should be used and although these are difficult to find, every effort should be made to get them as they enhance the switching speed.

Variable resistors come in a wide range of types. It is probably best to use a preset type as they are very easy to adjust and hold their settings very solidly. Also, when the correct setting is found, the component will be left on that position permanently. Some common types are:

where some can be adjusted from the top and others adjusted from the side. All of them can be mounted directly on the strip-board or printed circuit board used to construct the circuit.

However, the problem is to decide the direction of current flow and provide solid state components accordingly, as the Tesla Switch circuit almost certainly does not run with conventional electronic design. If you were to reverse the diodes shown in the first circuit diagram in this section, then the circuit will remain solidly COP<1 although some people have managed an operational improvement of 32 times over just using the batteries straight to power the load. With the diodes as shown in the first two diagrams in this section, the circuit operates by drawing in energy from the environment and that operates in an entirely different way in a circuit.

It is interesting to note that in the 1989 patent US 4,829,225 granted to Yury Podrazhansky and Phillip Popp, their evidence is that batteries charge much better and have a longer life if they are pulsed in a specific way. Their formula is that the battery should be given a powerful charging pulse lasting for a period of time between a quarter of a second and two seconds, the pulse being the Amp-Hour rating of the battery. That is, for an 85 AHr battery, the charging pulse would be 85 amps. That pulse is then followed by a discharging pulse of the same, or even greater current but only maintained for only 0.2% to 5% of the duration of the charging pulse. Those two pulses are then followed by a resting period before the pulsing is repeated. They quote the following examples of their experiences when using this method:

Battery:	**9V alkaline**	**1.25V NiCad 0.5 AHr**	**15V NiCad 2 AHr**	**12V lead-acid 40 AHr**
Charging current:	0.5 Amps	1.2 Amps	3.0 Amps	48 Amps
Charging period:	550 mS	700 mS	500 mS	850 mS
Discharge current:	6 Amps	6 Amps	14 Amps	85 Amps
Discharge period:	2 to 3 mS	2 mS	2 mS	3 mS
Rest period:	15 to 20 mS	7 to 10 mS	10 mS	15 mS
Charging range:	50% to 100%	20% to 100%	20% to 100%	20% to 100%
Total charging time:	12 to 15 mins	20 mins	35 to 40 mins	40 mins

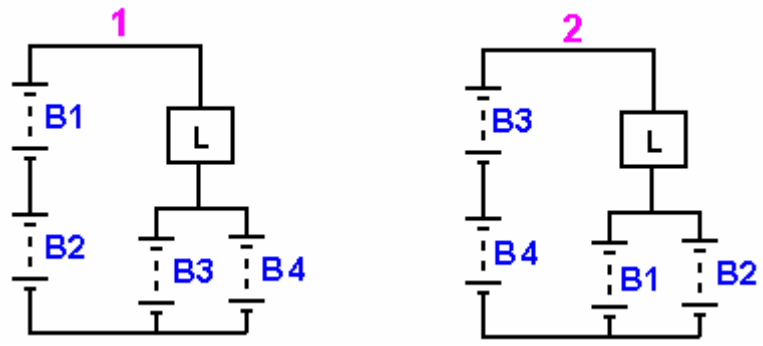
Interestingly, this appears to confirm the charging potential of the Tesla Switch style of operation, especially if there is a short rest period between the two sets of switch operations.

A Three Battery Switching System

Continuing the Tesla Switch style of operation, it is possible to get the same effect as the Tesla Switch circuit, using only three batteries (or three capacitors). Discussed almost a century ago by Carlos Benitez in his patents, and more recently described by John Bedini, just three batteries can be used if more complicated circuit switching is used. Carlos points out that there has to be an energy loss due to wires heating up and batteries not being 100% efficient. He overcomes these problems with some very clever circuitry which is covered in the following section. However, it is not at all certain that this is actually the case as experimentation indicates that it is possible for this kind of battery switching to maintain the battery charge levels far beyond the expected.

Here is an untested suggestion for how it might be possible to produce a portable, self-powered powerful light. There are many possible variations on this, and the following description is just intended as an indication of how a three battery switching system might be constructed. If you are not familiar with simple electronics, then I suggest that you study the basic electronics tutorial of chapter 12.

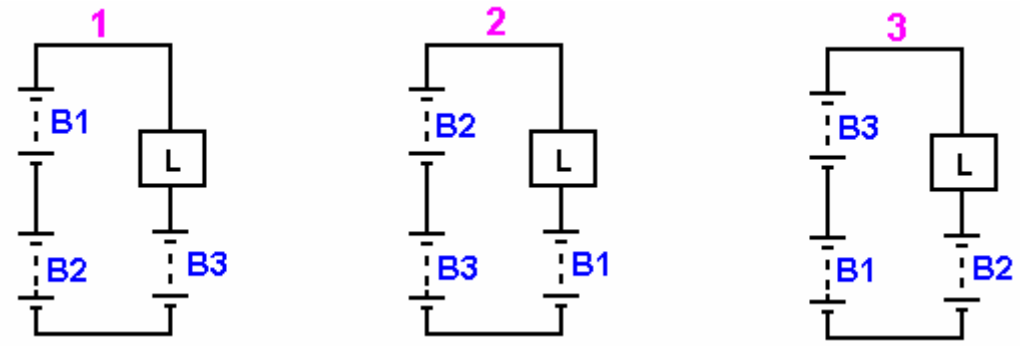
Battery charging can be accomplished in various different ways. Obviously, the more the electrical loading can be reduced, the lesser the need for recharging. Two methods for doing this involve passing the same electrical current repeatedly through the load, as shown here:



The switching for this arrangement can be implemented in various different ways, but essentially, in Stage 1, batteries ‘B1’ and ‘B2’ provide twice the voltage of batteries ‘B3 ‘ and ‘B4’, causing current to flow through the load ‘L’ and into batteries ‘B3’ and ‘B4’, driven by the voltage difference which is normally, the same as the voltage of any one of the batteries on its own. Each of the batteries ‘B3’ and ‘B4’ receive only half of the current supplied by batteries ‘B1’ and ‘B2’, and so, there is, not surprisingly, an energy loss. However, for half of the time, batteries ‘B3’ and ‘B4’ are receiving charging current instead of supplying current to the load.

In Stage 2, the batteries are swapped around and the process repeated with batteries ‘B3’ and ‘B4’ supplying current to the load and batteries ‘B1’ and ‘B2’. Tests have shown that with this arrangement, the load ‘L’ can be powered for longer than if all four batteries were connected in parallel and used to supply the load directly. With this system, each battery receives half of the load current for half of the time.

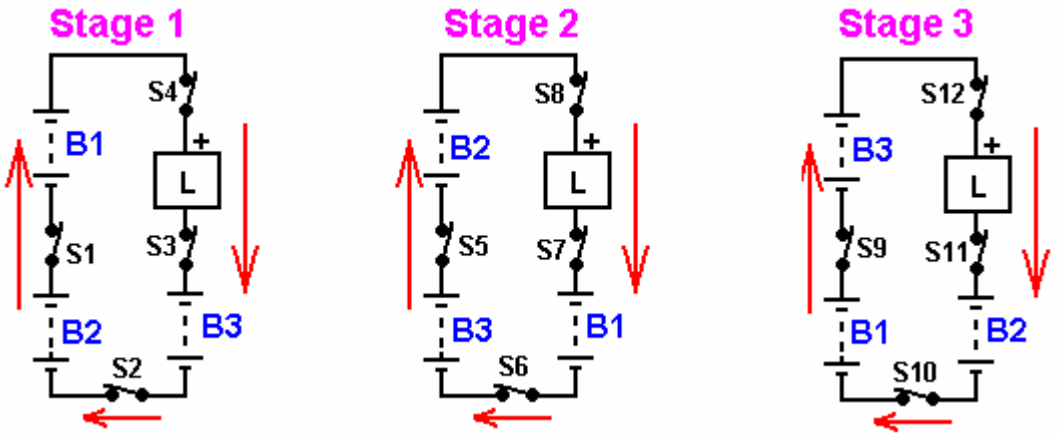
An alternative method which uses the same principle, but three batteries instead of four, and where each battery receives all of the load current for one third of the time, is like this:



Here, the batteries are switched around sequentially, with two of them in series causing current flow through the load ‘L’ and into the third battery. There is, of course, an overall energy loss, and so, additional energy from an external source needs to introduced to keep the load powered continuously. However, as with the four-battery system, the load ‘L’ can be kept powered longer by the batteries arranged like this than would occur if all three batteries were connected in parallel and used to power the load directly.

As before, the switching for a system of this kind can be implemented in various different ways. For long-term reliability, solid-state switching is preferred, and as NPN transistors are low-cost and readily available, they are shown here in one of the preferred configurations:

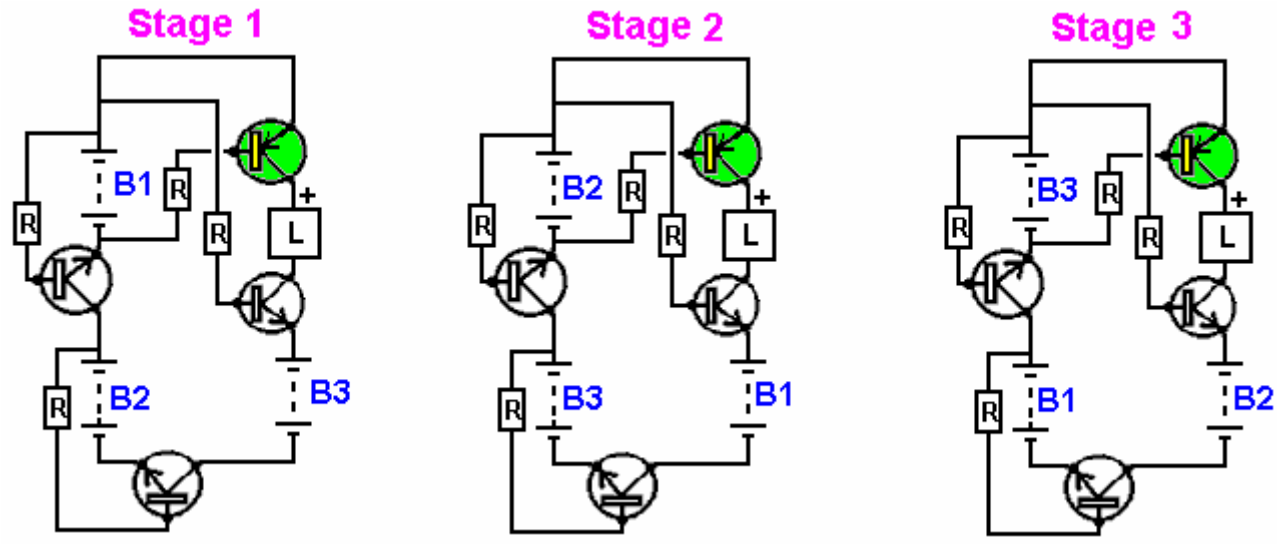
As each inter-battery connection is different for each of the three stages of operation of this circuit, it is necessary to have four switches for each stage. In order to establish the necessary details for connection of the transistors, as this circuit does not have the normal positive and negative rails, the (nominal) current flow directions need to be examined. These are shown here:



Obviously, the current flows from the higher series-connected voltage to the lower single battery voltage. The twelve virtual switches are numbered from 'S1' to 'S12' respectively, and if each represents an NPN transistor, then we also need to ensure that the current flow direction is correct for the transistor and to identify a higher voltage point which can be used to feed current into the base of each transistor. These details are listed here:

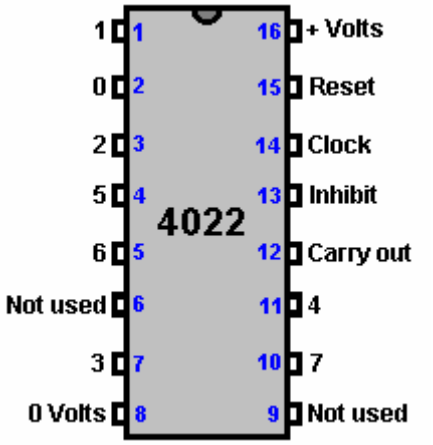
Stage	Switch	Type	Collector	Base resistor	Emitter
1	1	NPN	B2 Plus	B1 Plus	B1 Minus
	2	NPN	B3 Minus	B2 Plus	B2 Minus
	3	NPN	Load Minus	B1 Plus	B3 Plus
	4	PNP	Load Plus	B1 Minus	B1 Plus
2	5	NPN	B3 Plus	B2 Plus	B2 Minus
	6	NPN	B1Minus	B3 Plus	B3 Minus
	7	NPN	Load Minus	B2 Plus	B1 Plus
	8	PNP	Load Plus	B2 Minus	B2 Plus
3	9	NPN	B1 Plus	B3 Plus	B3 Minus
	10	NPN	B2Minus	B1 Plus	B1 Minus
	11	NPN	Load Minus	B3 Plus	B2 Plus
	12	PNP	Load Plus	B3 Minus	B3 Plus

The suggested switching arrangement therefore, looks like this:

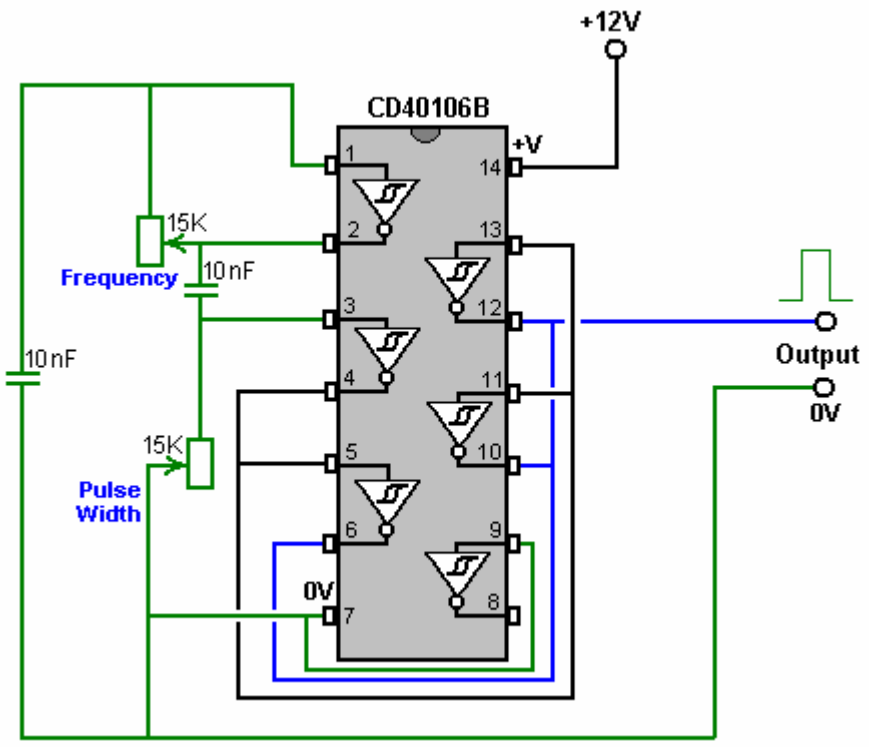


While the above diagram shows each stage with permanently connected base resistors, that is, of course, only to display the conceptual arrangement. Each resistor is passed through an opto-isolator and each set of four opto-isolators are driven by one of three separate outputs of equal duration. One possible arrangement for this could be as indicated below.

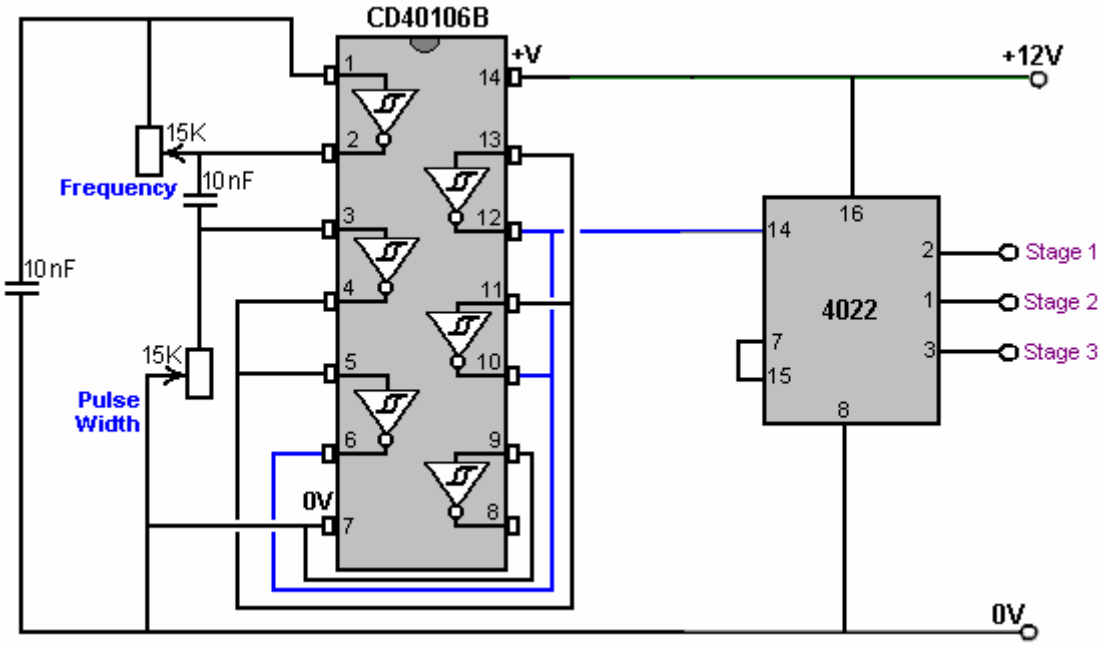
The CD4022 Divide-by-Eight chip can be arranged to divide by three rather than eight, by connecting its pin 7 to pin 15. The physical chip connections are:



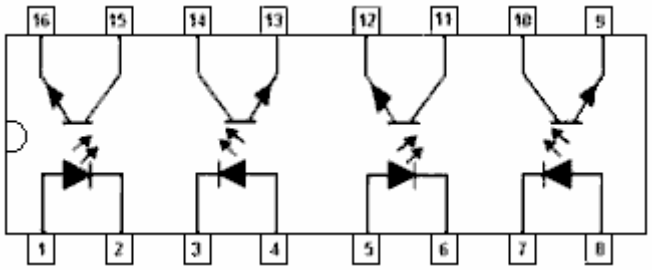
The chip needs a clock signal in order to function. There are many different ways of generating a clock signal, and the one shown here is very cheap, simple and has adjustable frequency and adjustable Mark/Space ratio, although, as the signal is to be used to trigger the action of a Divide-By-Three chip, there is no need for this clock signal to have a 50% Mark/Space ratio. The chip supply current is so tiny, that it really does not matter what the Mark/Space ratio is:



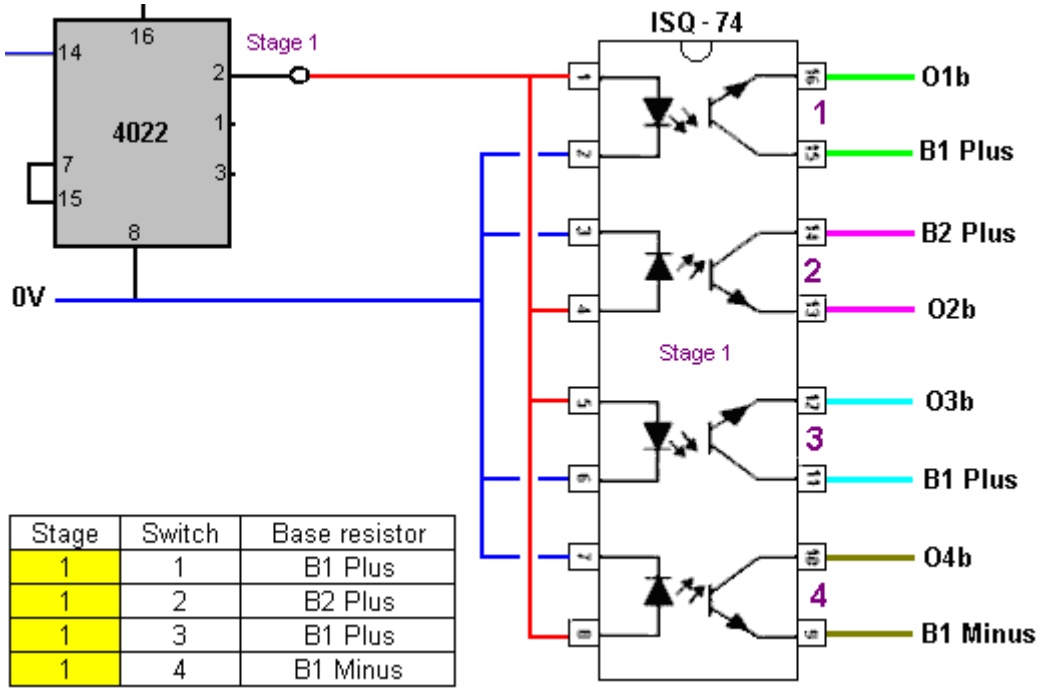
Using this circuit as the clock signal, the opto-isolator circuit could be:



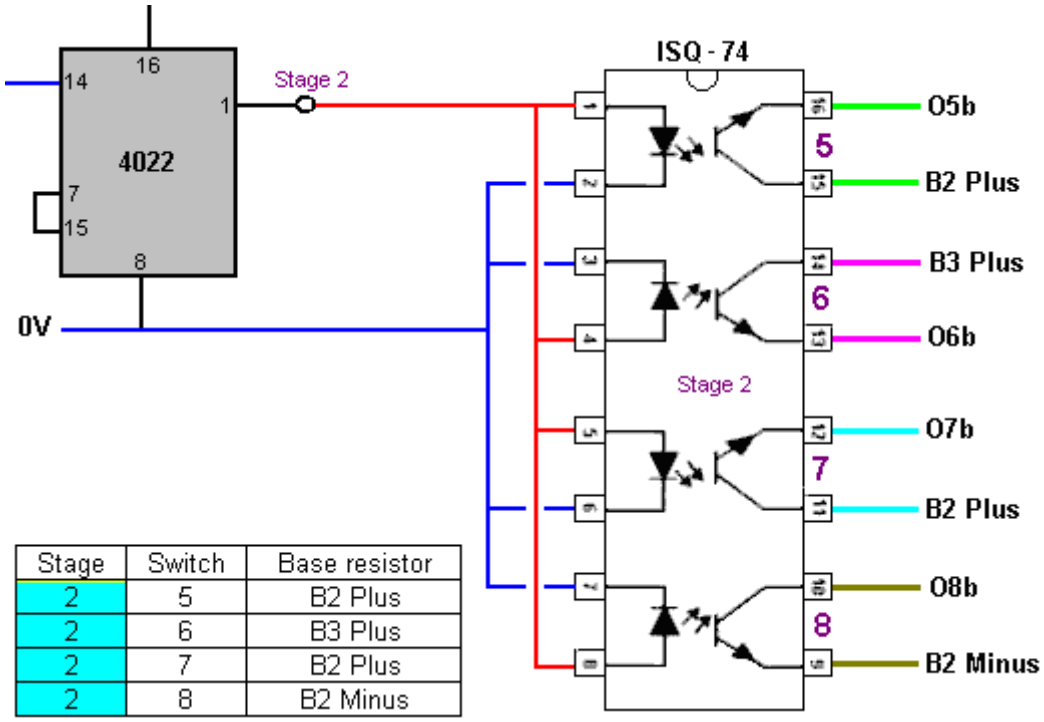
There are various opto-isolators available and while the rather expensive high-speed varieties are tempting, since we have to provide three sets of four, the ISQ-74 quad chip seems very suitable for this application although it is slower:



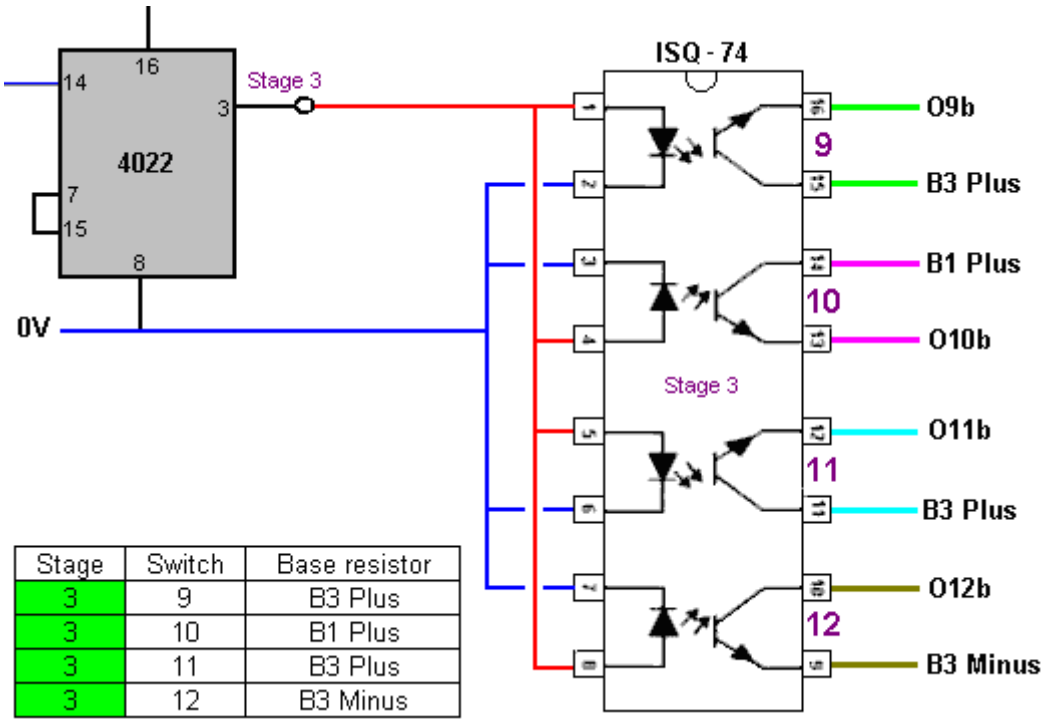
The overall circuit for the opto switching is then:



Stage	Switch	Base resistor
1	1	B1 Plus
1	2	B2 Plus
1	3	B1 Plus
1	4	B1 Minus



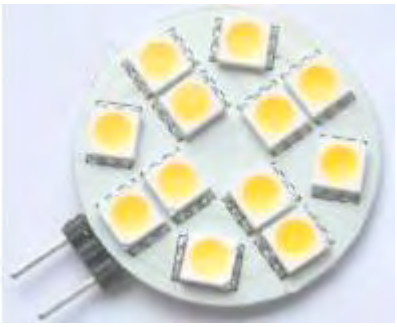
Stage	Switch	Base resistor
2	5	B2 Plus
2	6	B3 Plus
2	7	B2 Plus
2	8	B2 Minus



Stage	Switch	Base resistor
3	9	B3 Plus
3	10	B1 Plus
3	11	B3 Plus
3	12	B3 Minus

The output transistors are expected to switch 1 amp and so the TIP132 NPN and matching TIP137 transistors have been selected. These are cheap, Darlington transistors with current gains in excess of 1000 which means that the base current requirements are about 1 milliamp, which suggests that the base transistors could be 8.2K for a 12V system. These transistors can switch 12A at up to 100V and have a power dissipation of 70 watts, indicating that they will be running so far below their capability that they should run cool.

With this kind of circuit, it is desirable to have a fairly large current flow (relative to the battery capacity) in order to give a marked difference between the discharging and charging cycles for each battery. One possible load for this circuit could be the potentially low-cost G4 LED lighting unit shown here:



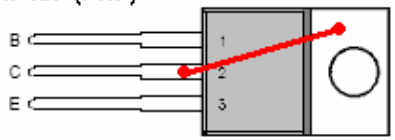
This quite remarkable device has a massive 160 lumens output with a lighting angle of 160 degrees and an input power of just 1.2 watts (100 milliamps at 12 volts). That light output is startling when seen in a completely dark place and some heat is generated, which is unusual for LEDs. A 100-watt filament light bulb has a light output of about 1600 lumens and a lighting angle of 360 degrees (some of which is normally not used usefully), and so, for the equivalent level of lighting, we would need ten of these G4 LED units, with a total power input of about 1 amp at 12 volts. Checking this in dark conditions, suggests that a much lesser lighting level would be more than acceptable. These LED lighting units are available in pure white and in “warm white” versions, and it is probable that the “warm white” version would suit most people better than the pure white versions.

Tests on one of the pure white units, shows a quite remarkable variation in the light output as the current is reduced, as the effect is highly non-linear:

At 12 volts the current is 1 amp. At 9.8 volts the current has dropped to a tiny 23 milliamps and while the light is nothing like as bright, there is still a considerable amount of light. At 9.42 volts, the light level is still significant and the current has dropped to a mere 10 milliamps. This suggests two main options: 10 LED units at 12 watts, providing a massive lighting level, or perhaps the same LED units run at 9.42 volts for just 1.2 watts of input power.

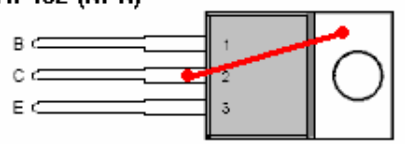
Using a 104 mm x 50 mm board size which will slot directly into a standard plastic slotted-side box, a stripboard layout (where the red circles indicate a break in the copper strip on the underside of the board) for the transistor switching section might be:

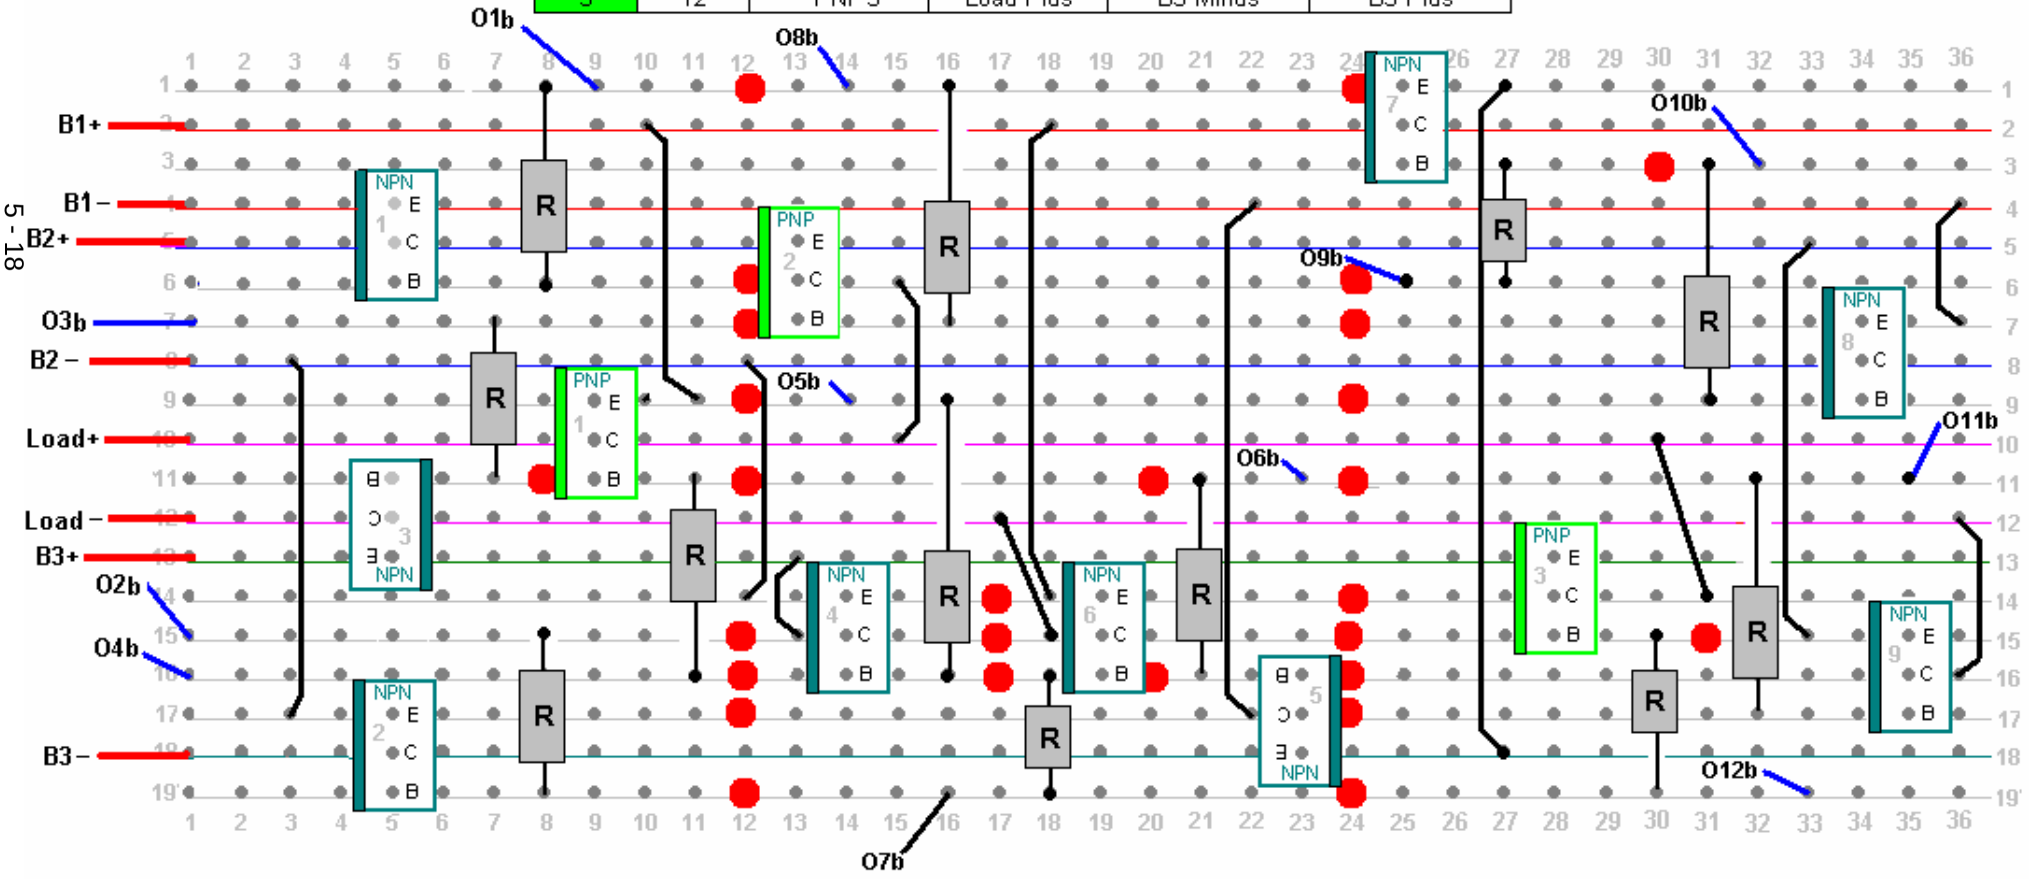
TIP137 (PNP)



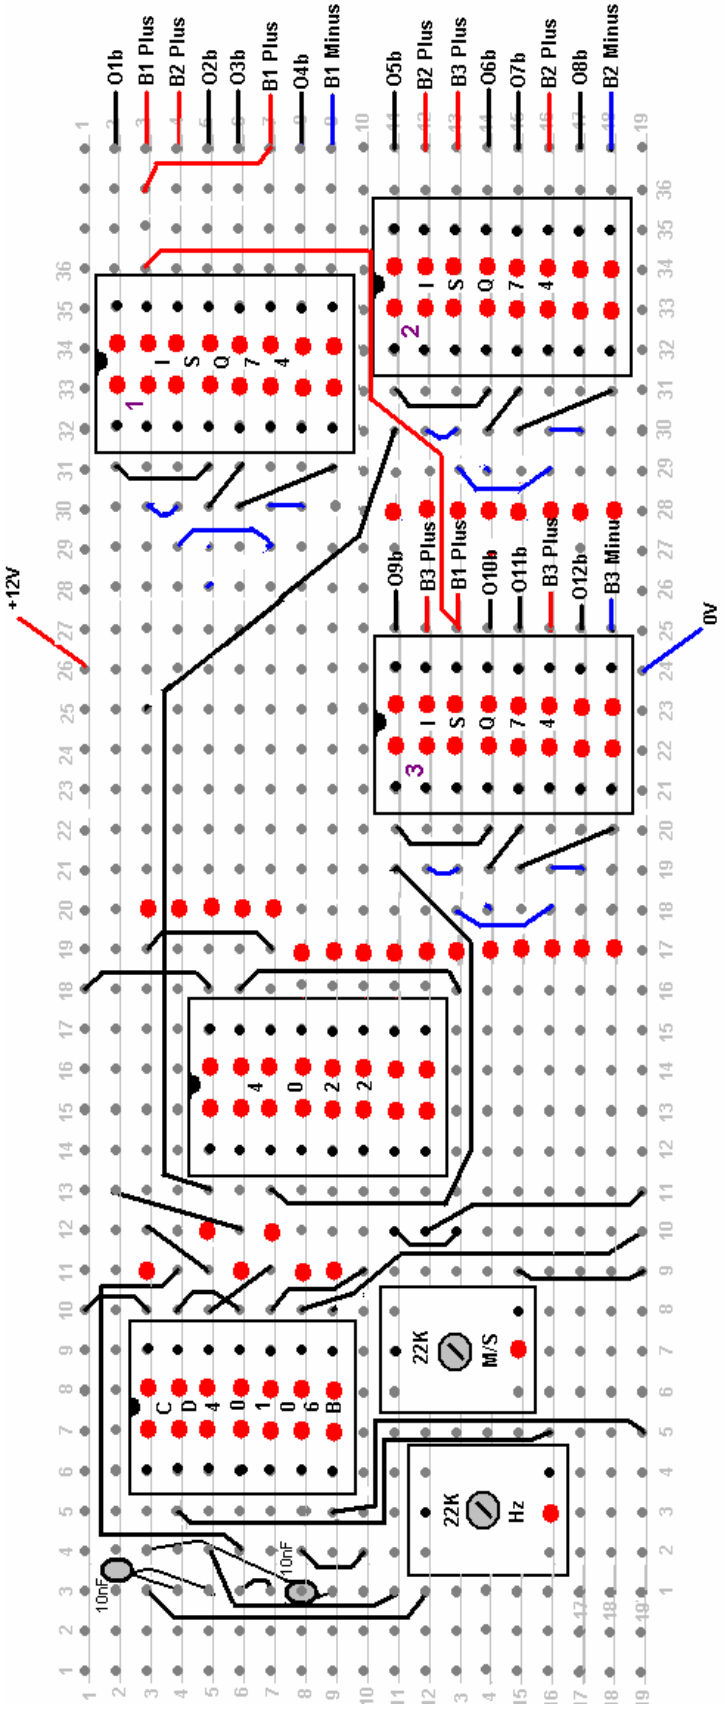
Stage	Switch	Type	Collector	Base resistor	Emitter
1	1	NPN 1	B2 Plus	B1 Plus	B1 Minus
1	2	NPN 2	B3 Minus	B2 Plus	B2 Minus
1	3	NPN 3	Load Minus	B1 Plus	B3 Plus
1	4	PNP1	Load Plus	B1 Minus	B1 Plus
2	5	NPN 4	B3 Plus	B2 Plus	B2 Minus
2	6	NPN 5	B1Minus	B3 Plus	B3 Minus
2	7	NPN 6	Load Minus	B2 Plus	B1 Plus
2	8	PNP2	Load Plus	B2 Minus	B2 Plus
3	9	NPN 7	B1 Plus	B3 Plus	B3 Minus
3	10	NPN 8	B2Minus	B1 Plus	B1 Minus
3	11	NPN 9	Load Minus	B3 Plus	B2 Plus
3	12	PNP3	Load Plus	B3 Minus	B3 Plus

TIP132 (NPN)





Each base resistor has an output link (O1b through O12b) which is connected through it's opto-isolator to the destination shown in the "Base" column in the table. Each set of three NPN transistors and one PNP transistor are switched together via a single ISQ-74 quad opto isolator chip. Each of the three ISQ-74 chips is powered in turn by one of the outputs from the CD4022 Divide-by-Three connected chip, which driven by the CD40106B hex Schmitt inverter chip wired as a clock as shown above. It is expected that a suitable clocking frequency would be about 700 Hz. A possible layout for the clock, Divide-by-Three and twelve opto-isolators on a 104 mm x 50 mm strip board, is shown here:



The timing and switching circuits form part of the load which is being switched. However, if we assume that there will be a power loss when running this system, then we should consider the very clever designs of Carlos Benitez in 1915.

The Self-powered Free-Energy Generators of Carlos Benitez

The Mexican Civil Engineer Carlos Benitez devised what is essentially the 3-battery switch discussed above. He was working at a time when solid-state electronics was not available and so his design is all the more impressive for that. Here is some of his patent information:

Carlos Benitez Patent GB 17,811 13th May 1915

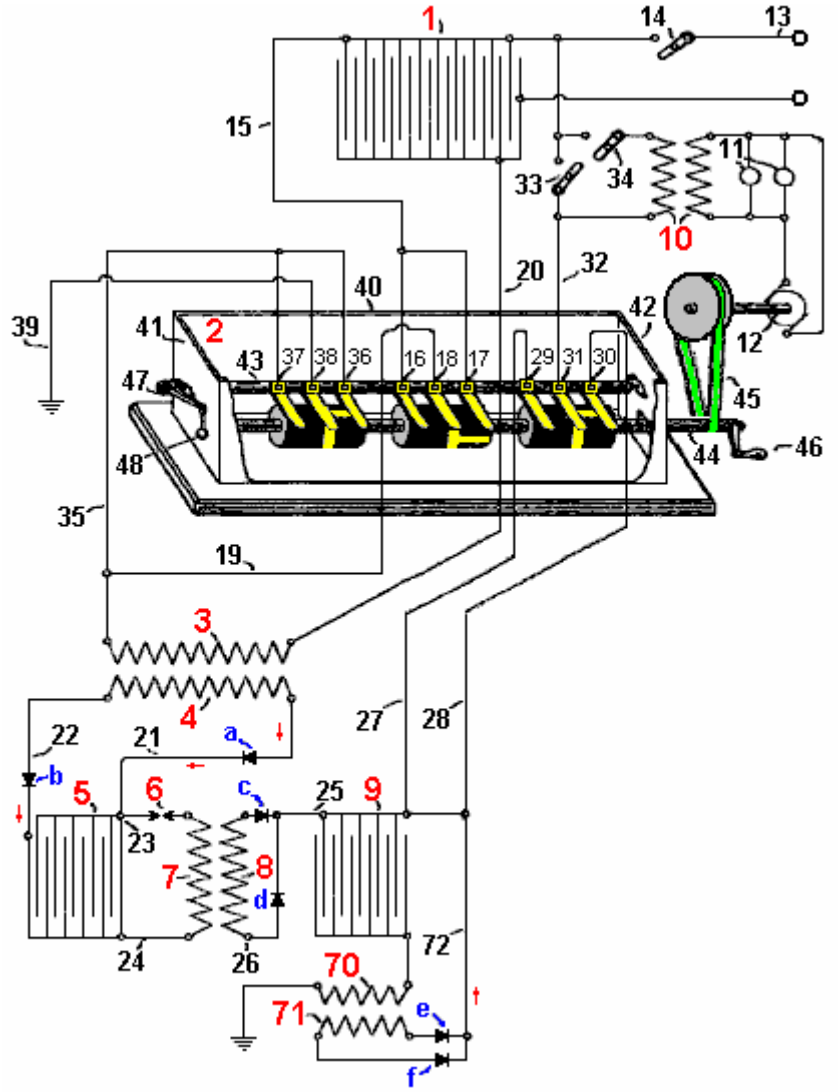
System for the Generation of Electric Currents

I, Carlos F. Benitez, Civil Engineer, 141 Ocampo Street, Guadalajara, Mexico, do hereby declare the nature of this invention:

The invention relates to a new process for obtaining electric currents under unusually simple, economic and practical conditions. I use synthetically in combination: apparatus for the production of electric currents for charging one or several capacitors whose collectors or inner coatings are connected to one of the terminals of the primary winding of one or several induction coils and the other coatings of those capacitors are alternately grounded through the primary winding of a transformer, or connected through the transformer primary to the above collectors, appropriate means for collecting the currents produced in the secondary windings of these transformers and for applying charging to the above collectors, and an appropriate means for discharging those collectors, and for the application of all or part of its energy to the successive replication of the process already described, in this way, increasing the generation of electrical energy, or maintaining a constant, pre-determined electrical output.

Furthermore, the invention consists of a new combination of parts from which are derived advantages which will be fully understood by the consideration of the two different cases illustrated in the accompanying drawing, in which:

1 is a bank of capacitors.
2 is a rotating commutator to make and break the circuit connections at the appropriate instants.
3 is the primary winding of a transformer or induction coil.
4 is the secondary winding of that transformer or induction coil.
5 is a second bank of capacitors.
6 is an oscillator spark gap.
7 is the primary winding of a second transformer.
8 is the secondary winding of that transformer.
9 is a third bank of capacitors.
70 is the primary winding of a third transformer
71 is the secondary winding of that transformer.
10 is a fourth transformer.
11 is a series of incandescent lamps.
12 is an electric motor.
(a), (b), (c), (d), (e) and **(f)** are mercury-vapour converters or cathodic valves, allowing electric current flow only in the direction shown by the arrows.



The capacitor bank **1**, is connected through wire **13** to a source of electric current, providing the initial charge to capacitor bank **1**. This initial charge is used to start the system running and can be disconnected at any time by means of switch **14**.

Wire **15** connects the inner leaves of capacitor bank **1** with poles **16** and **17** of the commutator **2**, and it's pole **18** is connected via wire **19** to one of the terminals of transformer primary winding **3**, whose other end is connected through wire **20** to the outer leaves of capacitor bank **1**. The secondary winding **4**, of this transformer, is connected by wire **21** to the inner plates of capacitor bank **5**, and by wire **22**, to the outer plates of capacitor bank **5**. In the same manner, wires **23** and **24** pass those connections on to the two sides of the primary winding **7** of the second transformer. Wire **23** also contains an oscillator spark gap **6**, and wires **21, 22, 25, 26** and **72** contain the one-way cathode valves **a, b, c, d, e** and **f**. The secondary winding **8**, of this second transformer, connects to the inner plates of capacitor bank **9**, whose outer plates are connected to ground through the primary winding **70** of the third transformer. The secondary winding **71**, of this third transformer is also connected through wire **72**, to the inner plates of capacitor bank **9**. Wires **27** and **28** also connect these inner plates to commutator poles **29** and **30**, which form a change-over switch through commutator contact **31** which is connected to the inner plates of capacitor bank **1** through wire **32**. Switches **33** and **34**, allow the connection or disconnection of the primary winding of transformer **10**, whose secondary winding supplies current to the incandescent lamps **11** and motor **12**. Finally, one of the ends of primary winding **3** is connected through wire **35** to both pole **36** and pole **37** of the commutator **2,** and their corresponding commutator contact **38** is connected to ground by wire **39**.

As the construction and use of all of these components (with the exception of the commutator) is perfectly understood, it would be pointless to describe them. The commutator **2**, is enclosed in a tank **40**, whose end walls **41** and **42** support the ends of the contact-mounting bar **43,** and the bearings of the rotating shaft **44**. The contact bar is made of a non-conducting material to which are immovably attached, the copper contact strip brushes **16**, **17** and **18**, **36**, **37** and **38**, and **29**, **30** and **31**. Secure contact between these brushes and the rotating cylinders mounted on shaft **44** is ensured by the rotating lever arm **47** and its associated weight **48**.

The three rotating cylinders mounted on shaft **44**, are made of a non-conducting material and have a conducting strip around their centre. This strip has two conducting spurs running outwards, one to the right and one to the left, positioned 180 degrees apart around the circumference of the cylinder. When shaft **44** is rotated, this causes the central contact (for example, **18**) to connect first to one of its associated contacts (say, **17**) and then disconnect and connect to the other contact (say, **16**) forming a change-over switching mechanism.

The switching strips on the central cylinder are positioned 90 degrees around the circumference when compared to the position of the switching strips on the two outer cylinders which are aligned with each other.

This can be seen in the diagram, where in the shaft position shown, **38** and **36** are connected and **31** and **30** are connected, while **18** is not connected to either **16** or **17**.

When shaft **44** is rotated through 90 degrees, **18** will be connected to **17**, while **31** and **38** will both be isolated.

When shaft **44** is rotated through an additional 90 degrees, brush **18** will be isolated while brush **38** will be connected to **37** and brush **31** will be connected to **29**.

When shaft **44** is rotated through an additional 90 degrees, brush **18** will be connected to brush **16**, while brushes **31** and **38** will be isolated.

[Note: if the diagram is correctly proportioned, there will be four positions in each rotation where the three central brushes are not connected to any of the outer brushes, producing the switching sequence Make, Break, Make, Break, Make, Break, Make, Break for each revolution. These breaks in the switching sequence have been shown to have a significant effect when batteries are being charged.]

Shaft **44** is elongated and projects through the end wall **42**, so that a belt drive **45**, or other suitable method, may be used to rotate the shaft, driven by motor **12** or possibly by crank handle **46**. The tank **40**, is filled with oil or any other insulating liquid, in order to prevent sparking between the brushes, which would lower the efficiency of the system.

This system is operated as follows:

With the commutator in the position shown in the drawing, that is, with brush **36** connected to **38** and brush **30** connected to **31**, and supposing capacitor bank **1** is connected through wire **13** to a source of electric power (say, a Wimshurst Machine), switch **14** being closed, electric current passes through wire **13** to charge capacitor bank **1**, causing a current to flow through wire **20**, primary winding **3**, wire **35**, brush **36**, brush **38** and wire **39** to earth. This current flow through primary winding **3** induces an inverse current in secondary winding **4**, which flows through wire **21**, charging capacitor bank **5** and then a direct induced current flowing through conductor **22**, charging capacitor bank **5**.

The current flow to both sets of plates in capacitor bank **5**, charges it and creates a spark across the spark gap **6**, causing a very sharp current pulse through primary winding **7**. This in turn, causes a considerable number of high-frequency oscillating current flows in the secondary winding **8** and these pass along wires **25** and **26**, and via diodes **c** and **d**, thus charging capacitor bank **9** and causing a corresponding set of high-frequency pulses to flow to ground through the primary winding **70**. This induces current flow in the secondary winding **71**, which flows through diodes **e** and **f**, and onwards via wire **72**, further boosting the charge on capacitor bank **9**.

Therefore, capacitor bank **1** being charged by an external source, capacitor bank **9** will be charged indirectly and successively re-charged several times, resulting in a quantity of electricity considerably greater than that of capacitor bank **1**. By this means, the system can be self-powered with no need for the power source used to start it, which means that switch **14** can be opened.

When shaft **44** rotates through 90 degrees, brush **17** connects with brush **18**, while brushes **31** and **38** are both disconnected. This causes capacitor bank **1** to be completely discharged through transformer primary **3**, causing the already described process by which capacitor bank **9** receives a substantially larger electrical charge. This results in capacitor bank **1** being totally discharged and capacitor bank **9** being highly charged with a great deal of electricity. Consequently, if we now close switch **33** and rotate shaft **44** through another 90 degrees, the following situation results:

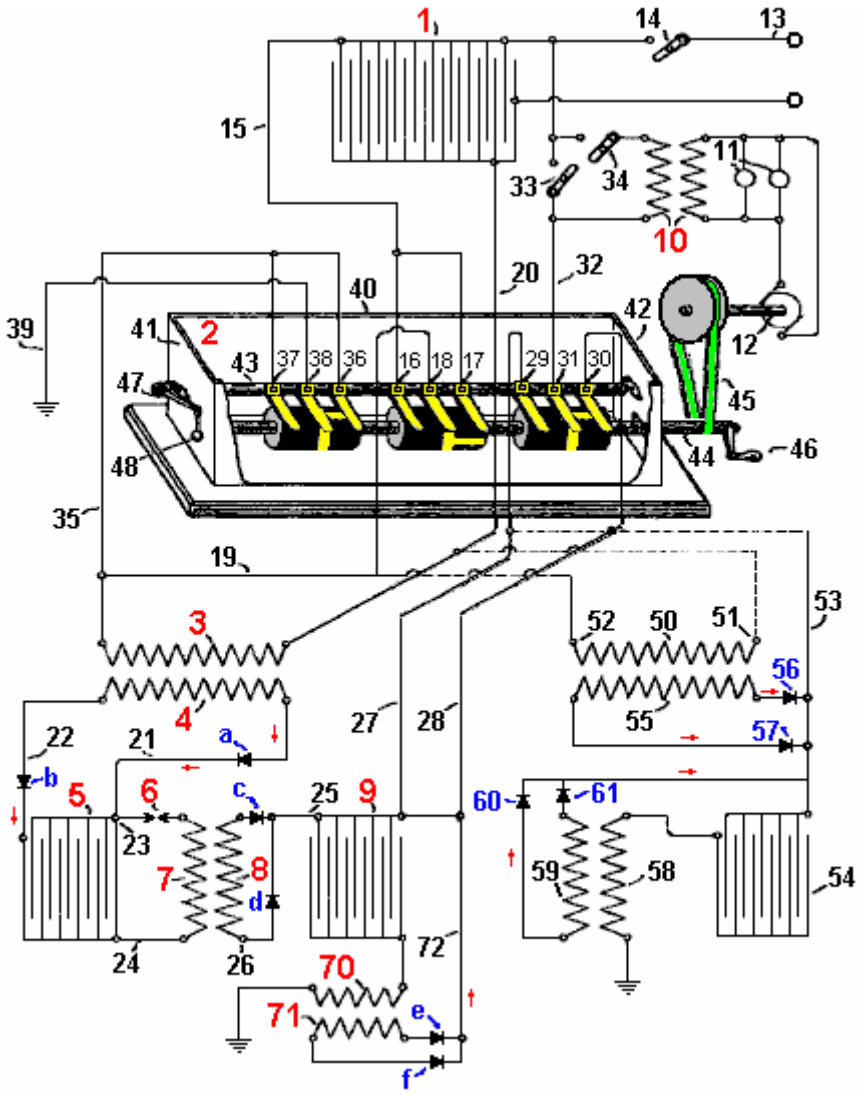
1. Brushes **17** and **18** will be disconnected.
2. Brushes **37** and **38** become connected which in turn connects the outer plates of capacitor bank **1** to ground. Brushes **29** and **31** are connected, which then connects the inner plates of capacitor bank **9** to the inner plates of capacitor bank **1**.

3. Part of the high charge on capacitor bank **9** will flow as an electric current, through wire **32** and into capacitor bank **1**.
4. This current flow from the inner plates of capacitor bank **9** causes an immediate matching negative charge to flow from ground through primary winding **70**, to offset the charge imbalance.
5. This induces a current flow in the secondary winding **71**, which passes additional electrical power to the outer plates of both capacitor bank **9** and capacitor bank **1**, and that further intensifies the current flow through primary winding **70** quite considerably.
6. Further, as capacitor bank **1** has just been newly charged, it drives additional current through primary winding **3**, causing new induced currents which will, as before, produce much increased charge on the inner plates of both capacitor bank **5** and capacitor bank **9**, as described earlier.

If shaft **44** is rotated through a further 90 degrees, then a connection between brushes **16** and **18** will be made and all other circuits will be opened, causing capacitor bank **1** to be discharged again, thus repeating the entire process described above provided that shaft **44** is rotated continuously.

This system produces a constantly increasing supply of electric current flowing through wire **32**, and so, switch **34** can be closed, allowing transformer **10** to provide the electrical power to run motor **12** which maintains shaft **44** in continuous rotation, making the system self-powered with no requirement for any form of outside power supply. Additional transformers inserted in wire **32** can be used to power additional equipment.

Without employing the high-frequency currents described above, similar results may be attained by means of the arrangement shown at the lower right hand side of the following drawing:



Here, primary winding **50** is connected as shown by the dashed lines, with wires **19** and **20** of the former arrangement, and wire **53** connects to both wire **27** and wire **28**. This arrangement has primary winding **50** connected through its end **51** to wire **20** and so is permanently connected to the outer plates of capacitor bank **1**, and its other end **52** being connected to wire **35** will be intermittently connected to ground. Wire **53** being

connected to wires **27** and **28** will intermittently connect together, the inner plates of capacitor bank **54** and the inner plates of capacitor bank **1**.

With this arrangement, both ends of the secondary winding **55** are connected through diodes **56** and **57**, to wire **53**. The outer plates of capacitor bank **54** are permanently connected through primary winding **58** to ground. Both ends of the secondary **59** are connected through diodes **60** and **61**, back to wire **53**. As a result, if capacitor bank **1** is charged, it drives a current through wire **20** and so, through primary winding **50**, and on to ground through wires **35** and **39**. This induces current in secondary winding **55** which gets stored in the inner plates of both capacitor bank **54** and capacitor bank **1**, as in this moment, the circuit is closed between brushes **29** and **31**, and so, wire **53** is connected to wire **32**. On receiving these new charges, both capacitor bank **1** and capacitor bank **54** will create new induced electric currents flowing through primary windings **50** and **58**. These multiple charging pulses will decrease with time until they are insignificant, at which time, due to the rotation of shaft **44**, the connection between brushes **29** and **31** and between brushes **36** and **38** will no longer be maintained, and instead, brushes **18** and **17** will become connected, discharging capacitor bank **1** through primary coil end **50** which is a very strong discharge, charging capacitor bank **54** as wire **53** is now disconnected from wire **32**. This, in turn, causes powerful current flow through primary winding **58**, further charging capacitor bank **54** which then feeds capacitor bank **1** when shaft **44** rotates further, making the system both self-powered and capable of supplying useful electrical power to other equipment.

It should be clearly understood that the use of mercury-vapour converters or cathodic valve diodes as described, are not in any manner indispensable in the system as those devices can be replaced by a suitable arrangement of capacitors which would receive separately, the direct and inverse currents of the secondaries.

When a bell is struck just once, it vibrates many times, passing those vibrations to the air and so, making the sound which we hear. The bigger the bell, the slower the vibrations and the lower the pitch of the note which we hear. The same thing happens when a sharp voltage pulse is applied to a coil of wire as just one pulse causes many vibrations in the coil. Like the bell, the frequency of the vibrations depends on the structure of the coil and not on how it is pulsed, although, like a bell, a sharp pulse for a coil or a sharp blow for a bell, produces a greater effect.

You will notice here that Carlos uses the resonant ‘ringing’ of an air-core coil to get an energy gain which is then used as positive feedback to further charge a capacitor bank. A single sharp pulse generated by one spark, causes a large number of coil oscillations, each of which contributes output power, producing an energy gain. The ringing frequency is liable to be around 3 MHz. It is also worth noting that with this design, electricity generation can be achieved without any battery and just the manual turning of a Wimshurst electrostatic generator and the initial operation of the commutator shaft **44**.

Carlos also produced another design, this time working with batteries (although he tended to think in terms of 60-volt battery banks rather than 12-volt batteries) and his patent includes what we tend to call the Tesla Switch nowadays. Perhaps we should call it the Benitez Switch. However, instead of switching it rapidly, Carlos uses a switching time interval of one hour. The lower voltage overcomes the need for the switching contacts to be submerged in oil.

Carlos Benitez Patent GB 14,311 17th August 1916

System for the Generation of Electric Currents

I, Carlos F. Benitez, Civil Engineer, 141 Ocampo Street, Guadalajara, Mexico, do hereby declare the nature of this invention:

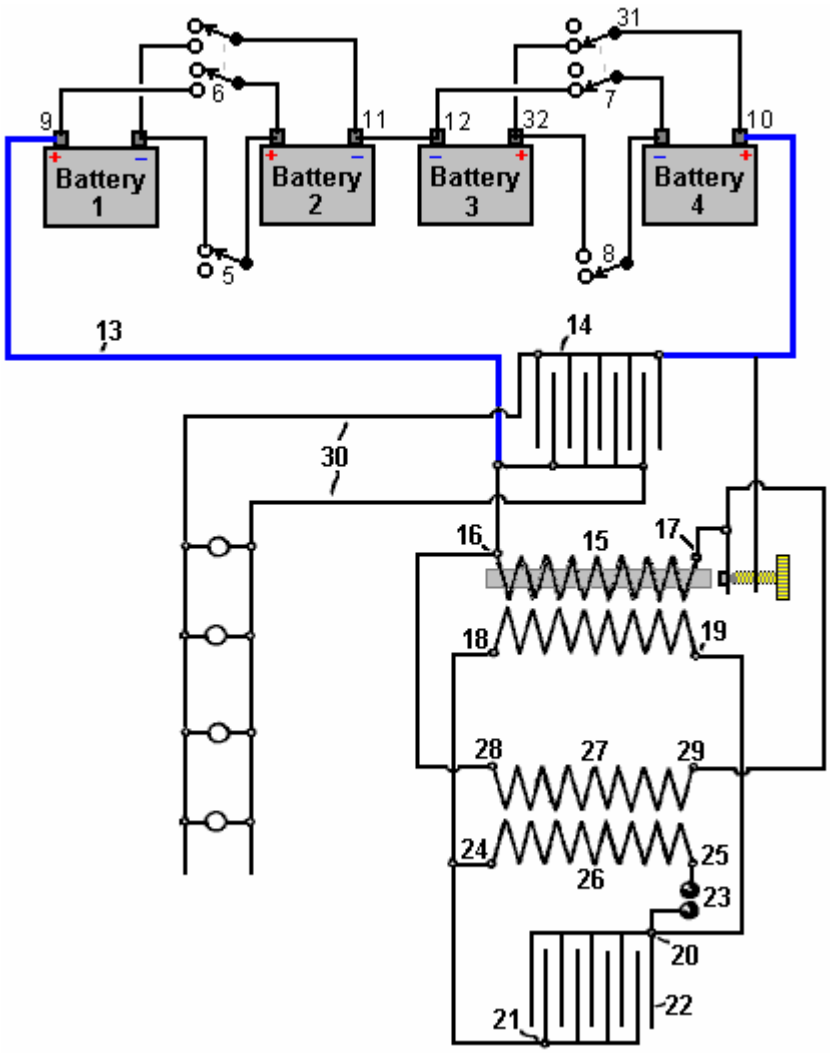
The invention which forms the object of this Patent of Addition, relates to new improvements in the system for the generation of electric currents, described in the main patent No. 17,811 and in the patent of addition No. 5591, filed 14th April 1915.

The system may be still further simplified and improved by the addition of batteries, which, suitably adjusted in conjunction with system previously described, can be charged and discharged alternately, producing an excess of electrical energy which can be used in any desired manner.

In other words, in this arrangement, I use in combination: two batteries connected in series and two batteries connected in parallel, these pairs being used so that the discharge of one pair is used to charge the other pair, and *vice versa*.

Another object of this new arrangement is to allow the use of low voltages, small capacity capacitors and additional facilities for starting the system.

The advantages of such an improvement will be better understood by considering the following drawing which illustrates one method of carrying out the invention:



In the diagram, **1, 2, 3** and **4** are batteries which, when charged from some external source, will maintain their charges indefinitely, in the following manner:

With the connections established as shown in the diagram, that is, with batteries **1 & 2** connected in series through switch **5** (switch **6** being open), batteries **3 & 4** are connected in parallel through switch **7** (switch **8** being open). Under these conditions, assuming that the four batteries are similar, having similar voltages, batteries **1** and **2** being in series will have a combined voltage greater than batteries **3** and **4** which are connected in parallel, and so, a load connected between them will have a current flowing from batteries **1 & 2** and into batteries **3 & 4**.

In other words, if wire **13** is connected to the positive terminal of the battery **1 & 2** combination, and to the positive poles **10 & 32** of the battery **3 & 4** combination, then an electric current will be established between the two sets of batteries, until their voltages match. Of course, the current provided by batteries **1 & 2** would produce a smaller charge in the batteries **3 & 4**, but that current can be increased by any of the methods described in my earlier patents (No. 17,811/14), and by these means it is always possible to alternately charge and discharge the battery pairs from each other, keeping a constant, pre-determined charge, and furthermore, producing an excess of electrical energy which can be used for any chosen purpose.

With these objectives in view, and using as an illustration, the arrangement shown in Figure 1 of the Patent of Addition No. 5591/15, wire **13** connects to capacitor **14**. The primary winding **15** of an ordinary induction coil provided with an interrupter, is connected by its ends **16** and **17**, to wire **13**. The ends **18** and **19** of the secondary winding of that induction coil **15** are connected to connections **20** and **21** of capacitor (or bank of capacitors) **22**. Connections **20** and **21** are also connected through spark gap **23**, to ends **24** and **25** of the primary winding **26** of a high-frequency transformer. The ends **28** and **29** of the secondary winding **27** of that transformer are connected

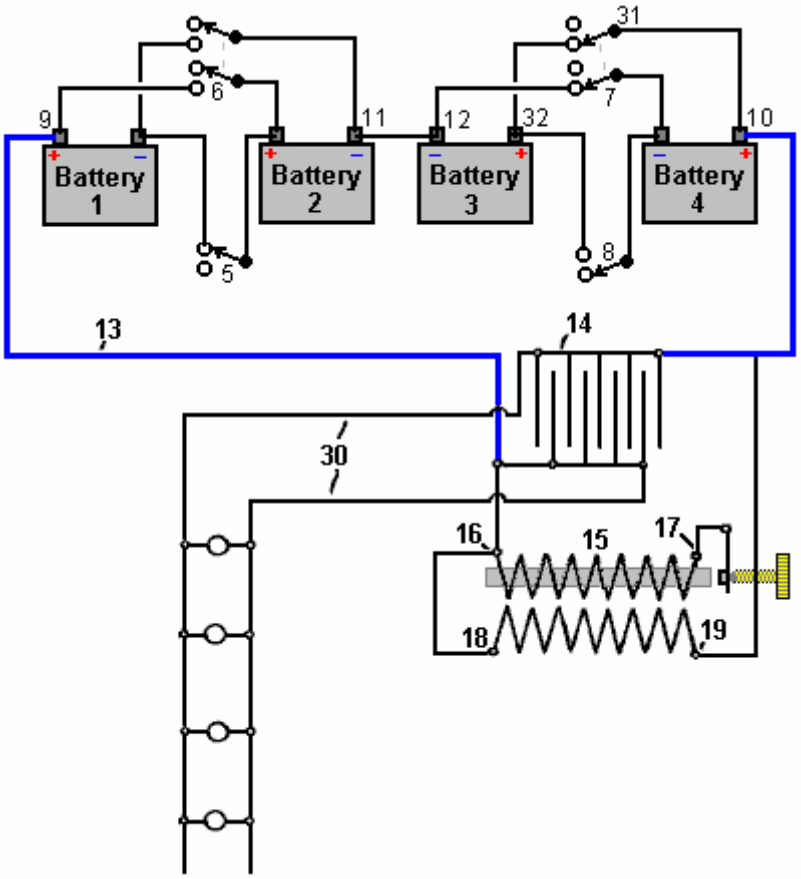
to ends **16** and **17** of the induction coil **15**. Finally, wires **30** are connected across capacitor **14** and they are used to power external loads such as the incandescent lamps shown in the diagram.

This arrangement being made, the electrical energy stored by batteries **1 & 2**, passing through terminal **9**, wire **13**, primary winding **15**, terminal **10** of battery **4**, pole **31** of switch **7** and terminal **32** of battery **3**, will go back through terminal **12** of battery **3** to the battery **1** and **2** combination.

As a consequence of the current passing through primary winding **15**, high-voltage current is produced in its secondary winding and collected in capacitor **22**, discharging through spark gap **23**, generates high-frequency currents in the high-frequency transformer primary and secondary coils **26** and **27**. As coil ends **28** and **29** are connected to coil ends **16** and **17**, this greatly augments the current flow provided by batteries **1 & 2** and so the storage batteries **3** and **4** now receive adequate charging current to keep them fully charged as well as driving additional loads via wires **30**.

Under these conditions, as the voltage in one of the batteries is decreasing while the other is increasing, after some hours, both voltages match and it is then impossible to produce any current flow unless switches **5, 6, 7** and **8** are operated, reversing the functions of the batteries and allowing the process to continue entirely as before with batteries **1 & 2** being connected in parallel and batteries **3 & 4** being connected in series.

When the resistance of the primary winding of transformer **15** is not high, it is possible to simplify the above circuit by obtaining the high-frequency currents directly from induction coil **15**, in which case, ends **18** and **19** of the secondary winding are connected directly to ends **16** and **17** of the same coil and the second bank of capacitors **22** and the high-frequency transformer **26/27** can be omitted. Under these conditions, the breaker or interrupter which is part of the induction coil construction, acts as a spark gap, and capacitor **14** discharges in the form of oscillations through the primary winding **15** of the same coil, thus directly increasing the amount of electrical energy furnished by the accumulators.



An essential part of this design which is not indicated clearly in the patent, is that what was common practice a hundred years ago, namely, that the input power connection to point **17** of the primary of the (step-up) transformer **15**, is fed through an “interrupter” contact. This connection opens when the coil **16-to-17** is energised, causing the insulated iron wire bundle core of the coil to become magnetised, and attract the pivoted arm of the interrupter, which breaks the current to the coil very sharply, causing high frequency resonant oscillations in both windings of the transformer **15**, which generates the excess power which runs the system and its additional loads. In Benitez’s day, door bells used this style of interrupter to produce a hammering action on a metal bell. These were very cheap, very simple and very reliable.

As I understand it then, the voltage difference between the two pairs of batteries, charge capacitor **14** and apply power to the primary winding **16-17** of step-up transformer **15**. This causes a current to flow in this winding, making the core attract the pivot arm of the interrupter in the same way that a relay operates. This breaks the current flow very sharply, causing a powerful back-EMF pulse in the primary winding. The primary winding has a resonant frequency, very considerably lowered by the presence of the iron core which itself is a low-frequency material, and the coil oscillates at its resonant frequency, not for just one cycle but for many cycles. Each of those cycles generates a high voltage in the secondary winding **18-19** and every one of those cycles contributes high-voltage power to the system. That power is fed to three outlets. Firstly, it flows back to provide charging power to one of the battery pairs. Secondly, it adds additional power to the capacitor driving its own primary winding. Thirdly, it provides power for the load which is shown as a series of lamps connected in parallel.

That is just for the first interrupter pulse. The broken current through the primary winding **16-17** causes its core to cease to be an electromagnet and so it ceases to attract the pivot arm of the interrupter and while that seems very quick in human terms, it is very slow compared to the multiple oscillations ringing in the winding. When the pivot arm returns to its starting position, it establishes the current flow through the primary winding once again. However, the charge on the capacitor powering the primary winding has been boosted by those resonant oscillations in the secondary winding and so is more highly charged than when the interrupter contact opened previously. This process continues repeatedly, providing battery charge and power to the load.

According to Carlos, there is a slight overall drain on the battery system and so, after about an hour, the switches are operated, changing the series-connected batteries to become parallel-connected and the parallel-connected batteries to become series-connected. This timing seems odd as switching the batteries over much more frequently only requires batteries with a much lower capacity.

As we are not familiar with induction coils and interrupters now that solid-state electronics is available, we can get constructional and operational information from that period in the book “Wireless Telegraph Construction for Amateurs” by Alfred Powell Morgan, published in 1913, which is available as a free download from here: http://www.free-energy-info.tuks.nl/Morgan.pdf.

For example, the interrupter details include:
“Some means of charging the capacitor is necessary. An induction coil is the most practical for the amateur. The induction coil consists of a primary coil of wire wound around a central iron core and surrounded by a secondary coil consisting of many thousands of turns of carefully insulated wire. The primary coil is connected to a source of direct current which also includes an interrupter to “make” and “break” the current in rapid succession. Every “make” of the circuit and consequent magnetisation of the core, induces a momentary inverse current in the secondary winding, and every “break” and corresponding demagnetisation induces a momentary direct current. Normally, the induced currents would be equal, but by means of a capacitor connected across the interrupter, the circuit when “made” requires considerable time for the current and magnetisation of the core to reach a maximum value, while when broken, the demagnetisation and current drop are nearly instantaneous. The value of the induced electromotive force in a circuit, varies with the speed at which the magnetic lines of force cut the circuit, and so, the induced e.m.f. at “break” becomes high enough to leap across a spark gap.

The formulas connected with induction coils depend on conditions which are never met in actual practice and cannot be relied on. To construct a coil of a given size, it is necessary to use dimensions obtained empirically. Therefore, the amateur should stick closely to the lines or hints given here, or which appear in some *up to date* book on induction coil building.

For a long time, the induction coil was an expensive, inefficient instrument, until wireless telegraphy demanded of it more rigid and efficient design and construction. It was the aim of manufacturers to produce the longest possible spark length with a minimum amount of secondary wire. As a result of this demand, wireless coils are now made with a core of larger diameter and give heavier and thicker sparks. The secondary in this case, is short and uses wire of large cross-sectional area in order to reduce the resistance and minimise the heating.

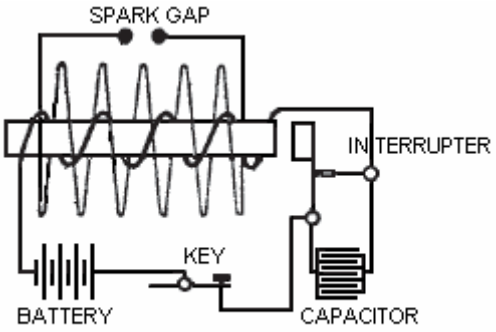


Diagram of an Induction Coil.

No one part of an induction coil may be developed to its maximum efficiency without seriously influencing and lowering the efficiency of the other parts. The following suggestions regarding the construction are given so that they may prove to be a useful guide for the amateur coil builder. The parts will be considered in their natural order of construction.

Core: Some experimenters who are not quite familiar with the principles of magnetism, think that if an induction coil were provided with a closed core like that of a transformer, then the efficiency of the coil would be materially increased. But that is not the case because then the magnetisation and demagnetisation of the iron cannot take place rapidly enough in a closed core when an interrupted direct current is used instead of an alternating current.

The core of an induction coil is therefore always straight. For the same reason, it is never solid but instead is always made up of a bundle of soft iron wires in order that rapid changes in magnetism may take place. The wires are always of as high a permeability (magnetic conductance) as possible so as to create a strong magnetic field. Swedish or Russian iron of good quality is the best as its hysteresis losses are small. The smaller the diameter of the wire, the less will be the eddy current losses and consequent heating, but the permeability is also reduced and the core will not be so effective, as the amount of iron is thereby decreased and the oxidised surface increased. No. 22 gauge wire is the best size for the average core.

Wires of a good quality may be purchased already cut to various lengths. To buy them in this form will save a great deal of the labour required when building a core. If the wires are not quite straight, they may be straightened by rolling them, one at a time, between two boards. It is best to re-anneal the wires. To do this, place the wires in an iron pipe and plug the ends of the pipe with clay. Then lay it in a coal fire until the whole mass reaches a red heat. The fire is then allowed to die out gradually, with the pipe and wires remaining in the ashes until cool. When cool, remove them from the pipe and rub each one with emery paper until bright. After this cleaning, the wires are dipped in hot water and then dried. They are then dipped in a good quality varnish and allowed to dry again.

The varnish provides a resistance to the flow of eddy currents in the core and reduces those losses very considerably. A strong paper tube having an internal diameter equal to the diameter of the finished core is made by rolling the paper on a form and cementing it with shellac. When it is perfectly dry, the tube is removed and the wires packed tightly inside it. The following table gives the core dimensions for practical coils of different sizes:

CORE DIMENSIONS

Spark Length	Core Diameter	Core Length
0.5 inch (12 mm)	0.5 inch (12 mm)	6 inches (150 mm)
1 inch (25 mm)	1 inch (25 mm)	8 inches (200 mm)
2 inches (50 mm)	1.25 inches (31 mm)	10.5 inches (262 mm)
4 inches (100 mm)	1.375 inches (34 mm)	12 inches (300 mm)
6 inches (150 mm)	1.5 inches (38 mm)	14 inches (350 mm)

Primary Winding: The ratio of the number of primary turns of an induction coil to the number of secondary turns, bears no relation to the ratio of the primary and secondary currents. It has been found in practice, that two layers of wire wound tightly on the core, form the best primary. The primary should always be thoroughly covered with shellac or other insulating varnish. Since there is almost no ventilation in the primary, the wire must be large enough to avoid all heating. A table containing the various sizes of primary wires is given here:

PRIMARY WINDINGS

Spark Length	Wire Gauge	Number of Layers
0.5 inch (12 mm)	18 (1.219 mm)	2
1 inch (25 mm)	16 (1.63 mm)	2
2 inches (50 mm)	14 (2.03 mm)	2
4 inches (100 mm)	12 (2.64 mm)	2
6 inches (150 mm)	12 (2.64 mm)	2

In large coils, the inductance of the primary causes a “kick-back” and sparks are liable to pass between the adjacent turns. For this reason, it is always a good idea to use double cotton covered wire and to further thoroughly insulate it by soaking the primary and core in a pan of melted paraffin wax and allowing the wax to harden with them inside it. Afterwards, the pan is slightly warmed to loosen the cake of paraffin and the excess wax removed by scraping with a blunt instrument so as to avoid damaging the wires. Paraffin wax contracts when it hardens and the proper method for impregnating a porous substance is to allow it to soak and become set in it upon cooling.

A good method of reducing the “kick back” as well as the size of the capacitor connected across the interrupter, is to make the primary with a number of turns of smaller diameter wire wound in parallel, the effect being to produce a conductivity equal to a wire of large diameter and at the same time, make a more compact winding of the primary on the core. This method of winding is very desirable in large coils, as it reduces the cross-section of the primary and allows the secondary to be placed nearer to the core where the magnetic field is the strongest.

The primary winding should cover nearly the whole length of the core, since there is no advantage in carrying the core very far beyond the end of the primary as most of the magnetic lines of force bend at the end of the primary winding and return without passing through the extreme ends of the core.

Insulating Tube: The successful operation of an induction coil without breaking down when heavily stressed, depends largely on the insulating tube which separates the primary and the secondary windings. Hard rubber tubes are perhaps the best. A tube may easily be built up of several layers of half inch sheet hard rubber by steaming it so as to soften it, and then wrapping it around a former. The tube should fit tightly on the primary and be about one inch (25 mm) shorter than the core. After the tube is in place, it is poured full of beeswax and rosin in order to fill all interstices and prevent sparks due to the capacitor effect of the windings from jumping from the inside of the tube to the primary.

Secondary: A coil used as a radio telegraph transmitter must have wire of a large cross-sectional area in its secondary, so as to produce a heavy disruptive discharge. Number 34 and number 32 gauges are generally used for small coils and number 30 and number 28 gauge for large coils. Silk covered wire is the usual practice, but enamelled wire is coming into use. Cotton covered wire takes up too much space and has poor insulating qualities.

Enamelled wire is insulated with a coating of cellulose acetate, which has a dielectric strength of about twice that of cotton and it takes up much less room than silk covered wire, giving a great saving in space and a greater number of turns may be wound in the secondary without increasing its mean distance from the core.

When winding enamelled wire, it must be taken into consideration that the insulation of enamelled wire is rigid and has no give. Consequently, to allow for expansion, enamelled wire must be wound more loosely than fibre or silk covered wire. The occasional insertion of a layer of paper in the winding gives room for expansion and does not add greatly to the diameter. The length of the secondary is generally not more than half the length of the core.

Coils producing sparks up to 2 inches (50 mm) in length, may be wound in two sections or in layer windings, but the layer winding is not recommended for coils giving sparks over one inch in length. It is best in a coil of this type, to insert an occasional layer of paper. The paper should be well shellacked or paraffined and be a good grade of linen. It should project about one quarter of an inch (6 mm) from the ends of the secondary as shown in this cross-section:

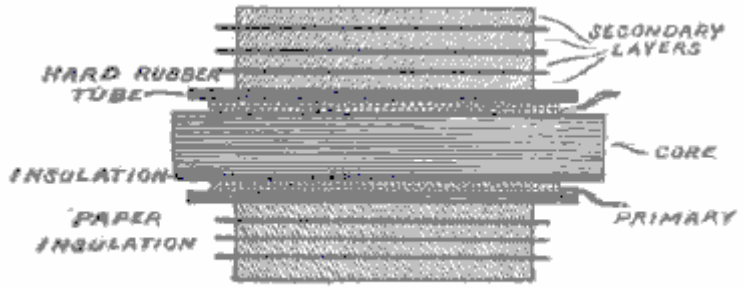

Fig. 28. Layer Winding for Small Coils.

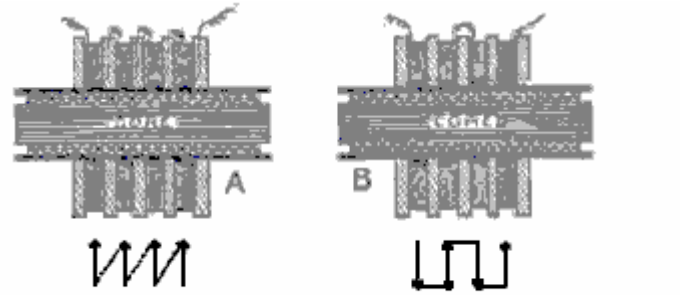
This insertion of paper increases the insulation and reduces the possibility of sparks jumping from layer to layer when the layers are very long. The secondaries of large coils are made up of "pies" or "pancakes" from one eighth (3 mm) to three eighths of an inch (9 mm) in thickness. The "pies" are separated from each other by a triple thickness of blotting paper which has been thoroughly dried and then soaked in melted paraffin. When each "pie" is completed, it is tested for continuity and rejected if not perfect. They are connected in series:



Methods of Connecting the Secondary Sections

If connected as shown in example "A", where the inside of one section is connected to the outside of the next section, the maximum voltage which can exist between the adjacent sections in this case is equal to the e.m.f. generated by one "pie" and is equal throughout. Connecting as shown in case "B" where the outside of one coil is connected to the inside of the next one, the voltage ranges from zero at the points where they are connected, to twice the e.m.f. developed by any one section. This is the better method and every second coil is turned around horizontally to allow for the reversed direction of current flow.

After the secondary is assembled, the coil should be submerged in an airtight tank containing melted paraffin wax. The tank is then connected to a vacuum pump and the air pumped out. This causes any air bubbles in the windings to be pumped out. After standing for a while, the vacuum is released and the air pressure then causes the bubble gaps to be filled with paraffin wax.

SECONDARY DIMENSIONS

Spark Length	Wire Gauge	Amount required	No. of sections	Length (1 inch = 25.4 mm)
0.5 inch (12 mm)	36 (0.193 mm)	0.5 lb (0.227 Kg)	1	3 inches
1 inch (25 mm)	34 (0.234 mm)	1 lb (0.454 Kg)	2	5 inches
2 inches (50 mm)	34 (0.234 mm)	2.5 lb (1.134 Kg)	4	7 inches
4 inches (100 mm)	32 (0.274 mm)	8 lb (3.629 Kg)	12	8.5 inches
6 inches (150 mm)	32 (0.274 mm)	12 lb (5.443 Kg)	20	10 inches

It should be noted that the very experienced Alfred Morgan flatly contradicts the standard theory of symmetrical transformer operation when he states that "*the ratio of the number of primary turns of an induction coil to the number of secondary turns, bears no relation to the ratio of the primary and secondary currents*". That is a highly significant statement.

Carlos Benitez also produced another very clever design, still using four batteries and a very slow switching rate, although no longer using the series and parallel switching which we think of as the Tesla Switch. In this design, he shows a remarkable high-frequency power-gain system where 400 watts of input power produces 2400 watts of output power (COP=6):

Carlos Benitez Patent GB 121,561 24th December 1918

New Process for the Generation of Electrical Energy

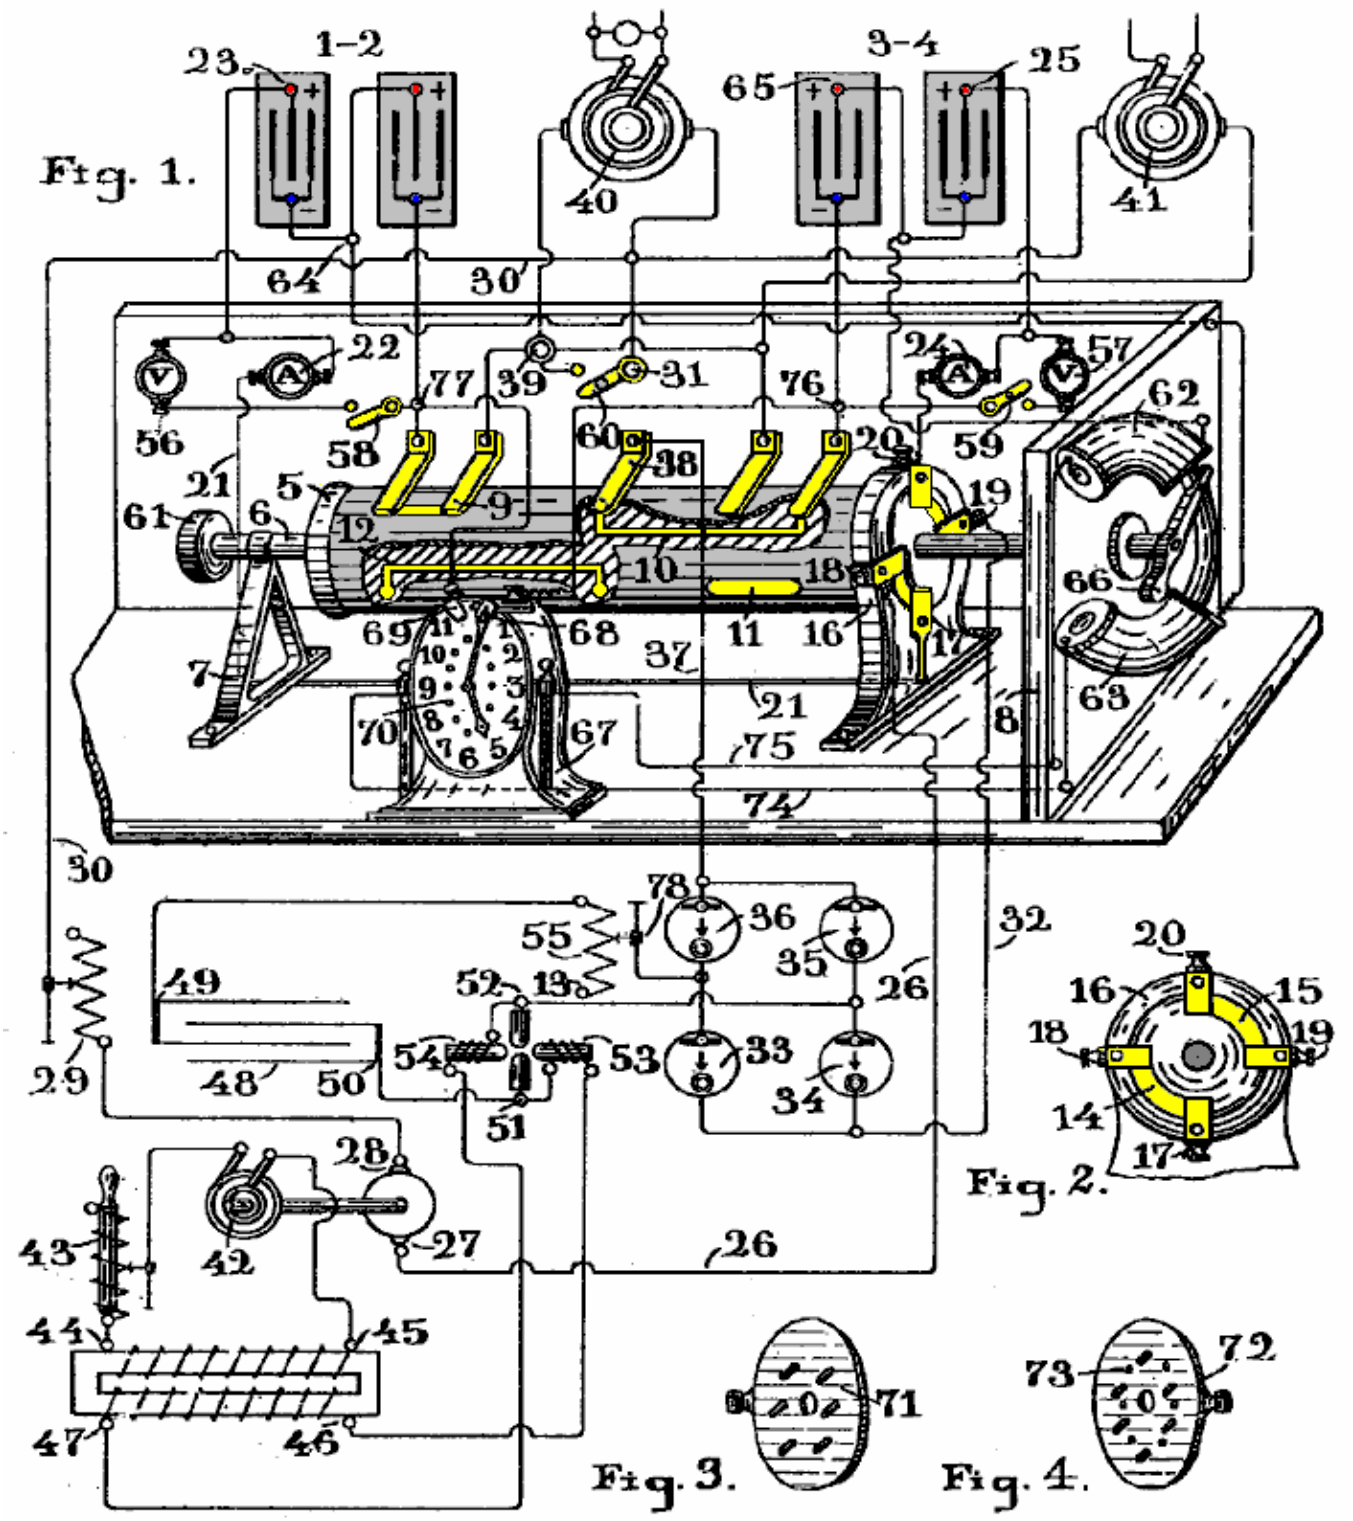
I, Carlos Benitez, Civil Engineer, of 141, Ocampo Street, in Guadalajara, Mexico, do hereby declare the nature of this invention and in what manner the same is to be performed, to be particularly described and ascertained in, and by, the following statement:

This invention relates to a new utilisation of the high frequency currents or electrical oscillations, by means of which, a constant production of electrical energy can be secured, under unusually simple, economic and practical conditions.

Such results are attained by means of the procedure disclosed in present applicant's English Patent specification No. 14,311, filed on October 9th, 1915, but in order to obtain a better utilisation the high-frequency currents and the automatic operation of the mechanisms employed in such a procedure, I have invented a novel arrangement of parts from which is derived several other advantages that will be here described and set forth.

Two batteries are used, one of which has already been charged. This charged battery discharges through a circuit which utilises the greater part of this power and the remainder drives an oscillating circuit connected to the second battery. This oscillating circuit contains a rectifier which directs the electrical oscillations in such a manner that they are forced to pass constantly through the second battery from the positive to the negative terminal. As the number of oscillations per second in that circuit can be varied at will, the current intensity developed by those oscillations can be regulated so that the second battery is fully charged in the same period of time during which the first battery is discharged. Therefore, it is only a matter of reversing the connections to the two batteries in order to obtain the continuous production of electrical energy.

The invention is illustrated here:



This circuit shows the circuit connections of the arrangement and a perspective view of a commutator. Figure 2 is a lateral view of a part of the same apparatus, and figures 3 and 4 are parts of the same machine, whose location and use will be explained later.

The figure shows two battery banks **1 & 2** and **3 & 4,** both of which are connected in series. Their positive poles **23** and **25** are connected to terminals **17** and **20** of the commutator, through the ammeters **22** and **24**. The commutator is a cylinder **5**, mounted on a rotating shaft **6**, which passes through two supports **7** and **8**. The cylinder is provided with conductive paths **9, 10, 11** and **12** insulated from the cylinder **5**. It also has conductive paths **14** and **15** which can be seen better in **Figure 2** and which make contact with brushes **17** & **18** and **19** & **20**, properly insulated and fixed to ring **16** which encircles cylinder **5** and is fastened to the base of the apparatus. These brushes connect to the batteries and terminal **17** is connected to the positive pole **23** of battery **1 & 2**. Terminal **20** is connected to the positive pole **25** of battery **3 & 4** through ammeter **24**. Terminal **18** connects through wire **26** to terminal **27** of a DC motor whose terminal **28** connects through the variable resistor **29** and wire **30** with terminal **31** of the commutator. Finally, terminal **19** is connected through wire **32** to terminals **33** and

34 of an electrolytic rectifier whose other two rectifiers **35, 36** connect via wire **37**, to brush **38** of the commutator.

This apparatus is also provided with terminal **39** which is alternately connected to the negative poles of the batteries through the brushes which can be seen in the figure, in contact with cylinder **5**. Under these conditions, the apparatus **40** and **41**, which are employed to provide a practical output independent of the running of the "plant", and which are connected to both terminals **31** and **39**, will be alternatively in circuit with the discharging battery, and thus, part of the power produced by the battery discharging, is used by this apparatus without impairing the normal running of the whole mechanism, as explained below.

On the other hand, an alternator **42**, is coupled to the motor **27-28**, which in this manner can be rotated at the speed needed to attain the desired frequency. Both terminals of the alternator are connected through the inductive resistance **43**, with the poles **44, 45** of the primary winding of a step-up transformer, whose secondary winding **46, 47**, connected to capacitor **48**, will finally produce the high-voltage alternating currents needed to charge the capacitor. However, the use of this motor and alternator is not essential in this process as the same results could be attained if the primary **44, 45** of the transformer, were connected through an ordinary interrupter to the discharging battery.

The terminals **49, 50** of capacitor **48** are connected through an arc lamp of the Poulsen type **51, 52**, or through an adequate spark-gap with the rectifiers **33, 34, 35** and **36**, and with the battery under charge (**3 & 4** in this case). Extending into the arc chamber are the poles of a strong electromagnet, the coils of which are in series with the arc, so that their excitation current is the arc current.

Connected in this manner, the strong magnetic field which exists between the poles of the magnets, acts on the arc, and owing to this action, combined with the influence of the voltage developed by the secondary of the transformer **46, 47**, it happens that this action and influence being about equal in value, are each of them alternately greater than the other, so that the voltage across the arc automatically rises and falls. Therefore, when the action of the magnetic field is greater than the voltage produced by the secondary winding of the transformer has not enough power to pass across the arc and so the capacitor **48** is charged to a higher voltage. But, an instant later the action decreases in value and the capacitor discharges again across the arc.

On the other hand, owing to the oscillatory nature of the circuit (which is arranged with proper values of capacity, inductance and resistance), the charging and discharging of the capacitor can occur several million times per second if desired, and in this manner, a current of a great number of amperes can be obtained through the oscillating circuit, even with a small amount of electricity stored in the capacitor.

In the same manner, one gallon of water could produce a flow of one thousand gallons per second through a pipe if such a pipe were connected with two different vessels and the gallon of water could be forced through the pipe by a piston which could transfer that gallon of water from one vessel to the other one thousand times per second. Obviously, what can be easily performed with electricity is not so feasible with water.

In other words, the small amount of electrical power taken by the DC motor **27, 28**, appears (with a small loss) at the alternator **42**, and that power is delivered to the transformer primary **44, 45**. Again, the inductive action of this transformer produces at the secondary **46, 47**, a similar amount of power (diminished slightly due to the efficiency of the transformer), and finally, the capacitor is charged with a small amount of electricity which is then converted into oscillitatory energy. Obviously, if such electric power, instead of being stored by the capacitor, had simply been rectified and used to charge one of the batteries, such power would produce only a very small effect on the battery and the entire discharge of one battery would never cause the complete charge of the second battery.

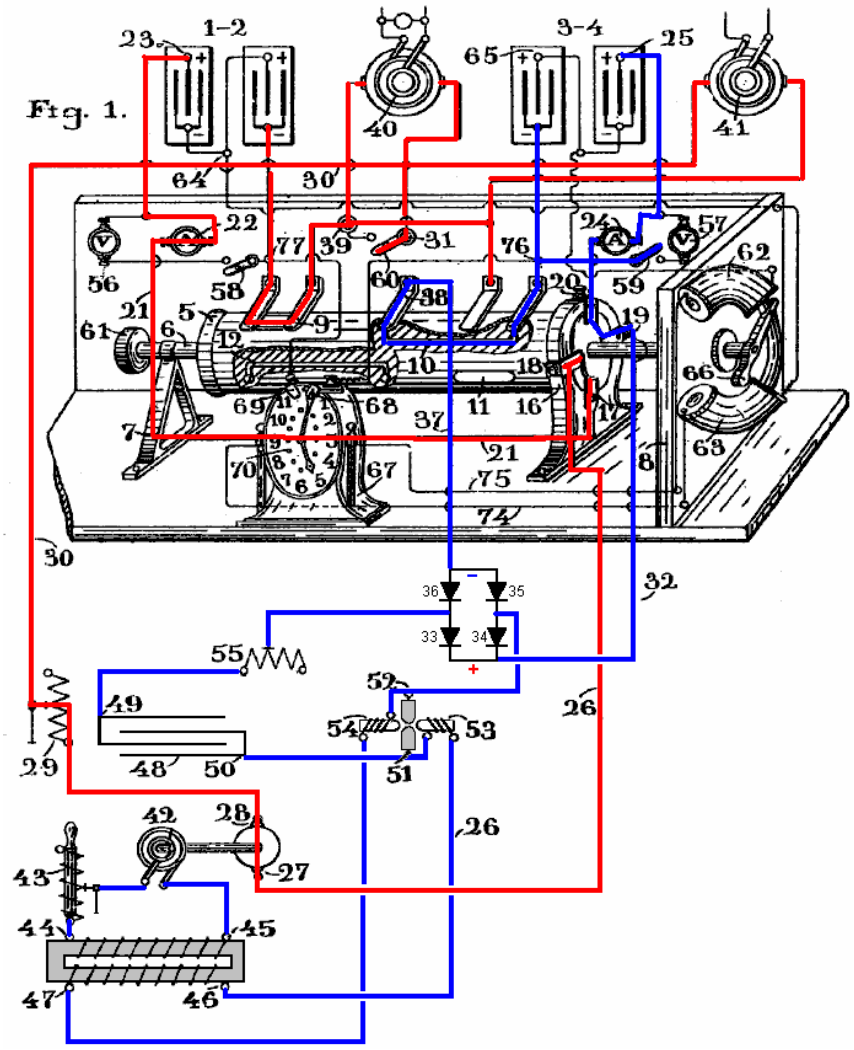
Contrary to that, if that same power is stored in capacitor **48**, and that capacitor is properly connected to an oscillatory circuit in which one of the batteries can be joined, and furthermore, if by means of a rectifier, the high-frequency currents produced in such an oscillatory circuit are forced to pass from the positive to the negative pole through the battery, it is obvious to state that it is always possible to secure by these means, the number of amperes required to charge the battery in the available time. That is to say, with a small number of coulombs stored in capacitor **48**, it is possible to produce in the oscillatory circuit, a great number of amperes, if that same small number of coulombs are forced to pass and repass through the circuit, thousands or millions of times per second, just as was explained in the water analogy.

On the other hand, the values of the above named quantities: capacity, resistance, inductance and voltage can be varied within very wide limits, and therefore it is always possible to attain the required conditions in each case, in order to produce a given number of oscillations per second: The capacity of the capacitor can be adjusted to a certain value by increasing or reducing the inter-meshed surface area of its plates. The resistance of the circuit can be adjusted to the required value by varying the length of the arc in the Poulsen lamp, or varying the number of lamps connected in series or parallel in the circuit. The inductance of the circuit can be varied by winding part of the circuit on an insulating frame, in such a manner as to obtain the number of turns required to produce the

desired inductance, and finally, the charging voltage can be regulated by increasing or decreasing the number of turns in the secondary winding of the transformer or by varying the diameter of the wire used in the coil. In order to obtain a better efficiency from alternator **42**, it is convenient to use the resonance coil or adjustable inductive resistor **43**. By so doing, it is possible to adjust the resistance in order to obtain a state of resonance in the circuit, and in that state, the current produced by the alternator will be in phase with the impressed E.M.F., therefore the effective watts will be a maximum in the primary and secondary circuits.

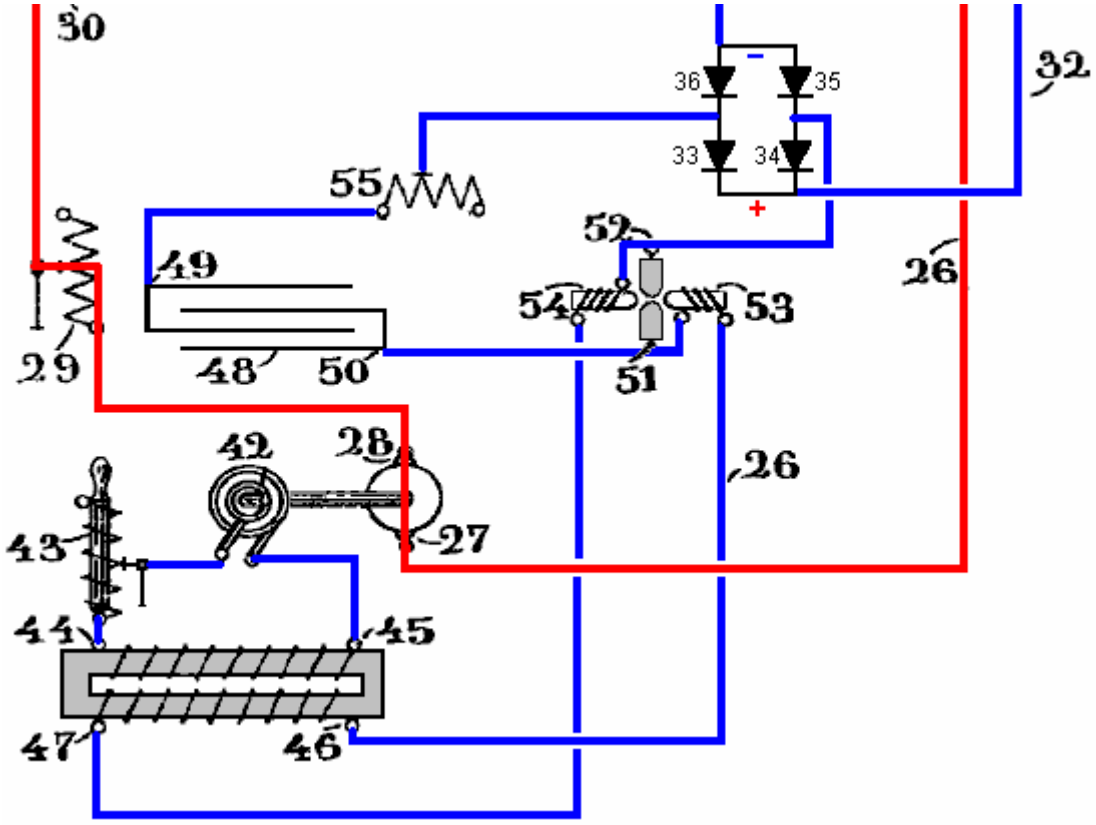
The variable resistor **29**, which is placed in the circuit which connects each battery with motor **27-28**, is used to adjust the current of the discharging battery to a fixed value, since it is important to obtain a constant number of revolutions per second of the alternator **42**.

The commutator is also provided with voltmeters **56** and **57**, and by means of the switches **58** and **59**, the circuits connecting both poles of each battery, can be closed and the voltage of the discharging current may be determined when desired. Finally, by means of switch **60** connected across the terminals of the apparatus **40** and **41**, the apparatus may be switched off when not required.



It is easy to understand the whole operation of this mechanism. Suppose initially that battery **1-2** has been charged and that cylinder **5** has been rotated to the position shown in the drawing. Battery **1-2** will immediately discharge via battery terminal **23**, ammeter **22**, wire **21**, contacts **17-18**, wire **26**, motor **27-28**, variable resistor **29**, wire **30**, rotary transformers **40** and **41**, (or through any other apparatus which may be used instead of those transformers in order to use part of the current flowing from the battery), pole **39**, and commutator path **9-12**, through which the whole discharging circuit is closed.

As a result of this discharge from the battery, the electrical power produced will be dissipated in three ways: A first part is wasted in overcoming the internal resistance of the various components in the circuit. A second part is used to power the DC motor **27-28**, and the third part powers the apparatus connected to poles **31-39** of the commutator, that is, the useful equipment powered in addition to the running of the system.



It is well known how the mechanical power developed by the rotary motion of motor **27-28** can be converted to electrical energy by alternator **42**, and in the same manner, it is well known how such electrical energy of low voltage can be transformed into one of high voltage using a transformer, and it is well known too, how such high voltage electrical energy can be converted into oscillatory energy, and how the alternating currents produced by such oscillations can be rectified in order to produce a direct current. However, all such combinations of apparatus arranged to charge a battery while another similar battery is discharging, was perfectly unknown before this invention, and a short consideration of the calculations involved in determining the different values of capacitance, resistance, inductance and voltage required by the various combined circuits of a small working plant of this kind, may be useful in giving an idea of the procedure which can be followed in general practice.

Suppose that both of the batteries are accumulators with a voltage of 60 volts each and a capacity of 40 AHr. Under such conditions, if battery 1-2 discharges at the rate of 40 amperes, it will be fully discharged in one hour. [Please note that this is not so and is only being stated here for discussion purposes. A lead-acid battery will be damaged if discharged at a rate greater than the "C20" rate which is the rated AHr value over a period of 20 hours, and so, a lead-acid battery of 40 AHr should not be discharged at more than 40 / 20 = 2 amps. Also, batteries are highly non-linear and discharging a 40 AHr battery at 40 amps will result in a fully discharged battery in a lot less than one hour.] The power developed over that time period will be 60 volts x 40 amps = 2,400 watts.

On the other hand, in order to charge battery **3-4** fully in one hour it is necessary to provide a current of at least 40 amps. Suppose that in order to develop such a current, it is desired to take from the power produced by the discharging battery only a portion, say 40 amps x 10 volts = 400 watts. With this objective in view, the DC motor should be arranged so as to create a current of 40 amps causing a drop of 10 volts on the line.

Suppose that the electrical efficiency of the DC motor is 95%, then the desired 400 watt output will not be attained but instead will be reduced to 400 x 0.95 = 380 watts.

Then, suppose that the electrical efficiency of alternator **42** is 95% then that will reduce the output to just 361 watts. Then, if this 361 watts is passed to the transformer and that transformer has an efficiency of say, 89%, then the resulting energy output will be further reduced to just 321 watts, and that is the amount of power passed to the oscillating circuit in order to obtain the required 40 amps of current.

Now, suppose that the frequency of alternator **42** is 500 Hz. As is well known, with an alternating generator, a high voltage is obtainable twice in each cycle and so there will be 1000 voltage peaks per second. As capacitor **48** discharges at the instant of maximum voltage, it will discharge 1000 times per second. Therefore, the quantity of electrical energy which must be stored in it can be calculated as follows: Suppose that the oscillating circuit has an impedance of 15 ohms. As the required current is 40 amps, the required voltage to develop such current will be 40 amps x 15 ohms = 600 volts. But in order to produce 600 volts from the discharge of the capacitor, it is

necessary to get it charged up to 1200 because the average voltage during discharge is V / 2.

If the energy produced by the transformer secondary is assumed equal to 321 watts and the voltage required for the charge of the capacitor is 1200 volts, then the current delivered by the secondary will be 321 watts / 1200 volts which is 0.267 amps.

On the other hand, as the frequency of the alternator is 1000 peaks per second, then in one thousandth of a second the secondary has to deliver to the capacitor 0.000267 coulombs which is 267 microcoulombs.

Hence, the capacity of capacitor **48** must be adjusted to store that amount of electricity, and its value can be determined by **Q = K x V** where K is the capacity of the capacitor in microfarads when Q is given in microcoulombs and V is the maximum voltage, and so, K = 267 / 1200 which is **0.222 microfarads**.

It is also well known that if you want to produce an oscillatory discharge through a circuit, the capacitance, resistance and inductance of the circuit must be arranged so that the square root of 1000 x L millihenrys / K microfarads is greater than the resistance of the circuit in ohms (K being the capacitance of the capacitor).

It has been supposed that the resistance of the oscillatory circuit is 15 ohms. Using 20 ohms in the above equation will allow a suitable value of inductance to be calculated, one which will satisfy the required conditions for the production of the oscillatory discharge in the circuit, and so the inductance in millihenrys is 400 x K / 4000 or 400 x 0.222 / 4000 which is **0.0222 millihenries**, or equal to 22,200 centimetres of wire.

It is possible to determine the number of oscillations per second which can be achieved in any such circuit, and that is given by Hz = 5033000 / the square root of L x K where L is in centimetres and K is in microfarads. And so, knowing the inductance and the capacitance we get Hz = 5033000 / sqrt(22200 x 0.222) which is **71900 Hz**. That represents 72 oscillations in each of the 1000 sparks per second.

The current strength developed by these oscillations can be determined from the formula below which uses the Voltage **V** in volts, the resistance of the circuit **R** in ohms, the inductance **L** in henrys, and the capacitance **K** in farads:

Current = V / sqrt(R x R + (6.28 x Hz x L – 1/(6.28 x Hz x K)^2) or in our case:

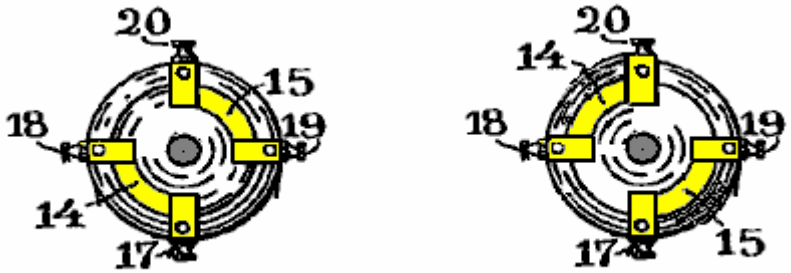
Current = 600 / $\sqrt{}$ 15 x 15 + (6.28 x 71900 x 0.0000222 – (1/(6.28 x 71900 x 0.00000222)))^2

Which works out as 40 amps, meaning that the impedance of the oscillating circuit is equal to the resistance in ohms of that circuit, since the inductive reactance and the capacitative reactance are so combined that the resultant value of the total reactance is equal to zero, and the only voltage required to produce the current of 40 amps is that needed to overcome the ohmic resistance of the circuit which is 15 ohms. This also means that the E.M.F. is in phase with the current, and therefore, the watts are a maximum.

Hence, there can be no doubt that battery **3-4** will be fully charged during the period when battery **1-2** is discharging, especially since the charging current can be further increased at will, even without taking more power from the discharging battery. In fact, it is easy to increase the number of turns in the transformer secondary **46-47** in order to increase the voltage. Obviously, as the amount of power delivered to the primary **44-45** of this apparatus is always 321 watts, if the voltage is increased, the quantity of electricity which the capacitor **49** receives will be reduced accordingly. Consequently, the value of that capacitor must also be reduced and so the number of oscillations per second will also be increased. Finally, by increasing the voltage, the current intensity is increased proportionately.

Therefore, it is always possible to combine, in the manner described, the values of resistance, inductance, capacitance and voltage in the oscillating circuit, so as to obtain the required current strength to fully charge one of the batteries during the period when the other battery is discharging.

Once this battery charging has been attained, if the plant is to continue in operation, then the batteries need to be swapped over by altering their connections to the circuit. To accomplish this, cylinder **5** is rotated until the conductive paths **11** and **12** come into contact with the brushes which are connected to the negative poles of the batteries, and then, battery **3-4** which is fully charged will be connected with the motor **27-28**, and its discharge will now be produced by this path: battery terminal **25**, ammeter **24**, commutator poles **20** and **18** (now connected together due to the rotation of the cylinder **5** through 90 degrees), wire **26**, motor **27-28**, variable resistor **29**, wire **30**, apparatus **40** and **41**, and commutator path **11** which closes the circuit to the negative pole of battery **3-4**.



In other words, the motor **27-28**, apparatus **40** and **41**, and alternator **42**, will still be operating in exactly the same way as described above, and in the same manner, the high-frequency currents are still developed, producing the same current intensity which is now passing via terminal **50** of capacitor **48**, arc-lamp **51-52**, diode **34**, wire **32**, commutator contacts **19-17**, wire **21**, ammeter **22**, and positive terminal **23** of battery **1-2** (which is now connected to contact **38** of the commutator through path **12**), wire **37**, diode **36**, inductor **55**, and capacitor terminal **49**; also through duplicate path from capacitor terminal **49**, diode **33**, wire **32**, commutator contacts **19-17**, wire **21**, ammeter **22**, positive terminal **23** of battery **1-2**, commutator path **12**, commutator pole **38**, wire **37**, diode **35**, arc lamp **52-51**, and capacitor terminal **50**.

It is obvious to state that this same procedure can be repeated indefinitely by the simple altering of the battery connections from time to time in accordance with the battery capacity and the rate of discharge. Only 400 watts is taken from the discharging battery for battery recharging, leaving 40 amps at 50 volts (2000 watts) available for doing continuous useful work.

The patent continues with a description of how a modified clock can be made to move the commutator once every hour. This is a brilliant 2 kilowatt, self-powered, free-energy design. However, operating the design as described would not be realistic. Batteries nowadays have limited operational lives offering, typically, between 400 and 1000 charge/discharge cycles within the C20 discharge current limits. Exceeding the C20 discharge rate will reduce the battery life by a major amount, that amount being determined by the degree of abuse which the battery suffers. If we ignore that factor and say that our batteries will manage 1000 cycles, at the proposed rate of say, one hour discharge and one hour charging time, then battery replacement is liable to be required in just 500 hours of operation. That is, within three weeks of continuous operation.

The essential, rapid switching of this circuit is performed by the spark-gap but in contrast to that, the commutator switching of the batteries does not require high speed operation. It is feasible then, to replace the commutator with simple solid-state switching and swap the batteries over every second or two. That way, the batteries are never discharged and long battery life can be expected.

Bozidar Lisac's Power-Boosting System.

Recently, a patent application has been lodged on what is effectively the **Ron Cole** one-battery switch and the Tesla Switch. I am including the re-worded patent here. Some experimenters have reported overall battery energy gains with switching speeds of 0.5 Hz or less, which means that in circuits of that type, mechanical switching should give a reasonable switch contact life. This patent has needed a fair degree of attention as the person writing it does not have a full grasp of English and confused the word "load" with the word "charge". Let me say again, that the following patent application is included here primarily for interest sake, rather than being the definitive way of making a circuit of this type.

Patent Application US20080030165 7th February 2008 Inventor: Bozidar Lisac

METHOD AND DEVICE FOR SUPPLYING A LOAD WITH ELECTRIC ENERGY RECOVERY

ABSTRACT

In the invention an electric current circulates from the battery **UB**, through the electric motor **M**, and the diode **D1** charges the capacitors **CA** and **CB**, connected in parallel, which, once charged, are connected in series, giving rise to a difference in voltage in relation to the battery, causing half the charge of the capacitors to be returned to the battery through the diode **D2**, whilst with a new parallel connection, the capacitors recharge, this charge being

equal to that which had been previously transferred from the capacitors to the battery, so that by means of the cyclic connection of the capacitors in parallel and series the energy is transferred from the battery to the capacitors and from the capacitors to the battery, thus considerably extending the range of the battery and operation of the motor.

OBJECT OF THE INVENTION

This invention relates to a method and device enabling the electrical energy with which a charge is supplied to be recovered using a self-rechargeable electricity source in which, which by means of a circuit, the current circulating from an accumulator or battery through a load, e.g. a motor, is fully returned to the same energy level, thereby considerably extending its range.

More specifically, two capacitors that are connected cyclically from parallel to serial and vice versa are charged through a motor during the connections in parallel, whilst in series connection, when its voltage doubles, they return the electricity, recharging the battery. This source represents a closed system which does not require an energy supply from the outside, except to compensate for the losses produced, the range of the battery being limited by the number of charges and discharges that the same technically permits.

BACKGROUND TO THE INVENTION

A load, such as an electric motor, is connected to a battery or accumulator with a certain charge, which will be progressively discharged by it, this discharge being directly proportional to the connection time and to the current circulating through the motor. It is therefore necessary to supply fresh energy from an external source to recharge it. Systems that enable the energy consumed by the load to be reused are not known in the state of the art.

DESCRIPTION OF THE INVENTION

A first aspect of the invention relates to a method for supplying a load with recovery of electrical energy, which comprises supplying a load with electrical energy deriving from the first electrical energy accumulator, and returning at least a proportion of that electrical energy after it passes through the load to the first accumulator for the purpose of recovering the energy supplied.

The electrical energy, after passing through the load, is recovered by second electrical energy accumulator, from where it is transferred to the first accumulator, giving rise to cyclic transfer of electrical energy between the first and second energy accumulators.

The recovery of energy from the second accumulator and transfer to the first accumulator may be achieved without passing the energy through the load. In another alternative implementation, the energy is recovered from the second accumulator and passed to the first accumulator through the load, in which case the polarity of the load is reversed during the recovery of energy through the load.

The transfer of energy is brought about by cyclically connecting two or more electrical energy accumulators between parallel and serial connections.

A second aspect of the invention relates to a device for supplying a load with recovery of electrical energy, which comprises a first electrical energy accumulator and a second electrical energy accumulator, where the load is connected between the first and second accumulators. The device may be provided in one embodiment with a unidirectional connection device, for example, a diode which is connected in parallel to the load, causing circulation of the electrical energy recovered after passing through the load, and via which the electrical energy is returned to the first accumulator.

The first electrical energy accumulator may be a battery. The second electrical energy accumulator might be two or more capacitors with switching to cyclically connect them between parallel and serial connection configurations.

The invention constitutes a self-rechargeable source of electrical energy which enables the range of a battery to be considerably extended so that the current circulating from the same through a motor charges two capacitors connected in parallel, up to the voltage level of the battery, by means of contacts. These capacitors, once charged, are connected in series, producing double their voltage, and they then return the energy to the battery, thereby extending its range. Once the losses have been compensated for, the duration of the extended range depends on the charging and discharging properties of the capacitors.

The existence of the difference in voltage between the battery and the capacitors connected both in parallel and in series, and which give rise to the displacement of energy from the battery to the capacitors and vice versa, is

used to supply the motor connected between the battery and the capacitors, comprising the self-rechargeable source of electrical energy.

When connected in parallel, the capacitors are charged through a motor and a diode, and when connected in series, they are charged through another diode, the voltage of the motor being half that of the battery. On the other hand, if the motor is connected between the battery and the serially-connected capacitors, the latter, which are charged in parallel through a diode and are discharged by means of the motor and the other diode, will supply the motor with a voltage equal to that of the battery, whilst a capacitor connected in series to the winding of the motor guarantees its operation without loss of power.

Instead of the two capacitors, two batteries connected in series and another two connected in parallel may be used, between which batteries a motor is connected, the current circulating in this case from the batteries connected in series through the motor to the batteries connected in parallel. The serially-connected batteries are then connected in parallel, by means of switching contacts, and the other two parallel-connected batteries are then connected in series, reversing the direction of the current, whilst the connections of the motor are inverted by means of the simultaneous switching of other contacts in order to maintain the polarity and direction of rotation of the motor.

In one possible embodiment of the invention, another two capacitors and a transformer with two primary windings, or a motor with two windings are added to the device previously described, each pair of capacitors cyclically switching from parallel to serial connection and vice versa so that during the parallel connection cycles, two of the capacitors are charged through one of the windings up to the voltage level of the battery at the same time that the other two capacitors are connected in series, double their voltage and are discharged by means of a second winding to the battery.

The reduced level of energy losses brought about mainly by the dissipation of heat and in the capacitors, as well as by the charge factor of the batteries, is compensated for from an external source, and because the sum of the current circulating through a winding of the motor or transformer charging two of the capacitors and the current simultaneously circulating from the other two capacitors through the second winding, recharging the battery, plus the current which is supplied from the external source, is equal to zero, because of the work carried out by the motor or the loads which are connected to the alternating voltage induced in the secondary of the transformer, no discharge of the battery takes place.

DESCRIPTION OF THE DRAWINGS

In order to supplement the description now being given, and with the aim of contributing to a better understanding of the characteristics of the invention, according to a preferred practical embodiment, a set of drawings is attached as an integral part of this description, in which, for informative and non-restrictive purposes, the following is shown:

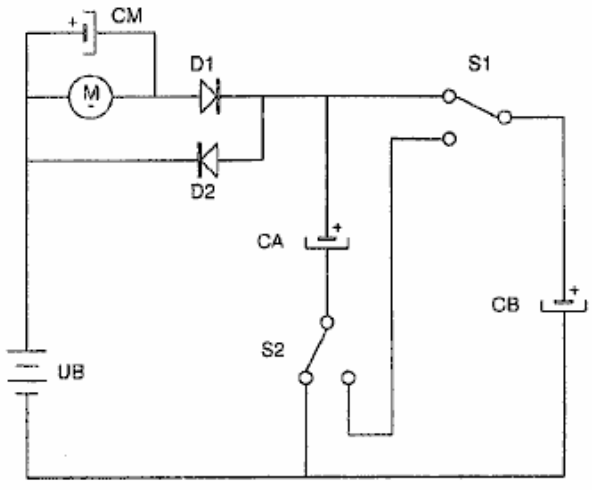


FIG.1

Fig.1 shows a practical circuit in which, by means of switching, two capacitors connected in parallel are charged from a battery through a motor and a diode, and after the contacts are switched, they are connected in series, thereby discharging the battery through another diode.

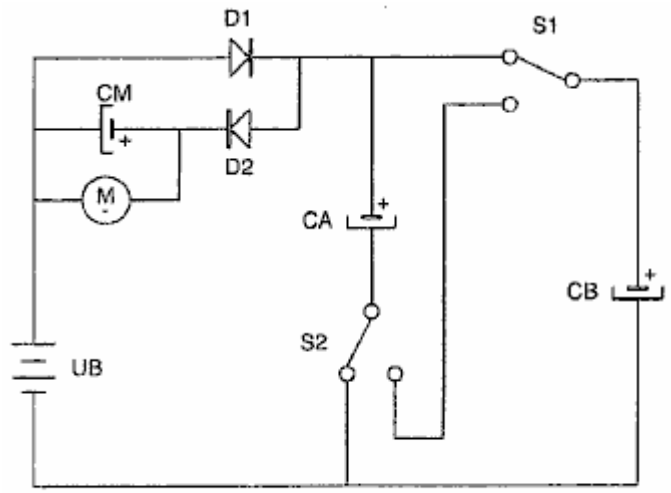

FIG.2

Fig.2 shows a practical circuit in which, through switching, the two capacitors are connected in parallel and are charged from a battery through a diode, and after the switching of the contacts they are connected in series, thereby charging the battery through the motor and the other diode.

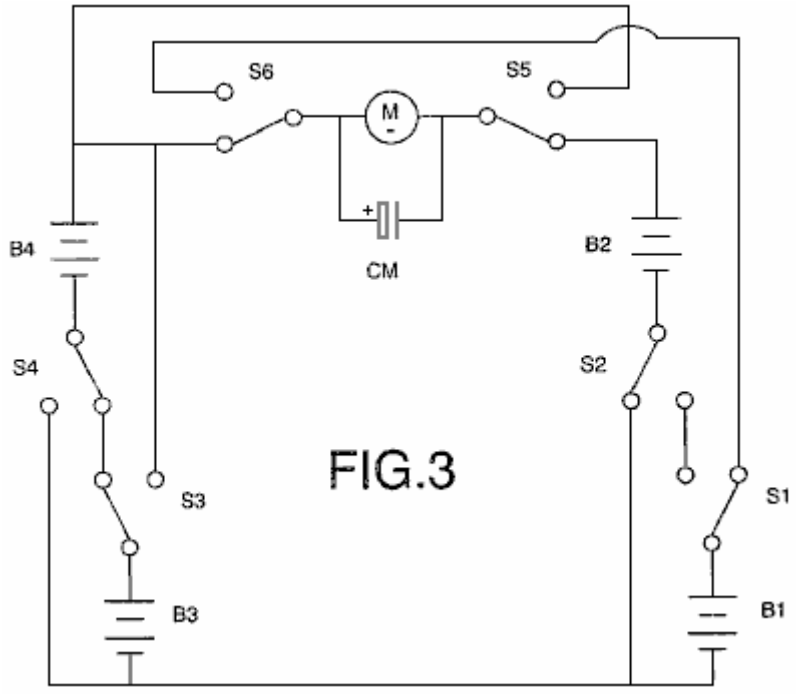

FIG.3

Fig.3 shows the connection of the two batteries in series, connected through a motor to another two batteries connected in parallel, and which, by means of contacts, switch alternatively, this giving rise to effects similar to those described in relation to the use of the capacitors.

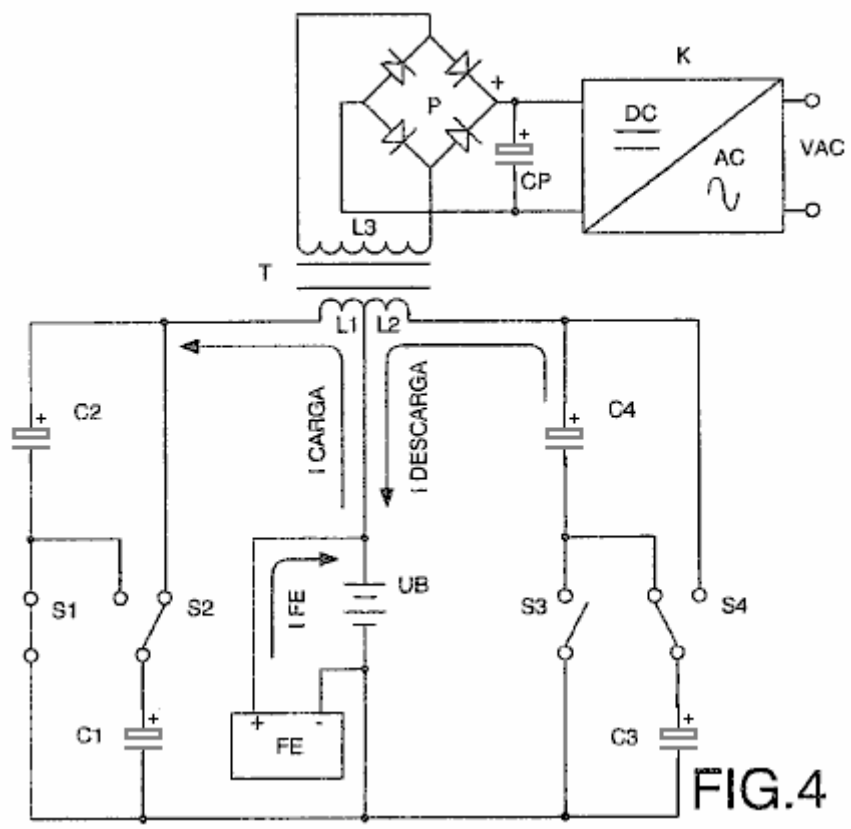

Fig.4 shows the electrical diagram corresponding to the connection between the battery and the two pairs of capacitors of a transformer with two primary and one secondary winding, in which an alternating voltage is induced which is rectified, filtered and converted to a sinusoidal voltage.

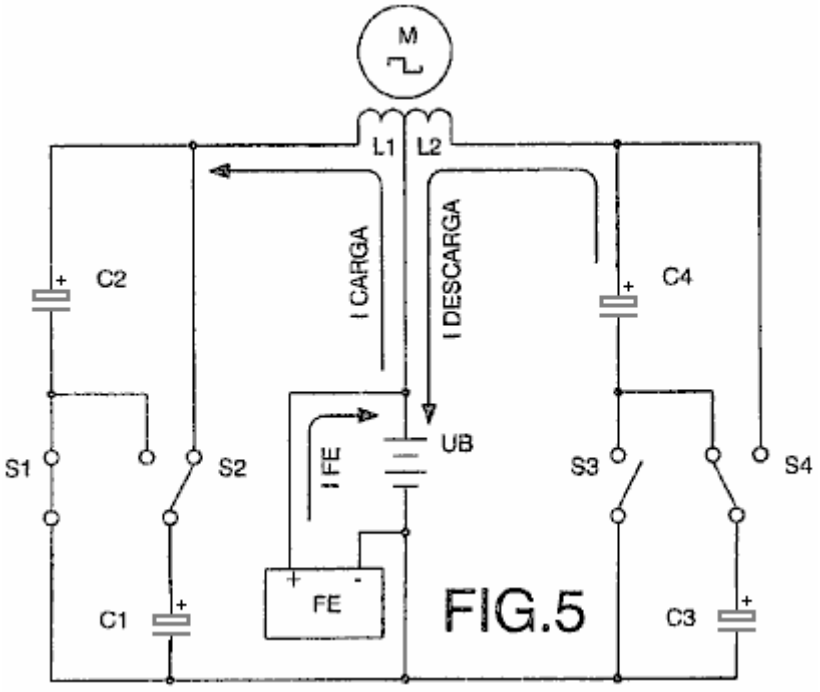

Fig.5 shows the electrical diagram of an alternating current motor with two windings connected between the battery and two pairs of capacitors.

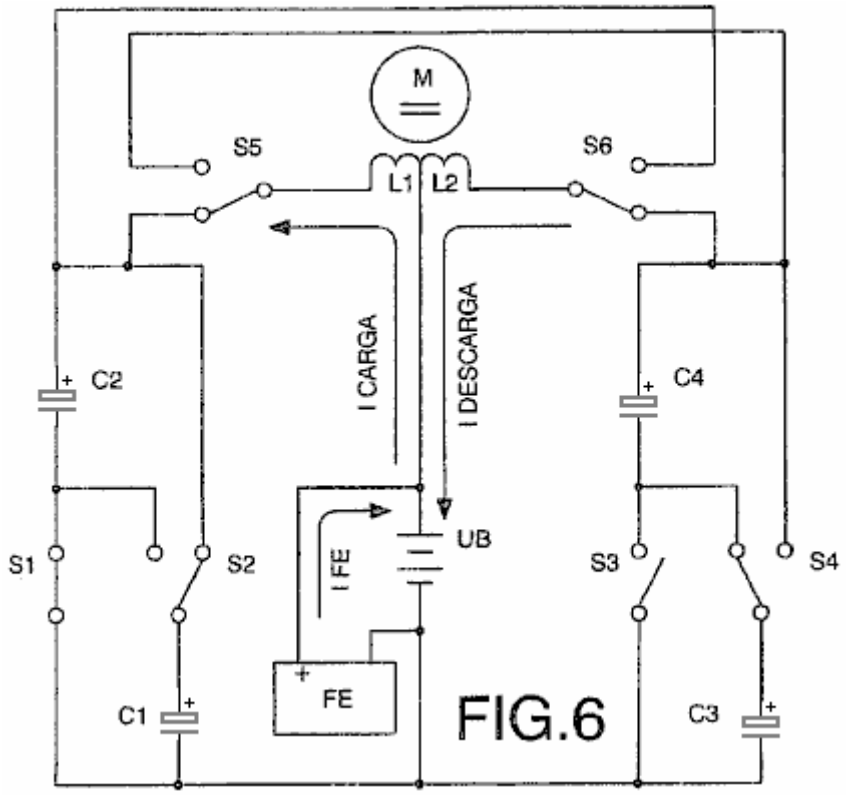

Fig.6 shows the electrical diagram of a direct current motor with two windings connected between the battery and two pairs of capacitors, in which two switch contacts ensure their correct polarisation and direction of rotation.

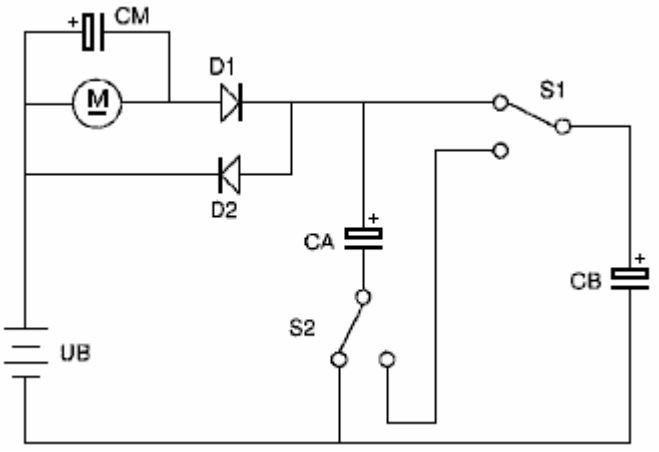
PREFERRED EMBODIMENT OF THE INVENTION

In a preferred embodiment shown in **Fig.1**, the load consists of a direct current motor **M**, the battery **UB**, and the second accumulator which consists of a pair of capacitors **CA** and **CB**. The capacitors **CA** and **CB** are connected to each other in parallel by means of two switches **S1** and **S2**. These capacitors are charged through the motor **M** and diode **D1** to a voltage level equal to that of the battery **UB**, the charge being Q = (CA+CB)UB, and while these capacitors are being charged, the motor **M** is rotating.

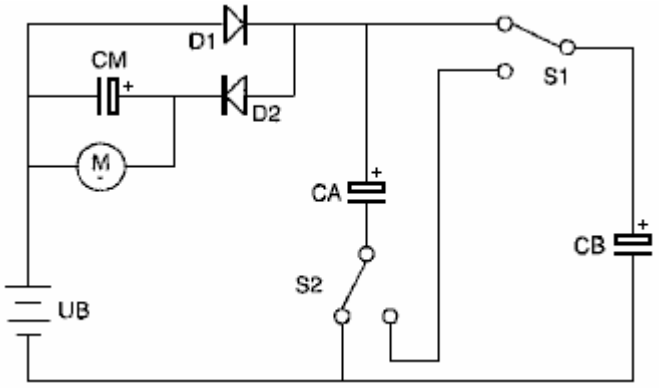


When both capacitors are fully charged, they are connected in series by the switch contacts **S1** and **S2**. This produces a voltage which is twice the value of the voltage of the battery **UB**, resulting in the charge which is given by Q = 2 x UB x (CA+CB) / 2 which is Q = (CA+CB)UB, which shows that once charged, the charge Q of both capacitors is identical both in parallel and in series.

Diodes **D1** and **D2** ensure that current flow through the motor **M** is only ever in one direction. Immediately after capacitors **CA** and **CB** are connected in series, they return half of their charge through diode **D2**. Switches **S1**

and **S2** then connect the capacitors **CA** and **CB** in parallel. In this arrangement, they start off with half of the battery voltage. They charge immediately, regaining the battery voltage through the motor **M** and the diode **D1**.

By means of repeated cyclic switching of the capacitors **CA** and **CB** from parallel to serial connection mode, the current circulating from the battery **UB** through the motor **M** to the capacitors, and from these to the battery, recharging it and extending its range, constitutes a self-rechargeable source of electrical energy.



In a second practical embodiment shown in **Fig.2**, the motor **M** is connected between the battery **UB** and the capacitors **CA** and **CB** by means of the diode **D2**. The capacitors are charged directly through the diode **D1** and are discharged through the motor **M** and the diode **D2**, the values of the charges on the capacitors **CA** and **CB** previously described in the example shown in **Fig.1** remain unchanged, the difference in this circuit is that the voltage applied to the motor **M** is the full battery voltage in this case.

The charging rate of the capacitors **CA** and **CB** is determined by the intensity of the current flowing through the motor **M**, to which is connected in parallel, the capacitor **CM** which guarantees that the operation of the motor is maintained at maximum power. It is possible to substitute a battery, preferably a rapid charge battery, for capacitor **CM**.

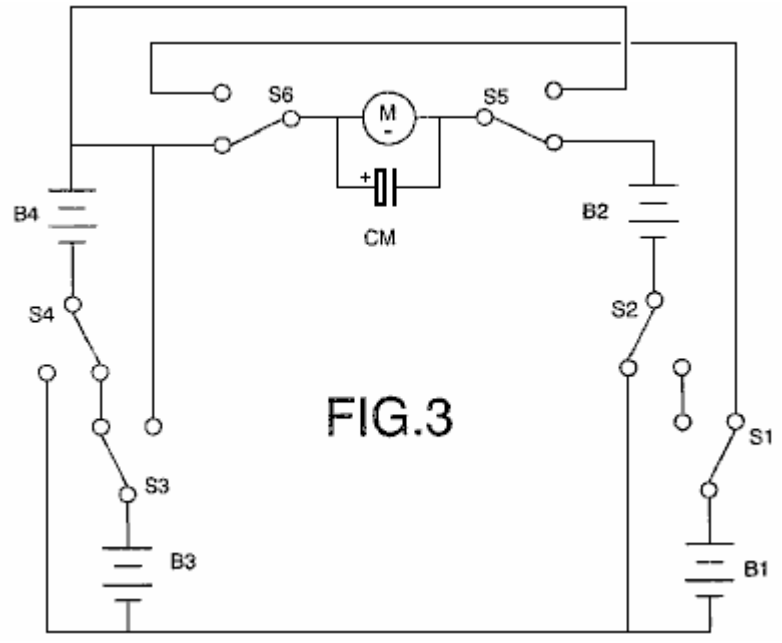


FIG.3

In another embodiment shown in **Fig.3**, the first and second accumulators consist of pairs of batteries **B1**, **B2** and **B3**, **B4**. Therefore, in this embodiment, two pairs of batteries are used instead of the capacitors **CA** and **CB**. Batteries **B1** and **B2** are connected to the switches **S1** and **S2**, and the pair of batteries **B3** and **B4** are connected to the switches **S3** and **S4**. The switches **S1** to **S4**, connect the pairs of batteries with which they are associated, into series or parallel configurations, depending on the position of the switches.

While the batteries **B1** and **B2** are connected in parallel, the other two batteries **B3** and **B4** are connected in series, and the motor **M** rotates as a result of the difference in voltage between the batteries, as it is connected

between both pairs of batteries. At the same time, the current circulating through the motor from the serial connected batteries recharges the two parallel-connected batteries. The switches **S1** to **S4**, which connect the batteries **B1** and **B2** in series and the batteries **B3** and **B4** in parallel then switch, thus reversing the direction of the current flow, and at the same time, the switches **S5** and **S6** change positions in order to maintain the correct polarity for the motor and its direction of rotation.

The two capacitors and the batteries may be switched by means of any mechanical, electromechanical, electrical, electronic or other element that meets the conditions described with the purpose of obtaining a self-rechargeable electrical energy source. These switching operations may be controlled by any known method, for example, a programmable electronic circuit.

In the preferred embodiments previously described, the load consists of a direct current motor, but as an expert in the field may understand, the load may also consist of any type of resistive (?) and/or inductive load.

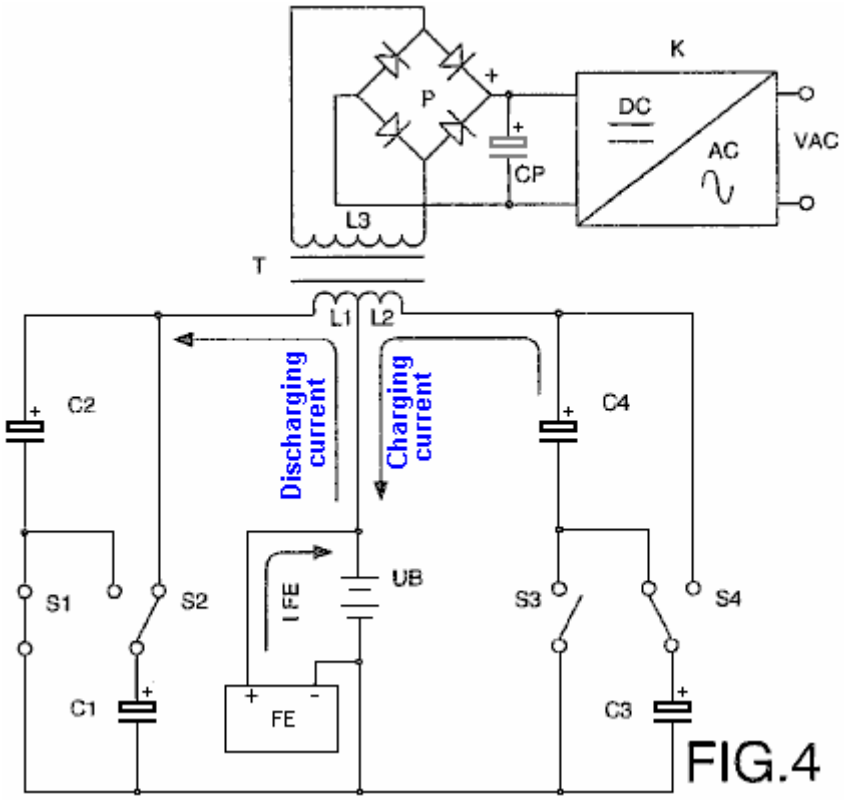

FIG.4

Another preferred embodiment is shown in **Fig.4**, where a transformer **T** with two primary windings **L1** and **L2** is connected between the battery **UB** and the two pairs of capacitors **C1** and **C2**, plus **C3** and **C4**, causing the two capacitors **C1** and **C2** to switch their connections from parallel to serial and back again by means of the contacts **S1** and **S2**, and causing the capacitors **C3** and **C4** to switch by means of contacts **S3** and **S4**, so that during the cycles of connection of the capacitors **C1** and **C2** in parallel, the latter are charged via the winding **L1** up to the voltage level of the battery, whilst at the same time the capacitors **C3** and **C4** are connected in series and provide double their voltage, the battery being discharged by means of the winding **L2**, in which case the charging and discharging currents to circulate in the same direction. On the other hand, during the cycles of connection in parallel of the capacitors **C3** and **C4**, which are charged through the winding **L2** up to the battery voltage level, the capacitors **C1** and **C2** are connected in series to provide double their voltage and are discharged into the battery through the winding **L1**. The direction of the charging and discharging current therefore changes, thus inducing in the secondary winding **L3** an alternating voltage whose frequency depends on the speed of switching of the contacts mentioned, and after being rectified by means of the bridge of diodes **P** and filtered by the capacitor **CP**, the resultant DC voltage is converted to a sinusoidal voltage by means of a circuit **K**.

The connection in parallel of one pair of capacitors and the connection in series of the other pair take place at the same time. Therefore the sum of the current circulating from the battery through one of the windings, charging two of the capacitors, and the current circulating from the other two capacitors through the other winding to the battery, is approximately zero.

From an external energy source **FE** the minimum energy losses caused essentially by dissipation of heat and in the capacitors, as well as by the charging factor of the battery, are compensated for, with the result that the sum

of the current circulating from this source external to the battery and the charging and discharging currents of the capacitors is equal to zero. Therefore the battery is not discharged and its range does not depend on the work developed by the motors or the loads connected to the secondary winding **L3** of the transformer **T**, since the greater the power of the loads, the higher the intensity of the charging and discharging currents of the capacitors.

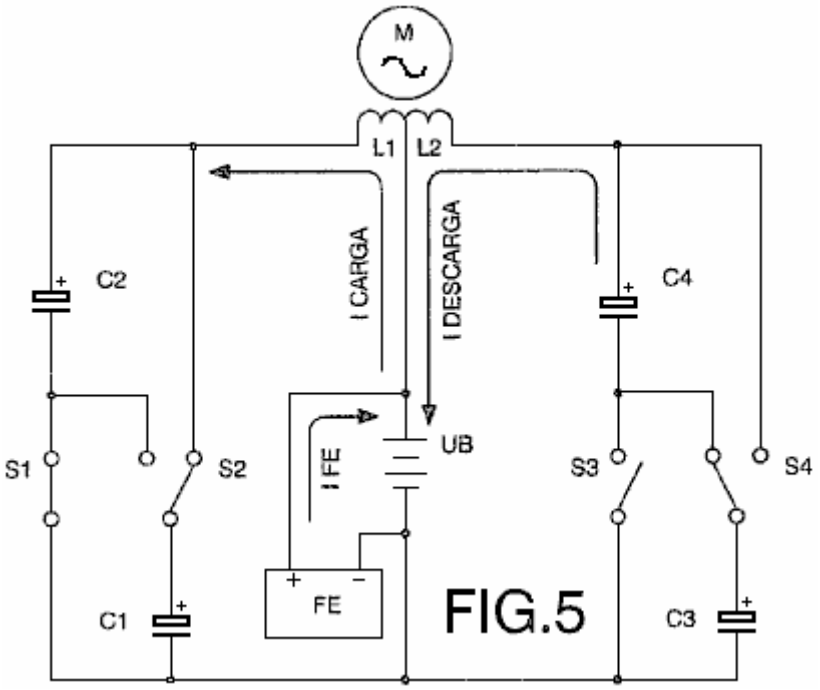

FIG.5

Fig.5 shows another embodiment in which an alternating current motor **M** is connected to two windings **L1** and **L2** so that during the connections in parallel of the capacitors **C1** and **C2**, the latter are charged by means of the winding **L1** at the same time that the capacitors **C3** and **C4**, connected in series, are discharged by means of the winding **L2** to the battery **UB**, the charging and discharging current circulating through the windings in the same direction. The capacitors **C1** and **C2** are then connected in series and the capacitors **C3** and **C4** are connected in parallel. The direction of the charging and discharging current of the capacitors is therefore reversed, thus producing at terminals of the motor an alternating voltage with a frequency that depends on the speed of switching of the contacts. The energy losses caused are compensated for from an external source **FE**, the sum of the current circulating from this source to the battery and the currents circulating through the two windings during charging and discharging of the capacitors being equal to zero. The battery is therefore not discharged as a result of the work developed by the motor.

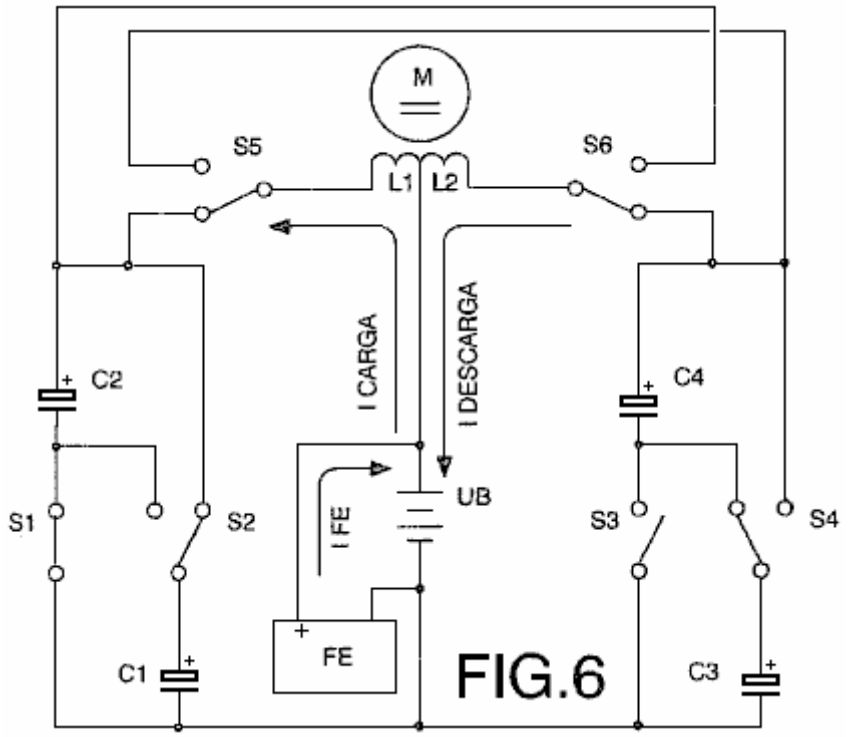

FIG.6

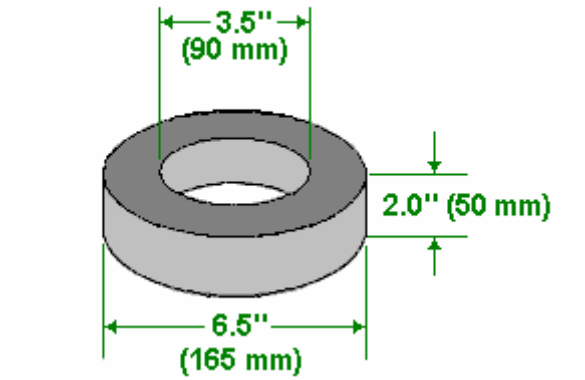
Fig.6 shows the connection of a direct current motor **M** to two windings **L1** and **L2** between the battery **UB** and the two pairs of capacitors **C1** and **C2** plus **C3** and **C4**, so that during the connections in parallel two of the capacitors are charged by means of the winding **L1**, and during the simultaneous connections in series, the other two capacitors are charged by means of the winding **L2** to the battery. Coinciding with the switching of the contacts **S1**, **S2**, **S3** and **S4**, which connect to each pair of capacitors from parallel to serial and vice versa, the contacts **S5** and **S6** switch, polarising the windings of the motor so that the charging and discharging currents of the capacitors circulate in the same direction, producing a direct voltage. The sum of the current supplied from the external source **FE** and the charging and discharging currents of the capacitors is equal to zero, and thus there is no battery discharge.

Bob Boyce's Toroid.

Consider also, Bob Boyce's very effective pulsed toroid system. As the waveform fed to the toroid has to have very sharp rising and falling voltages, the toroid needs to be able to handle very high frequency signals, far higher than the number of pulses per second fed to the toroid. If the rising edge is very sharp (and it needs to be so fast that it won't show on a 150 MHz oscilloscope), then as far as the toroid is concerned, there may be a similar falling edge one nano second later and so it needs to be able to respond to that sort of frequency. Consequently, the material and the windings need to be selected very carefully.

The toroid is a 6.5 inch iron-dust unit from MicroMetals, part number "T650-52" and it can be purchased through their web site: http://www.micrometals.com/pcparts/torcore7.html and it can be purchased in small quantities via their "samples requests", which can be submitted at http://www.micrometals.com/samples_index.html

The Micrometals T650-52 Toroidal Core



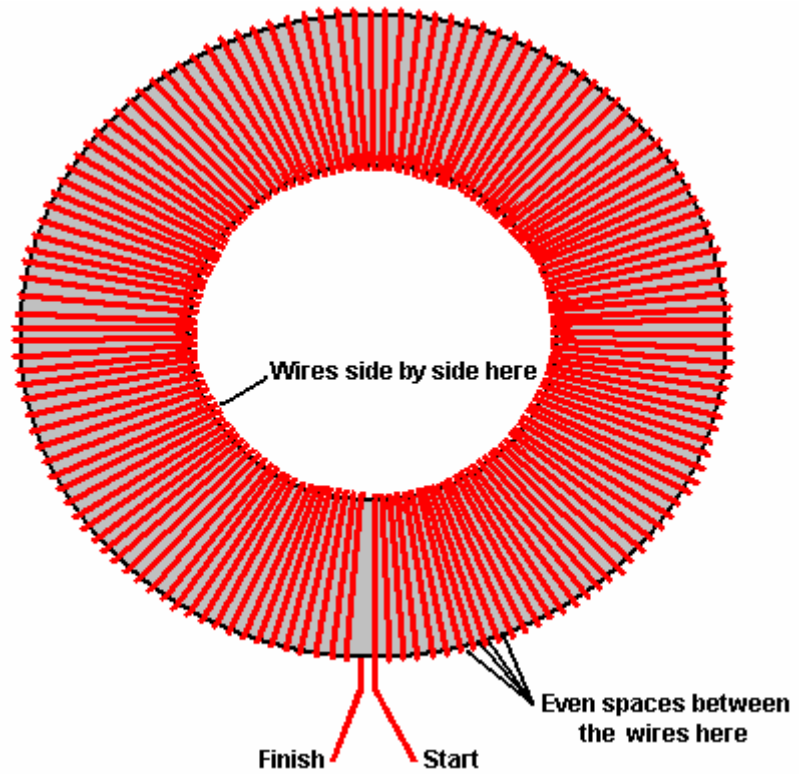
There are four windings made on this core. The wire chosen to wind the transformer is most important. Bob uses **solid** teflon-covered silver-plated copper wire. It is very important that this wire is solid core and **not stranded** as stranded wire does not work here (due to the generation of inter-strand, phase-differential induced eddy currents). At this time, a supplier of this wire is http://www.apexjr.com.

Before any winding is done, the toroid is given a layer of the yellow 1P802YE winding tape available in 3" rolls, both the 1" and 2" widths from: http://www.lodestonepacific.com/distrib/pdfs/tape/1p802.pdf. It is very important to avoid using fiberglass winding tape anywhere in the construction of this wound toroid. Bob comments on this as follows: "Big warning here !!!! **DO NOT USE FIBERGLASS WINDING TAPE !!!!** A big box of 3M winding tape was ordered by accident so I tried it to see if it would work. It not only suppressed the acousto-resonance response of the entire wound toroidal core, but for some strange reason it also caused the electrostatic pulse response of the secondary to **reverse polarity** as well as reducing the signal amplitude to a mere 10% of what it was !! It totally negated the benefit of the teflon insulation".

Having covered the toroid with a layer of the 1P802YE winding tape, the secondary winding is made. Again, it is very important that the teflon-covered, silver-plated solid copper wire is used. This is not a system which provides COP>1 performance if any old components are thrown together carelessly during the building process.

The winding turns must be evenly spaced where they fan out from the center of the core. They are tightly packed side by side in the centre opening and they must be wound tightly and the gaps between adjacent turns along the outer edge must be exactly the same. This is not to make the winding look "pretty" but if this is not done, then it will cause magnetic field errors that will lower the overall efficiency when the toroid is being used.

The secondary winding is made using 16 gauge wire which covers the entire length of the toroid as shown here:



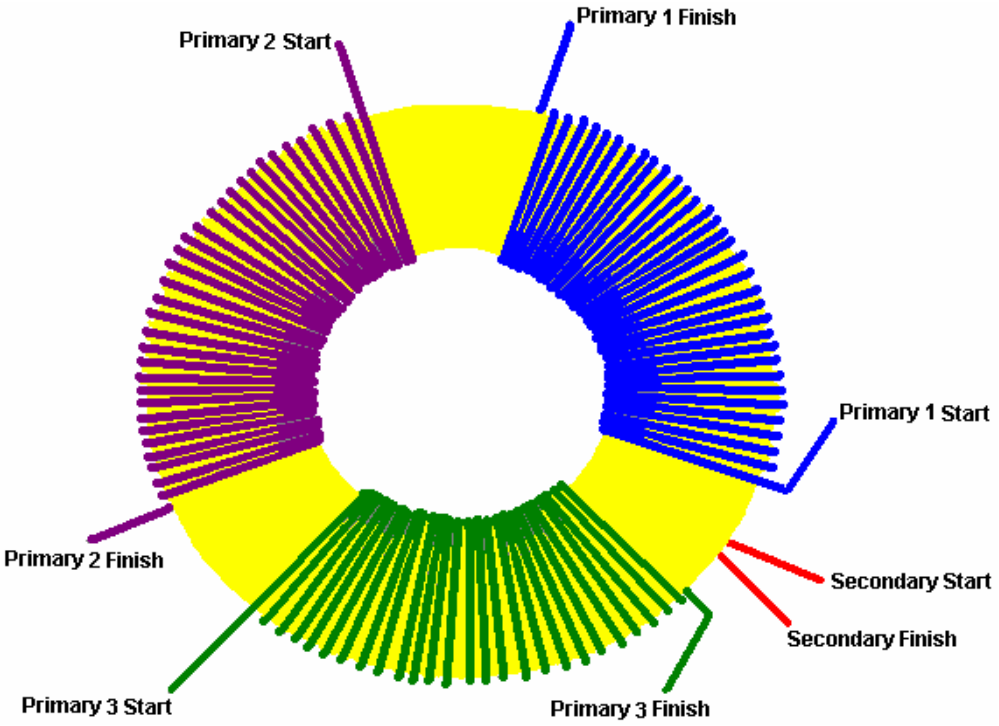
If the spaces between the wires are not quite even, then the turns can be pushed into exactly the right place. It is sometimes convenient to use two-inch lengths of plastic strimmer line placed between the turns in order to get the spaces between the turns exactly the same. These can be held in place with a strip of the yellow winding tape:

The picture above has been taken to show what a partially prepared secondary winding looks like when its windings are being moved into their exact positions. When a section of the windings has been spaced accurately, the triangular gaps between the evenly-spaced turns are filled in with beeswax, made pliable using a heat gun. A plastic bottle pushed into the central hole can be helpful when doing this filling. When the beeswax has hardened on both sides of the toroid, the process is then repeated for the next group of turns.

When the winding is complete, with even spacing of the turns and the gaps filled with beeswax, the whole of the toroid is then covered with a layer of the yellow winding tape, as shown here:

So, to recap: the toroid is wrapped in tape, the secondary winding completed, extending the entire way around the toroid, the windings carefully spaced out so that the gaps around the outer edge of the toroid are exactly equal, the winding gaps filled with beeswax, and then the toroid covered with a layer of the yellow tape. There will normally be anything from 127 to 147 turns in the secondary winding due to manufacturing tolerances in the insulation of the wire and so the overall wire length will be about 100 feet.

The primary windings are now wound on top of the tape layer covering the secondary winding. As with the secondary, the direction of the turns is very important.



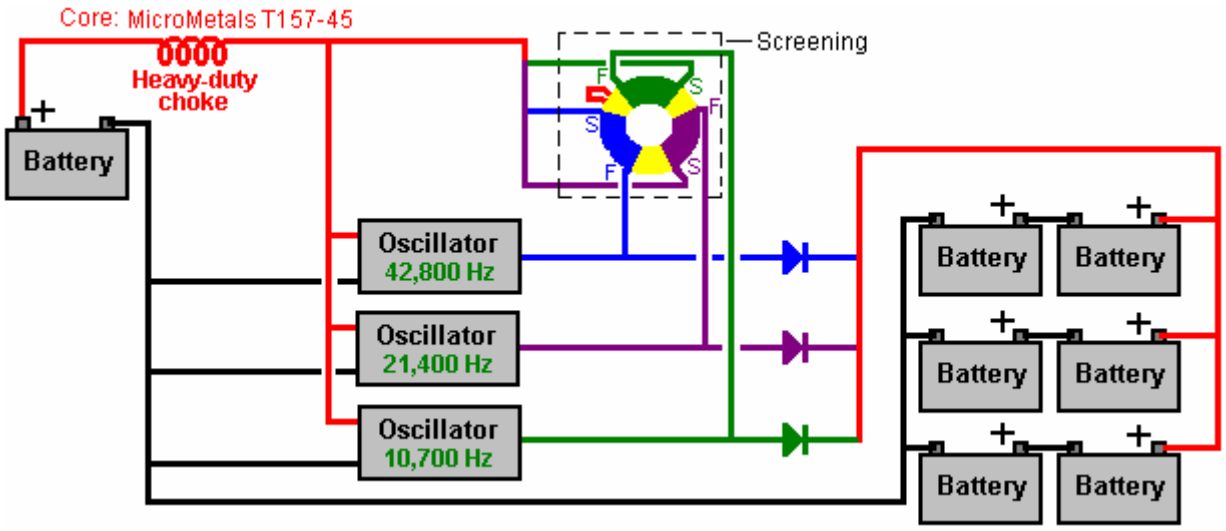
Please note that every winding starts by passing **over** the toroid and then being brought up on the outer side ready for the next turn. Each of the following turns proceed in a counter-clockwise direction, and finishes by passing **under** the toroid. Every winding is created in this way and the quality of workmanship is very important indeed when making these windings. Each winding needs to be tight and positioned exactly with turns touching each other in the centre of the toroid and positioned on the outer edge with exactly equal spaces between each turn. Your construction work **has** to be better than that of a commercial supplier and needs to reach the quality demanded by the military.

The three primaries are wound on top of the tape which covers the secondary winding. These three primary windings are spaced out equally around the toroid, that is, at 120 degree centres and the leads of the secondary winding are taken out through the gap between two of the primary windings and **not** taken out through the middle of a primary winding. As with the secondary winding, the primary winding turns are spaced out exactly, held in place with beeswax, and then tightly taped over. The primaries can have more than a single layer, and they are

wound with the same direction of winds as the secondary, and with the same care for exact turns spacing as needed for the secondary winding. Tape the entire core well with tightly-stretched PVC electrical tape after winding, to ensure that the primary windings do not move and then add an outer layer of the winding tape.

This toroid pulls in additional energy from the immediate environment when driven by very high quality voltage pulsing applied to each of the three primary windings. The full details of this system have not yet been disclosed, but Bob has said in open forum that he has demonstrated his toroid being pulsed with the secondary not connected to anything and the output is triple the current at twice the input voltage, with is COP=6. When the ends of the secondary are joined together the output current doubled, giving COP=12, that is, twelve times as much power output as the input which Bob had to supply to get that output. This is, of course, not a case of energy being created (which is not possible) but instead, it is a case of eleven times the input power being drawn in from the surrounding environment.

I have never seen the circuitry for this, but it may be as shown here:



As the output voltage is doubled, the battery bank being charged can be double the voltage of the battery supplying the input power. The choke in the lead from the input battery positive is to direct the power generated to the charging batteries. Each primary winding is driven by it's own separate oscillator which has adjustable frequency and adjustable Mark/Space ratio, or "Duty Cycle". The Duty Cycle is set initially to about 25% which means that the input power is turned off for three quarters of the time. The highest frequency oscillator is adjusted to give the largest charging output current. Then, the middle frequency oscillator is adjusted to give the highest charging output. Finally, the lowest frequency oscillator is adjusted to give the highest charging output. When that has been done, the Duty Cycle of each oscillator is lowered as far as possible without lowering the charging rate. An oscilloscope is not needed for any of these adjustments.

It should be noted that what was marked as the "Start" of each primary winding in the diagrams showing how each winding is done, is connected to positive power supply line and the end marked "Finish" is connected to the output of the oscillator. This connection arrangement is very important because connecting them the other way round is likely to give a much lower performance.

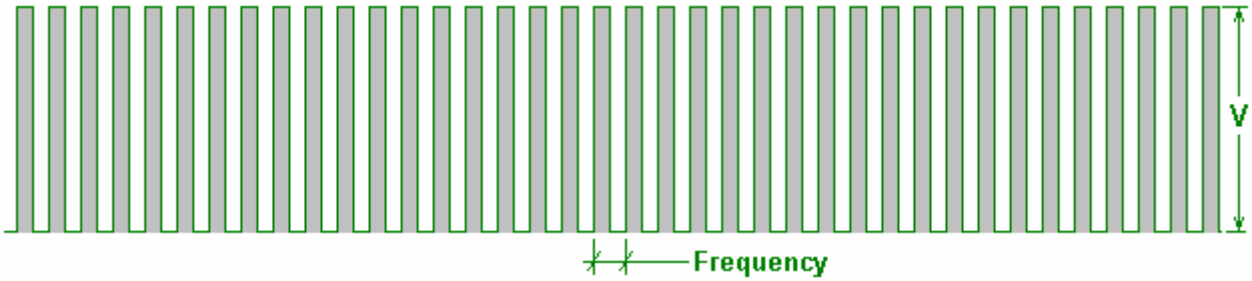
The three oscillators are quite independent of each other and are free-running. In other words, they are not synchronised in any way and will produce all sorts of different combinations of composite output waveforms as a result of this arrangement. It must be noted that this is **not** a system which produces a rotating magnetic field as the windings are **not** pulsed sequentially. As already mentioned, the voltage output waveform from each of the oscillators must have very sharp rise and fall times and the output must, of course, be capable of supplying sufficient current to power the primary windings.

I have never seen an explanation of how this system works, and please remember that the circuit shown above is based on my guesswork and does not come from Bob Boyce. However, I will now suggest a possible mechanism for the way that the circuit works, and for it, let us assume that there is only the highest frequency oscillator connected: When there is an output pulse from the oscillator, a powerful current passes through the primary winding to which it is connected. This generates a strong magnetic pulse. But, since the winding is around a high-quality toroidal core, nearly all of the magnetic flux races around the toroid instead of radiating outwards. That magnetic pulse induces an electrical pulse in both of the other two primary windings, and so all three windings provide a current surge to the battery bank being charged. One pulse in, produces three pulses out,

which matches the observed tripling of the input current.

(This suggests that if there were four primary windings that there would be an increased COP result for that arrangement. If that were done, then the fourth oscillator might run at around 85,600 Hz). The short-circuiting of the ends of the secondary winding produces a further increase in the output. I would suggest that this may be due to the fact that the turns ratio of the primary-to-secondary winding, produces a much higher voltage in the secondary winding. If the ends of the secondary winding are connected, then that induced voltage will generate a strong electrical current flowing through the secondary winding. That current will in turn, generate an even greater magnetic pulse, both in the toroid and in the primary windings which are wound around the secondary winding. This enhanced magnetic pulse may account for the enhanced electrical output to the battery bank being charged. Please remember that this not a matter of fact, but just a suggestion which I am putting forward as being a possible explanation of how the circuit is functioning.

Please remember that the toroid has to be able to handle frequencies far higher than the pulsing rate which is applied to it. A high-frequency waveform looks like this:



If you apply that frequency to Bob's toroid, then the toroid needs to be able to handle the waveform cleanly, without degrading it in any way. For this sort of application, an iron-dust toroid such as the MicroMetals product is essential. What many people have difficulty in seeing, is that even if the overall frequency of the signal is lower, as shown here:

in order for the rising edge of the waveform to be handled cleanly, the toroid has to be able to handle a very high frequency signal. The toroid doesn't "know" that the leading edge of the waveform is not going to be followed by a whole stream of very short, very fast, high-frequency pulses. So the toroid has to be able to handle high-frequency waveforms in order to deal with the very sharply rising leading edge which is essential for the successful operation of this and many other free-energy devices.

Bob Boyce has experimented with the much more dangerous rotating magnetic fields type of circuitry and he says:
While working as an engineer for a government subcontractor, I became aware of a problem with a switcher power supply, which under certain temperature and load conditions, would go into over unity operation. Sometimes these would fail in a big way and totally destroy the load. There was far more damage than the power source to the power supply was capable of delivering. The power supply used an on-board toroidal coil wound with teflon insulated, silver-plated solid copper wire on Honeywell powdered iron cores. I guess that this was what started my interest in this. When I went into business for myself, I had the time to devote to research and experimentation.

My early radiant energy research and experimentation were with attempting replications of Tesla and Moray devices, as well as many others. I found a copy of Dr. Hans A. Niepers' book "Revolution" ISBN 3-925188-07-X. In that book there is information about many devices related to the conversion of gravity field energy.

My first foray into a 3-phase device was during experimentation with a g-strain energy absorber as theorised by professor Shinichi Seike. Needless to say, the results were not what I expected when I connected a 3-phase air core toroid to the 3-phase outputs of the g-strain energy absorber board.

I had been doing these experiments at home and that was where my lightning strike injury occurred in 1995. That put an end to my 3-phase research for a number of years. When I did start back into it, I soon tired of the expense of burned out electronics and loads. I went back to the lower powered single-phase transformers and stuck with that until I worked out some of the control issues which would allow me to get back into the 3-phase design in a more controlled manner. I wish that I had heard of Steven Mark sooner as that would probably have saved me some time. Like Steven, I learned to have a very healthy respect for this stuff.

The interesting part is that the experiment was not running at the time of the lightning strike, but the strike did enter the room where I had been running an earlier experiment with the 3-phase toroid driven by the g-strain energy absorber board. I am under the impression that the running of the experiment had somehow imprinted an energy pattern upon me which may have attracted the lightning to me. The lightning entered the room, entered my right hand, exited my right ankle and left the room via the telephone line. I was quite understandably shaken up, but I was able to drive myself to St Mary's Hospital (in West Palm Beach, Florida), where I was treated in the emergency room, and released. The pain in my chest afterwards was something which I would not wish upon anyone! All I could really do was to take pain pills until the pain subsided. Considering that I had a well-grounded (by three 20-foot long half-inch diameter copper pipes, one connected to each leg of the base, and a 20-foot long half-inch diameter copper pipe at each guy point) 160-foot radio tower only twenty feet away from that room, the entire house should have been protected under the "cone of protection" provided by that tower. That particular lightning strike defied all common sense of good lightning protection. It was as if it targeted me directly, despite the well-protected location. I have had avalanches occur since then, but I make darned sure that I am very well protected against lightning before running any of these experiments now. I have had the metal building struck but it has not penetrated inside. There are 8-foot long, five-eighths inch diameter copper clad steel ground rods at each corner of the building. I have an 8-foot by 10-foot PVC utility building in which I can run an experiment while I watch on a closed-circuit TV monitor, from the safety of my metal building.

The core does provide stability. I use a low-permeability core in order to avoid saturation from the bias. The lower the frequency, the fewer impulses (kicks) there are per second which results in a lower power density but it also lowers the relativistic effects in the core. So sure, it is a trade-off of control versus power. If the controller were to be fitted totally within the "eye of the storm", that is, in the centre of the toroid space, then the power density could be greatly increased. My main concern would be losing control in a runaway situation with the controller ignoring command signals from the outside due to these relativistic timing changes. Energy induced in even DC control wiring can override those control signals. You would not want to be anywhere near that if it happened.

I do not like to use ferrite or laminated iron cores. With their high permeability, they can only be used at very low frequencies and very low power densities.

One of the features of this power source is that it seems to adapt to the load (within reason, of course). Load impedance is fairly important for getting maximum power output, due in part, to the High-Frequency portion of the energy riding on the DC output. Momentary short-circuiting of the output does result in a plasma-like discharge arc.

From what I can see, my toroid and that of Steven Mark do look to be very similar. The primary differences that I can see are the core material and the number of poles. It sounds and looks like Steven Mark used stranded copper wire and 4 poles, while I use powdered iron and 3 poles in my current device. Otherwise, both seem to build up a swirling electromagnetic vortex during operation.

Over the years, I have used other core materials with varying degrees of success. I started out with laminated iron cores on 2-phase devices bin the mid 1980s and ten progressed to air-core 3-phase devices in the early 1990s. One of the first units on which I tried 3-phase operation was a Seike "g-strain energy absorber" which I had connected to a hand-wound 3-phase air-core toroidal coil. Talk about uncontrolled operation! But I kept at it, unaware of the dangers. Since I was no longer doing the HHO gas research at that time, I was obsessed with trying to replicate Tesla and Moray research on a shoestring budget. After my lightning strike injury in 1995, I mothballed that line of research until I had the time, energy and funds to continue. I refused to apply this 3-phase design to practical application until the control issue cold be solved.

One technique which can be used to improve the power density at low frequencies is to go from 3 primaries to 6 primaries, that is, two phased sets of 3-phase drive coils.

In March 2012 a similar style of circuit design is to roll out the first 200 commercial units from a company in South Africa. The http://pesn.com/2012/02/22/9602042_South_African_Fuel-Free_Generator_Preparing_for_Market/ web site of Stirling Allan covers many of the details of these units. The expected price for a self-powered 5 kilowatt unit is US $6000 and there are other units of up to 40 kilowatt output. Stirling has visited the company in South Africa and witnessed the device in operation and was due to receive one of these units in March 2012, but

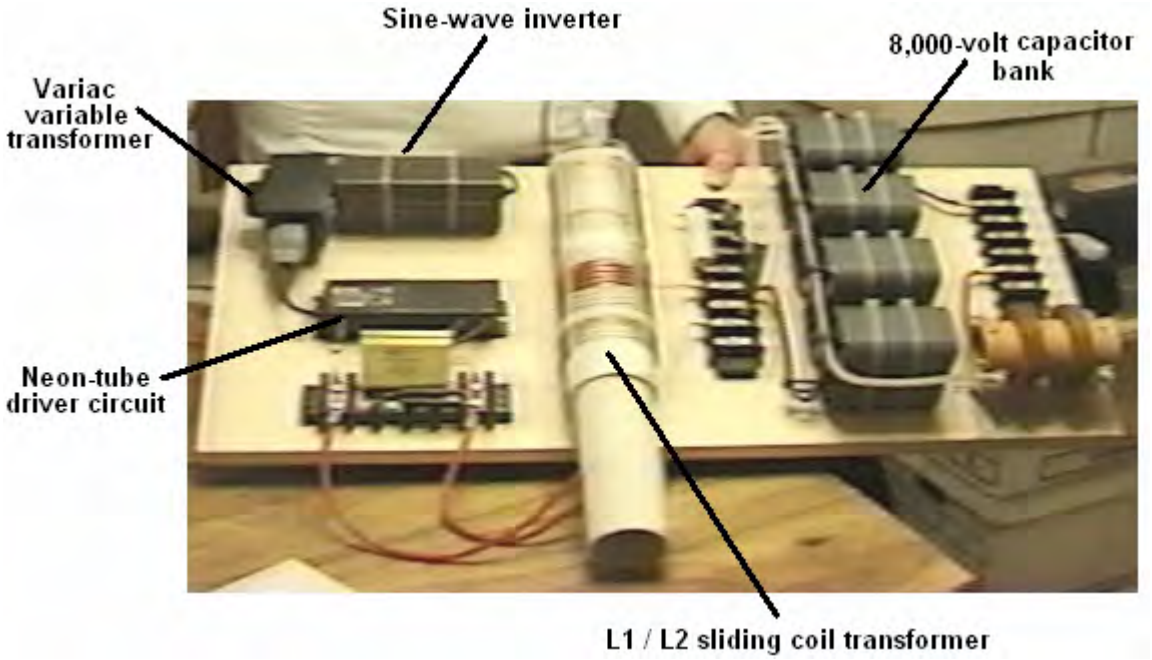
delivery has been delayed due to the batteries stopping operating after three months of use.

Don Smith's High-Power Devices.

Don Smith was a very talented American who has understood all of Tesla's work and has produced literally dozens of practical devices based on his understanding. You will find more specific details in chapter 3, but in broad outline, a twelve-volt battery can be used to generate the pulsing magnetic field needed to nudge the local environment into providing massive amounts of electrical energy. The device described in detail in chapter 3, has an output of around 160 kilowatts, which is far, far more than any individual would need. In other words, it is a device which could easily power your home, and considering that an electric car needs about 65 kilowatts, one could easily power a vehicle, making it into a fuel-less mode of transport. This is not magic, just standard electrical theory being applied correctly for a change.

The key component in many of Don's devices is the humble, commercial power supply used to drive neon sign displays. This module produces some 9,000 volts at a frequency of 35,100 Hz (cycles per second). As Don points out, when you double the pulsing frequency and double the pulsing voltage, the available power goes up by a factor of sixteen times, because the effect of both of these things is squared. You will recall that Bob Boyce is pulsing his toroid very sharply at 42,000 Hz and that high frequency has a major effect on the power produced in his system.

Don then boosts his working voltage further with a step-up transformer called a Tesla Coil. This brings us into an area of massive power. People have the very mistaken idea that a Tesla Coil can only produce voltage and not current. The reality is that if the primary coil is positioned in the centre of the secondary coil, then the voltage and current produced will be roughly the same, and that is a very, very high level of power. One device of Don's looks like this:



This prototype is actually more complicated than it needs to be. It uses three very high-voltage capacitors which are not necessary if you opt for a slightly different method of construction. However, in this version, the twelve-volt battery (which is not shown), powers a true sine-wave inverter in order to provide the mains voltage and frequency needed by the neon-tube driver circuit. The voltage limitations of the capacitors, in particular, the 8,000-volt output storage capacitors, make the 9,000 volt output of the neon-tube driver too much for safe usage. To deal with this, Don uses a Variac-style variable transformer to lower the voltage supplied to the neon-tube driver circuit, and this lets him limit the output voltage to the 8,000 volts of the output storage capacitors.

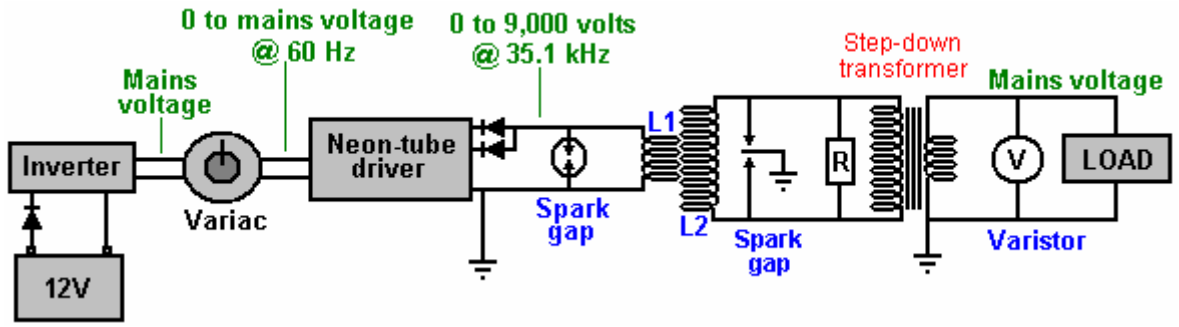
A key detail is that the wire length in the turns of the short primary winding of the Tesla Coil is exactly one quarter of the wire length of the turns in the long secondary winding. This makes the coils resonate which is a vital factor in the operation. The final, exact tuning, can be done by sliding the primary coil to a slightly different position. In this prototype, Don chose to do the final fine tuning by attaching a small capacitor across each of the windings. This is not necessary.

In the prototype shown above, Don then uses four diodes to rectify the output to DC to feed the storage capacitors. This results in an 8,000 volt supply which can provide 20 amps of current. That is an output power of

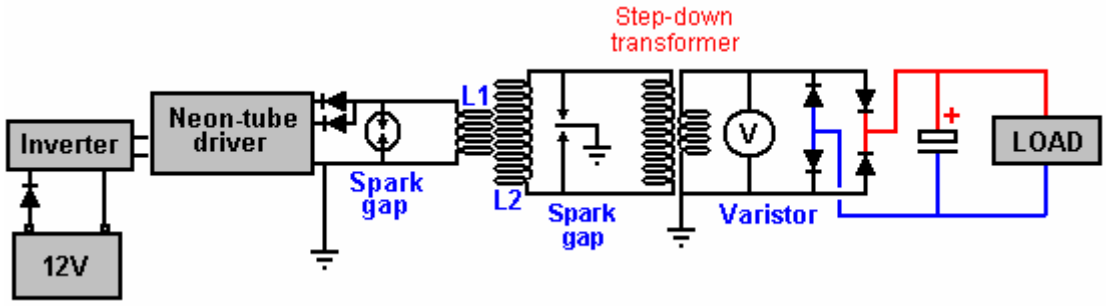
160 kilowatts, and is limited by the output capacitor voltage rating.

Don points out that it is not necessary to do it that way and instead, a step-down transformer can be used to lower the output voltage and boost the available current. If this is done, then the voltage limitations disappear (provided that you are using very high-voltage cables) and so no Variac is needed and no high-voltage capacitors are needed either.

There are two options. Either you can aim for a mains-voltage, mains-frequency, AC output, or you can produce a DC output and use an off-the-shelf inverter to run any mains equipment powered by the device. With the first option, Don connects a single resistor across the primary of the step-down transformer and that drags the frequency down to the wanted level, provided that the resistor has the right value:



The alternative method which aims for a DC output does not need to alter the frequency:



In both of these cases, the twelve volt driving battery can be charged continuously by part of the output power, and there are various ways of doing that. However, care needs to be taken that the battery is not overcharged as the input power is very low.

You will notice the similarity between Bob Boyce's toroid system and Don Smith's Tesla Coil system. In each case, a very carefully wound circular winding is pulsed at high frequency, and in each case, substantial amounts of excess electrical power becomes available, flowing in from the surrounding environment, courtesy of the pulsating magnetic field.

Tariel Kapanadze's Self-Powered Generators.

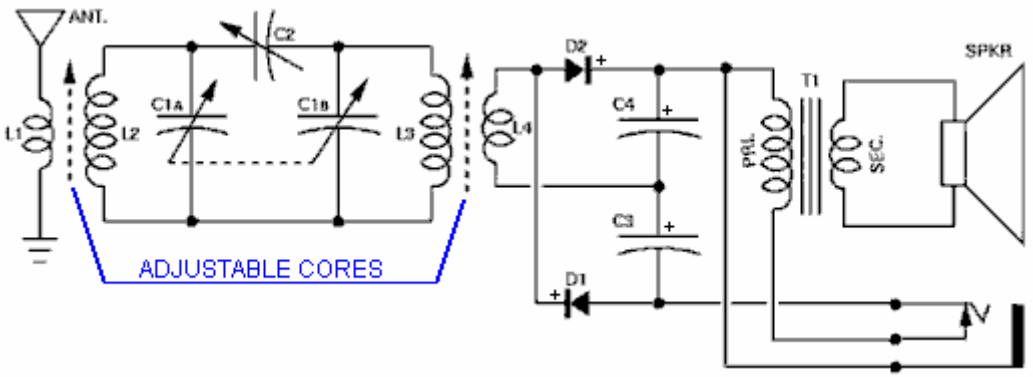
Tariel Kapanadze produced a similar style of device which is self-powered and produces a mains electricity output. He has demonstrated this for a TV documentary. Further details available are in chapter 3.

The Insights of Vladimir Utkin

Vladimir has issued a paper in which he describes some of the very important work done by himself and members of a Russian forum. He has major insights into the work of Tesla, Don Smith and others. With his kind permission, his paper is freely shared here http://www.free-energy-info.tuks.nl/VladimirUtkin.pdf.

Walter Ford's High-powered Crystal Set

In the 1961 edition of the Electronics Experimenter's Handbook, there is an interesting circuit from Walter B. Ford for a high-power crystal set capable of powering a 2.5-inch loudspeaker:



PARTS LIST

C1a/C1b-- 2-gang, 365-uuf. variable capacitor
(Lafayette MS-142 or equivalant)
C2-- 180-uuf. compression-type trimmer capacitor
C3, C4-- .005-uf. fixed capacitor
D1, D2-- 1N34A diode
J1-- Closed-circuit phone jack
L1, L4-- 22 turns of No. 24 cotton-covered wire
(see text)
L2, L3-- Ferrite antenna coil (Miller 6300 or
equivalent)
R1-- 47,000 ohm, 1/2 watt resistor
(*optional, see text)
T1-- Replacement-type output transformer; 3000-
to 10,000-ohm primary; 4-ohm secondary
Spkr.-- 2 1/2" speaker, 4-ohm voice coil (Lafayette
SK-65 or equivalent)
Misc.-- Hardware, wood, sheet aluminum, Fahnestock
clips, etc.

He says: Here's a pint-sized crystal radio with enough power to drive a 2·5" speaker. This little unit's selectivity is far better than you would expect to find in a crystal receiver and volume is equal to that obtained with sets using a transistor. No external power source is required.

The unusual selectivity of this radio is due to its special double-tuned circuit. A pair of diodes connected as a voltage-doubler provides the extra power to operate the small speaker. An output jack is provided for headphone listening and for connecting the set to an amplifier.

Construction: The model was built on a 2.5" x 4.5" wooden chassis with a 3.5" x 4.5" metal front panel. However, size is not critical, and other materials can be substituted if desired.

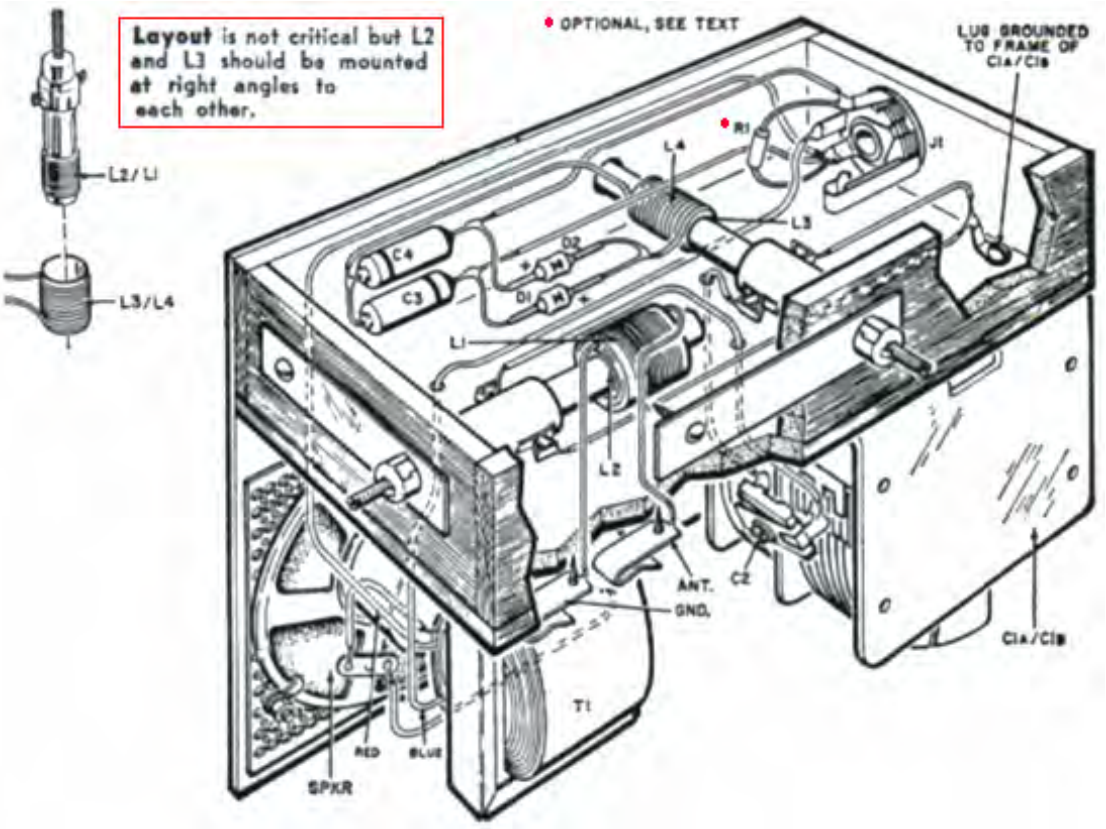
Two standard ferrite loopsticks, L2 and L3, are used. Both must be modified by the addition of a second winding. L1 and L4, respectively. Each of the added windings consists of 22 turns of No. 24 cotton-covered wire wound on a small cardboard tube as shown in the picture. (Actually, any wire size from No. 22 to No. 28 with cotton or enamel insulation will do the job).

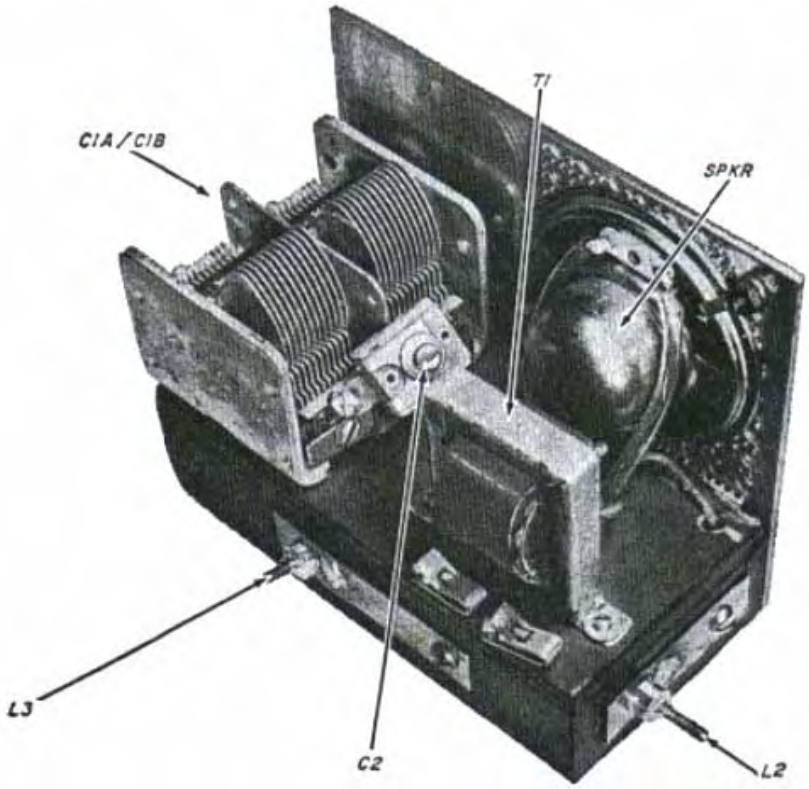
The diameter of the cardboard tube should be slightly larger than L2 and L3 so that L1 and L4 will slip overL2 and L3 easily.

Resistor R1 is used only for feeding the set into an amplifier; it should be omitted for both earphone and loudspeaker operation. Trimmer capacitor C2 should be soldered across the stator terminals of two-gang variable capacitor C1a/C1b as shown. The speaker and output transformer can be mounted wherever convenient.

If a metal chassis is used, then be sure to insulate the aerial and earth connection sockets from the chassis. When all of the parts have been mounted on the chassis, wire them together following the schematic and pictorial diagrams. Be sure that diodes D1 and D2 and capacitors C3 and C4 are connected correctly, paying attention to their polarity.

While this is interesting, what appears to be a key factor is contained in the drawings, where he states that the only important thing is that it is essential for the two sets of coils to be mounted perpendicular to each other:





Alignment and Operation. To align the receiver, connect it to an antenna and ground. The optimum length of the antenna varies with location, but 50 feet will usually be suitable in areas which receive several broadcast stations. Next, plug a high-impedance earphone into jack J1. Tune a station near the high frequency end of the broadcast band – say, 1500 kHz – and adjust the trimmer capacitors on variable capacitor C1a/C1b to get the loudest signal.

Trimmer capacitor C2 should then be adjusted for the best selectivity and volume over the entire broadcast band. Finally, Coils L1 and L4 can be moved to their optimum positions by sliding them backwards and forwards over coils L2 and L3. If a nearby station interferes with the reception of a weaker station, tune the slug of L2 to get minimum interference. For loudspeaker operation, simply unplug the earphone. Strong local stations should be received at fair volume.

How It Works: The receiver employs a double-tuned circuit feeding a crystal diode voltage-doubler/detector which drives a small loudspeaker. Radio frequency signals picked up by the antenna system are induced into coil L2 from coil L1. The desired signal is selected by the tuned circuit C1a/L2 and coupled through capacitor C2 to a second tuned circuit C1b/L3, which improves the selectivity by narrowing the radio frequency bandpass. The twice-tuned signal is then induced into coil L4 from coil L3.

The positive half of the radio frequency signal appearing across L4, passes through the 1N34A germanium diode D2 to charge capacitor C4. The negative half of the signal passes through diode D1 to charge capacitor C3. The polarity of the charges on C3 and C4 are such that the effective voltage is doubled. This voltage appears across the primary of output transformer T1 which converts the high-impedance signal to a low-impedance output suited to the loudspeaker.

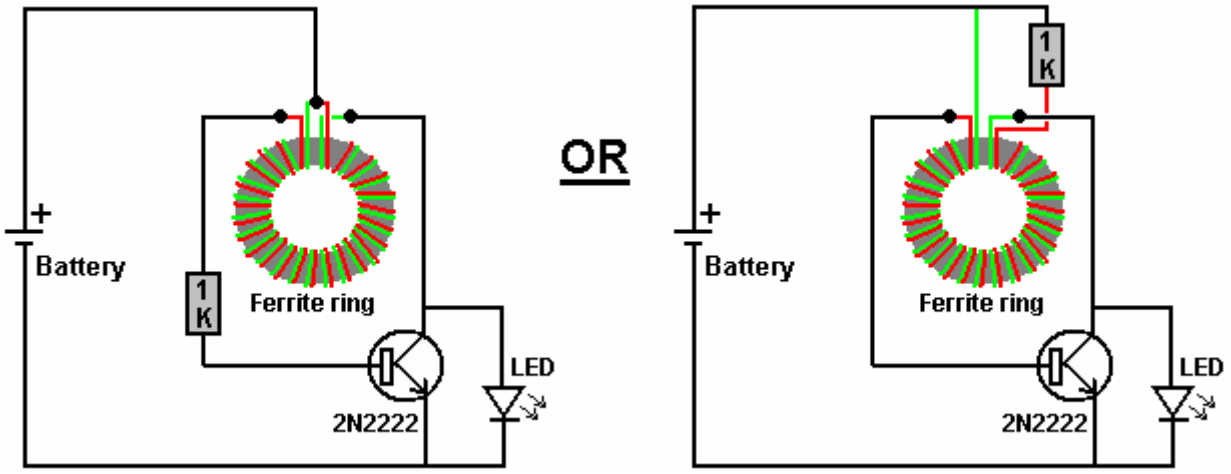
While this looks like a very good design for a crystal set, the fact that it is insisted that the coil pairs **must** be mounted at right angles to each other raises an interesting parallel with the above work of Vladimir Utkin where he states that if the high-frequency excitation field is at right angles to the output coil, then there will be a free-energy inflow into the circuit from the local environment. Perhaps this crystal set design gains extra power to drive it's loudspeaker from an inflow of environmental energy.

Lawrence Tseung's Self-Powered "FLEET" Generator.

The "FLEET" ("Forever Lead-out Existing Energy Transformer") device is a self-powered electrical generator which has no moving parts and which can be constructed cheaply. It has been developed by a Hong Kong based team of people: Mr Lawrence Tseung, Dr. Raymond Ting, Miss Forever Yuen, Mr Miller Tong and Mr Chung Yi Ching. It is the result of some years of thought, research and testing and it has now reached an advanced stage of testing and demonstration and is nearly ready for commercial production.

Mt Tseung has applied his "Lead-out" theory to the category of low-power circuits known as the "Joule Thief" circuits. These circuits originated with an article by Mr Z. Kaparnik, in the "Ingenuity Unlimited" section of the November 1999 edition of the "Everyday Practical Electronics" magazine.

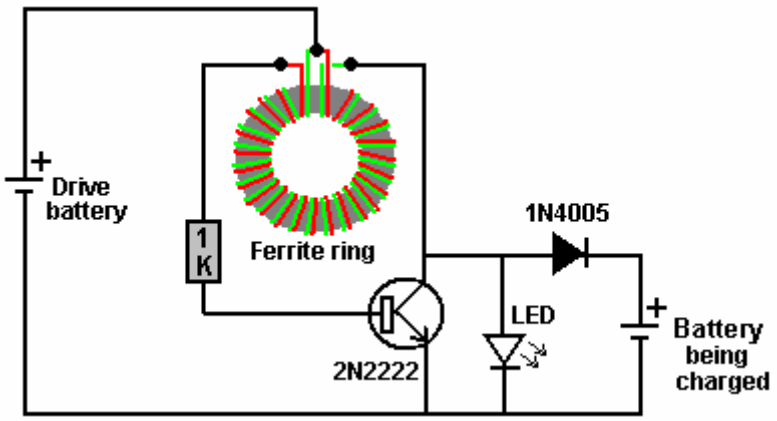
The initial circuit allowed the very last energy to be drawn from any ordinary dry-cell battery, and used to light a white Light-Emitting Diode ("LED") for use as a small torch. It allows a battery which is considered to be fully discharged, to drive the circuit until the battery voltage drops right down to 0.35 volts. The initial circuit uses a bi-filar coil wound on a ferrite ring or "toroid". Bi-filar means that the coil is wound with two separate strands of wire side by side, so that each adjacent turn is part of the other coil. A coil of that type has unusual magnetic properties. The Joule Thief circuit is like this:



It is important to notice how the coil is wound and how it is connected. It is called a "toroid" because it is wound on a ring. The ring is made of ferrite because that material can operate at high frequencies and the circuit switches On and Off about 50,000 times per second ("50 kHz"). Notice that while the wires are wound side by side, the start of the red wire is connected to the end of the green wire. It is that connection which makes it a "bi-filar" coil instead of just a two-strand coil.

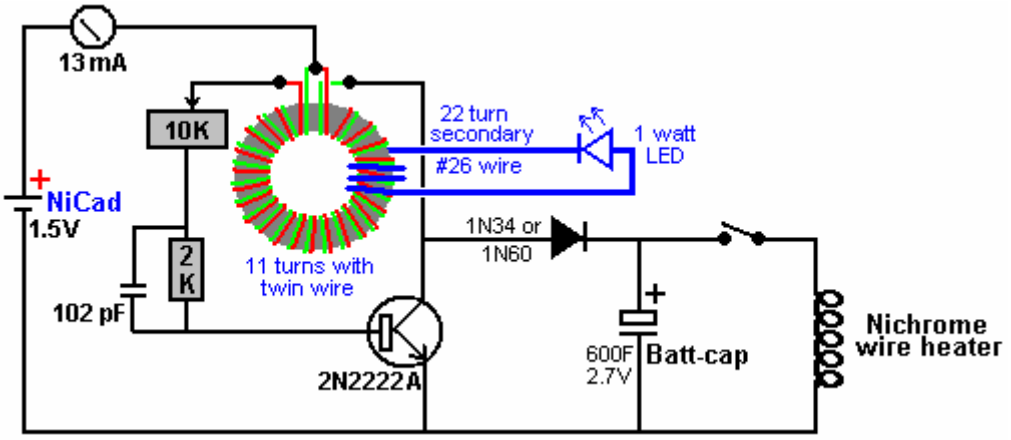
This "Joule Thief" circuit was then adapted by Bill Sherman and used to charge a second battery as well as lighting the Light-Emitting Diode. This was achieved by adding just one more component - a diode. The diode used was a 1N4005 type because that was to hand at the time, but Bill suggests that the circuit would work better with a very fast-acting Schottky-type diode, perhaps a 1N5819G type.

The circuit produced by Bill is:



When driven by a 1.5 single cell battery, this circuit produces about 50 volts with no load and can supply 9.3 milliamps of current when the output is short-circuited. This means that you could charge a 6-volt battery using a 1.5 volt battery.

“Gadgetmall” of the www.overunity.com Joule Thief forum has taken the circuit further and found a very interesting situation. He has modified the circuit and used a “batt-cap” which is a very high capacity, very low-loss capacitor. This is his circuit:



He has added an additional winding to his one-inch (25 mm) diameter ferrite toroid, and he uses that to power a 1 watt LED. Why he has done this is not immediately clear to me, except possibly, that it shows when the circuit is operating. He runs the circuit driven by a small rechargeable battery, which feeds 13 milliamps into the circuit, for a period of fourteen hours. At the end of that time, the batt-cap has gathered enough energy to fully recharge the driving battery in a minute or two, and then power a heater winding of nichrome wire (as used in mains-powered radiant heaters) for four and a half minutes. Alternatively, that amount of extra power could boil a kettle of water. The really interesting thing about this is that the driving battery gets recharged every time and so the circuit is self-sustaining although it is not a powerful circuit.

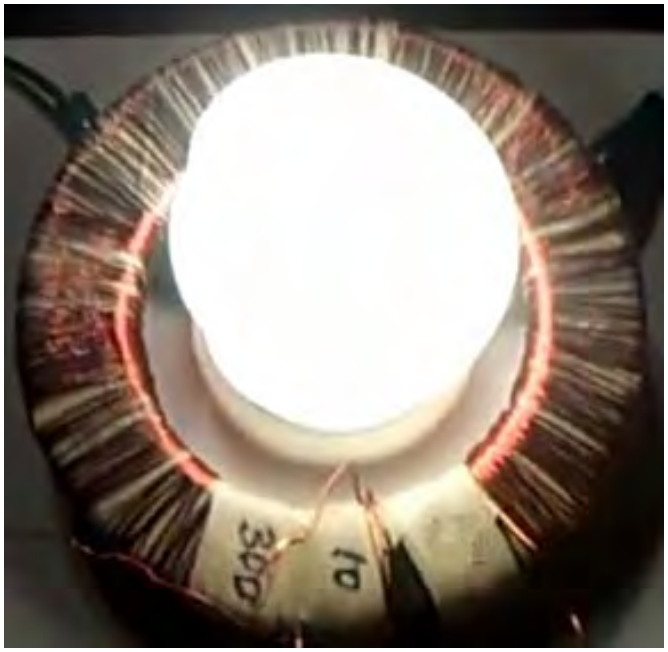
However, Jeanna has developed the circuit significantly as she shows in her series of videos:

http://www.youtube.com/watch?v=Y4IMgDRGpHE
http://www.youtube.com/watch?v=1tVlCJiuWH4
http://www.youtube.com/watch?v=y6pbzrhBR-8
http://www.youtube.com/watch?v=tNoZrV3w4f8
http://www.youtube.com/watch?v=XzhbsLBwc54
http://www.youtube.com/watch?v=4gj7IFCXw9Q

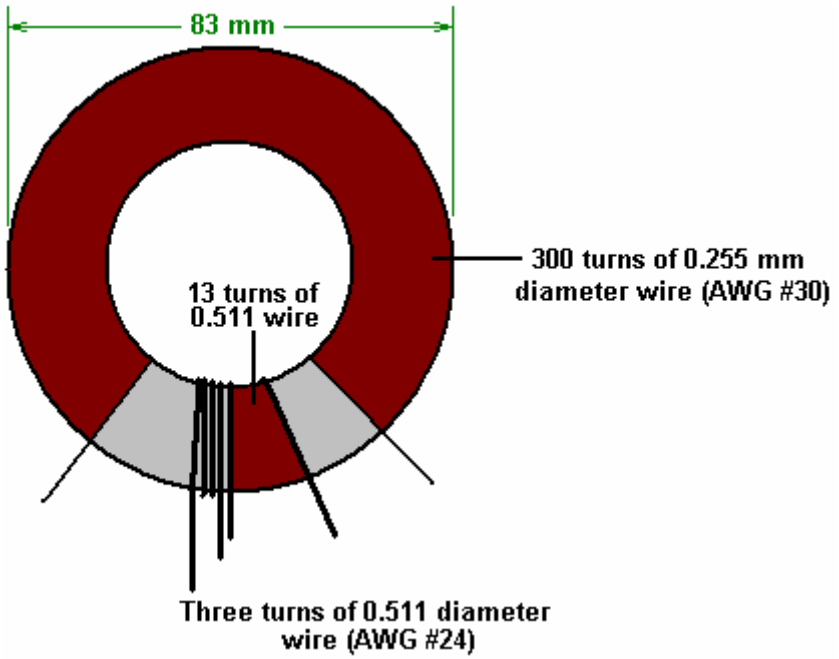
Her main point is that using the collector of the transistor as the power take-off point of the circuit, is inefficient as that draws a lot of input current without a corresponding increase in output current. She adds a 74-turn secondary winding on top of her two 11-turn Joule Thief bi-filar windings, and that appears to give a far better power output. She uses the very small AAA size 1.2V battery and further drops the output (because “the light is too blinding”) by putting a resistor in series with the battery and using many LEDs in series. She has recorded the following results:

With no resistor, the output voltage is 58V peaks at 62.5 kHz (open circuit output, with no load at all)
With a 10 ohm resistor, the output voltage is 49V peaks at 68 kHz.
With a 33 ohm resistor, the output voltage is 25V at 125 kHz.

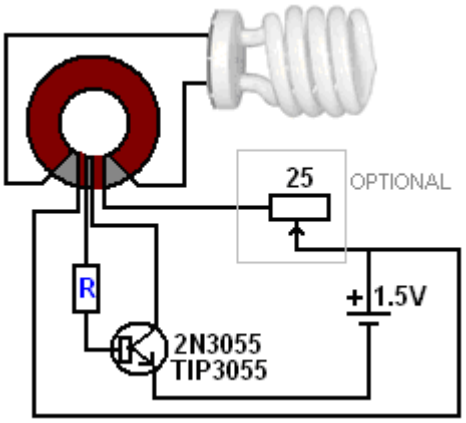
‘LidMotor’ states that Jeanna also produced a Joule Thief circuit which could light a 15-watt straight fluorescent tube for about five hours when being driven by a single AA battery. He states that he was not satisfied with that level of lighting and at https://www.youtube.com/watch?v=KAakZTR_4LE he shows a version (which he thinks is Jeanna’s design and which Jeanna thinks is his design) driving a 10-watt Compact Fluorescent Light which has had the ballast circuitry removed. The build uses an expensive 3.25 inch (83 mm) outer diameter ferrite toroid, and the lighting from a single AA battery looks like this:



The ferrite ring is wound like this:



The main winding is 300 turns of AWG #30 enamelled copper wire with a diameter of 0.255 mm. Please notice the gap between the ends of that winding. That gap is important as high voltage is developed between the two ends of the winding and if the winding were continued all the way round the toroid, then the insulating enamel coating the wire would be liable to burn out due to the very high voltage difference between the first and last turns, causing a short-circuit. The two other windings are with AWG #24 enamelled copper wire which has a diameter of 0.511 mm and those two windings are positioned closely side by side in the middle of the gap between the ends of the 300-turn winding. The circuit is like this:



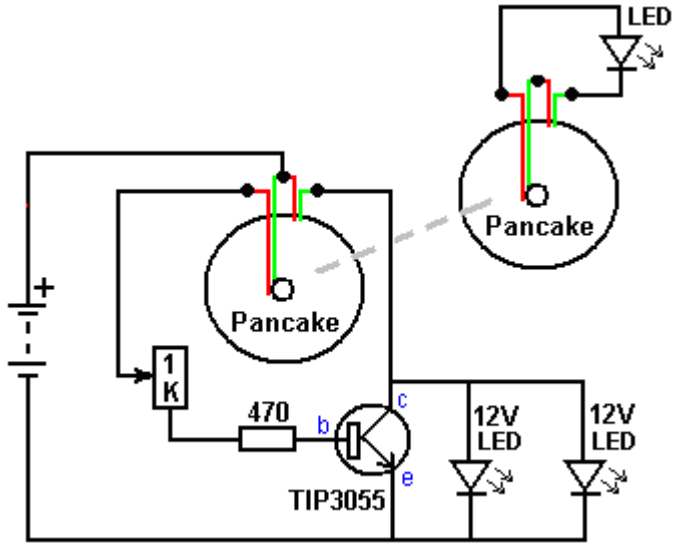
The optional 25 ohm wire-wound variable resistor wastes power but creates a voltage drop across it, reducing the voltage reaching the circuit and so, dimming the light progressively, all the way down to zero. The base resistor "**R**" has been set at 22 ohms by 'Lidmotor' who says that it really should be 100 ohms but he has lowered it to get brighter lighting. Please note which side of the 3-turn and 13-turn windings are connected in the circuit as the direction of winds is very important for those two windings.

It is not uncommon for people to comment on the faint whistling sound make by a Joule Thief circuit (especially a low-voltage version like this). It is my experience that the sound is caused by the transistor resonating with the frequency of oscillation of the circuit, the TIP3055 being particularly prone to this. I suggest therefore, that bolting on a heat sink (which is most definitely not needed to dissipate heat produced by this circuit) will alter the resonant frequency of the transistor/heat sink combination and so stop the whistling.

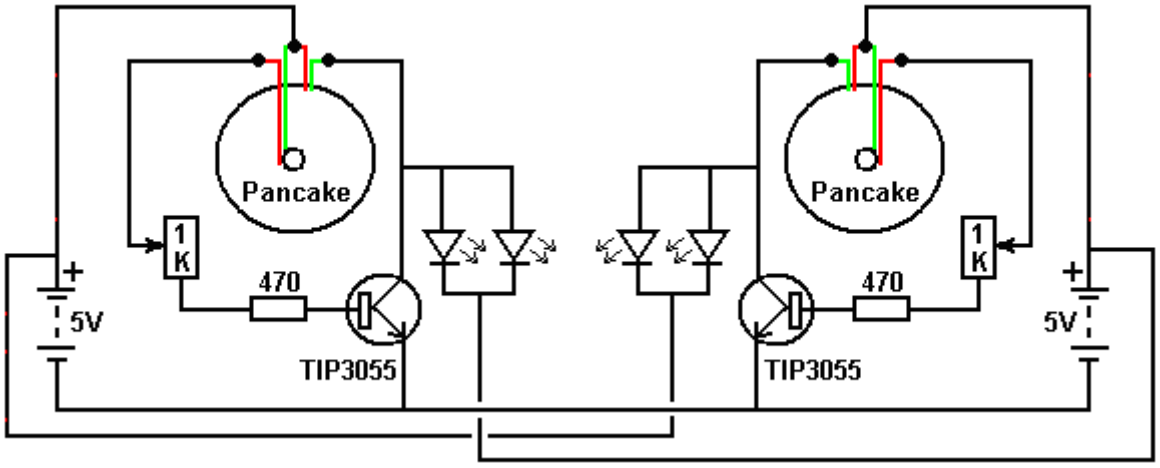
Personally, I have always had the greatest difficulty in getting any satisfactory light out of a Compact Fluorescent Lamp when driven by a Joule Thief circuit and so, for me, the best light source is one of the "G4" LED arrays with a "5050" driver chip. These look like this:

Quite good lighting can be had from a single Joule Thief circuit driving up to twelve of these simultaneously. The larger lighting area produces a more even and more gentle light which is quite effective in total darkness.

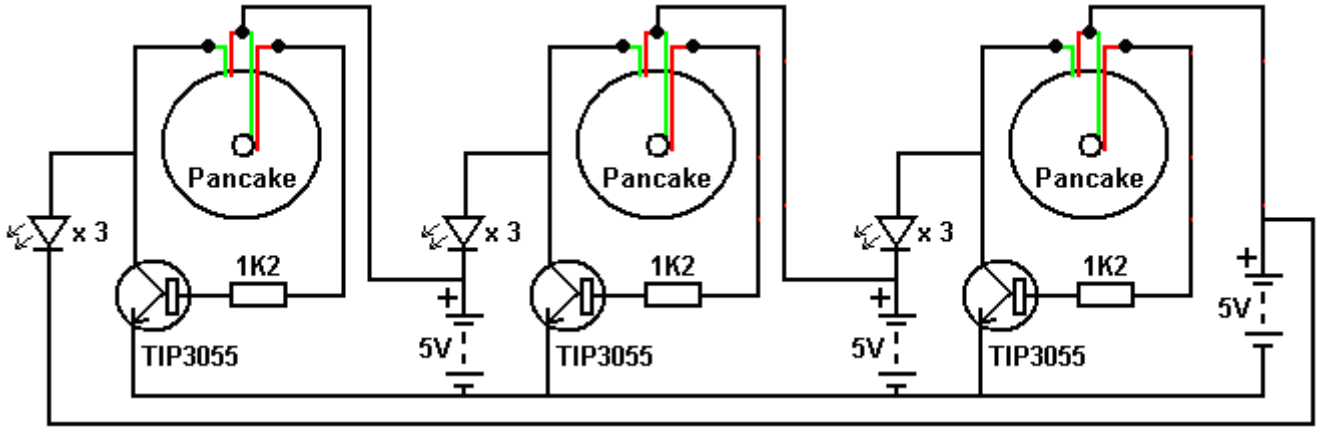
Most Joule Thief circuits specify a ferrite toroid, but a 75 mm diameter pancake coil also works well, and interestingly, pressing a second pancake coil tightly against the Joule Thief pancake coil, allows an additional LED array to be powered without increasing the current draw of the Joule Thief circuit:



It is also possible to cross-connect two or more Joule Thief circuits so that as well as producing 12V LED array lighting, each charges the battery being used by the other circuit:



And this works well with three circuits cascaded:



When working with these circuits, I bought a light-meter to take the guesswork out of assessing light levels as the human eye is very bad at doing that, although the visual impression of the lighting produced by any arrangement is actually more important than the measured lighting level. For example, there are 1-watt tiny LEDs, which have a theoretically high light output, but due to their tiny lit area are pretty useless for home lighting.

When I used the light meter (which measures in lux) I got a considerable shock. I used it with a light box to measure the light produced by two G4 LED arrays side by side, first with straight battery input and then with a Joule Thief input. The major shock was that the G4 LED arrays are actually more efficient at converting electric

current to light than when a Joule Thief is used to drive those same LED arrays. That was completely unexpected. The figures for voltage / current draw / light produced using 1.2V (nominal) NiMh batteries were:

9 batteries 11.7V 206 mA 1133 lux: 2.41 watts 470 lux per watt (the manufacturer's intended performance)

8 batteries 10.4V 124 mA 725 lux 1.29 watts 562 lux per watt

7 batteries 9.1V 66 mA 419 lux 0.60 watts **697** lux per watt (a very realistic performance level)

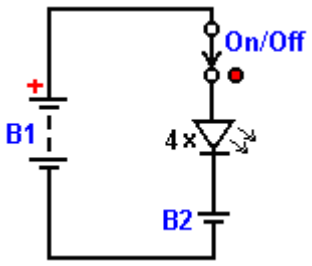
6 batteries 7.8V 6 mA 43 lux 0.0468 watts 918 lux per watt

A Joule Thief circuit driving two G4 LED arrays powered by 4 batteries giving 5.2V with the current draw controlled by selection of the transistor's base resistor:

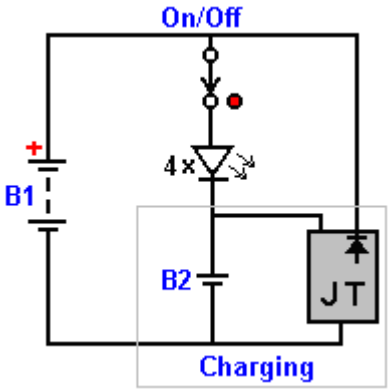
358 mA 259 lux 1.86 watts 139 lux per watt
200 mA 212 lux 1.04 watts, 204 lux per watt
180 mA 200 lux 0.936 watts 101 lux per watt
158 mA 182 lux 0.822 watts 221 lux per watt

This was quite startling, and the surprising conclusion is that using just four LED arrays driven by a 9V battery supply, produces a very respectable 800 lux for just 135 milliamps which is about 1.2 watts total – a very unexpected result. When the four LED arrays are fitted into a desk lamp and covered with frosted plastic to give a diffused light, the result is an excellent level of desk lighting which also lights the rest of the room quite well.

If you choose to do that, then it is possible to collect all of the current passing through the Joule Thief circuit, like this:

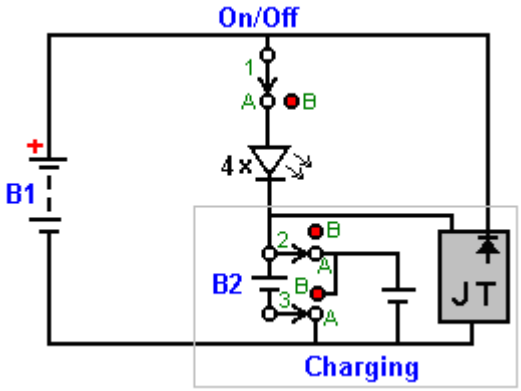


Here, the drive battery "B1" is made up with one battery more than the wanted voltage and all of the current passing through the four LED arrays is used as charging current for one additional battery which can be used to power a Joule Thief charging circuit:

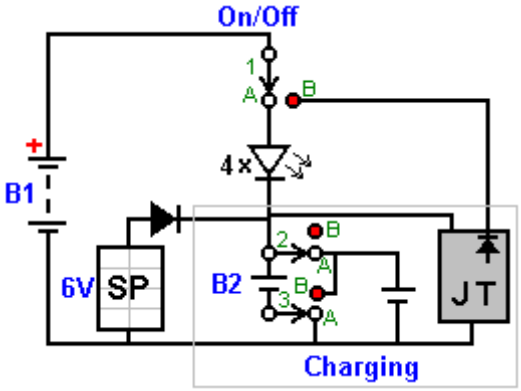


As the LED array lights are essentially diodes anyway, they have no problem with being supplied with current from a battery which is being pulse-charged by a Joule Thief, so there is the option of leaving the Joule Thief circuit connected all the time as shown above. That, of course, is optional.

One further thing which can be done is to allow for doubling the Joule Thief voltage when the light is off. While the Joule Thief charging circuit is perfectly capable of charging the "B1" battery when driven by a 1.2V battery, it can charge faster if its voltage is doubled, which can be done quite easily using a standard 3-pole, 4-way rotary switch:



or



Here, the “B2” battery is made using two 1.2V batteries connected in parallel when the light is on, and when the light is switched off, the two batteries are connected in series, driving the Joule Thief charging circuit with double the voltage. Another option is to connect in a 6V or higher solar panel to charge the “B2” battery during the day. It appears that although the charging circuit can run at all times, it is actually more effective if the battery charge is stored and the pulse-charging only starts when the light is switched off.

It needs to be remembered that NiMh batteries are only 66% efficient, which means that when they are driving a load, you will only ever get back again, two thirds of the current fed into them. Where the above circuits show just one Joule Thief charging circuit, there will normally be two, three or more charging circuits to raise the rate of charging during daylight hours. Also, if the battery powering the Joule Thief has a higher voltage than the battery being charged by it, extra diodes will be needed so that their combined voltage drop will prevent the charging battery feeding a large current directly into the battery being charged.

Mr Lawrence Tseung has taken the Joule Thief circuit and modified it to become a circuit with a very serious output, moving it into a completely different category.

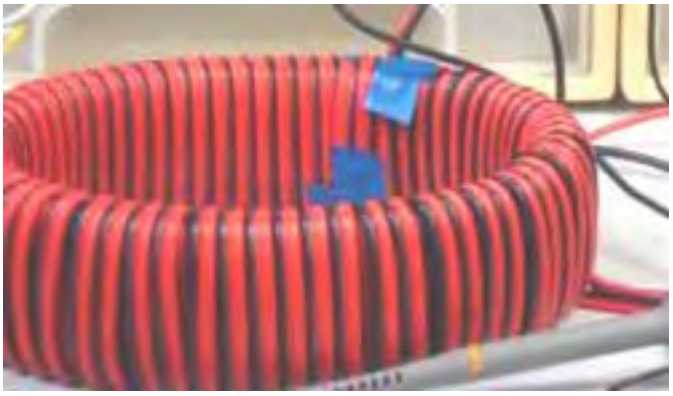
As a first step towards what the team calls their "Fleet" device, the toroid has been enlarged to a much greater diameter. The coil is now wound on a section of plastic pipe, 170 mm (6.5 inches) in diameter and 45 mm (1.75 inch) deep:

This section of pipe is "bi-filar" wound with two wires side by side as already described for the Joule Thief construction. As before, the start of one wire is connected to the end of the other wire. Then, the winding is given a layer of electrical tape to hold it in place and to provide an easy working surface for a second winding.

The wire used for the winding is the widely available red and black pair of wires, sometimes called "figure of eight" because the cut end of the wires looks like the numeral 8. The wire should be able to carry 2.5 amps. It must be side-by-side wire and **not** one of the twisted varieties. It looks like this:

The second winding is made in the same way but the connections are slightly different. As before, the end of the first wire is connected to the start of the second wire, but that connection is then insulated and not used in the following circuitry. This just connects the two windings one after the other, known technically as being connected

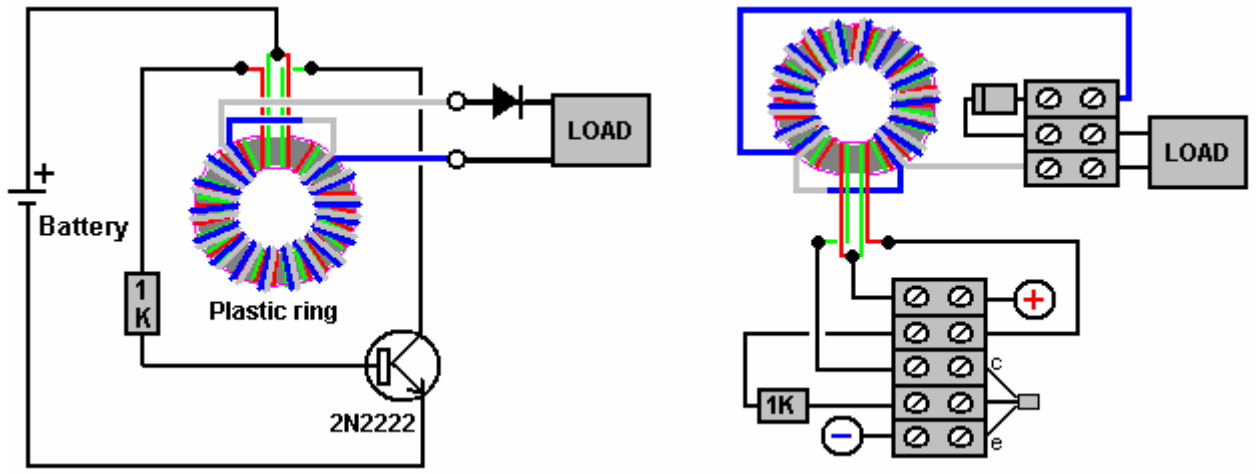
"in series" and is the equivalent of making the winding with just a single strand of wire. The completed coil may look like this:



This particular design is still in it's early stages and so many different coils sizes and constructions are being tested:

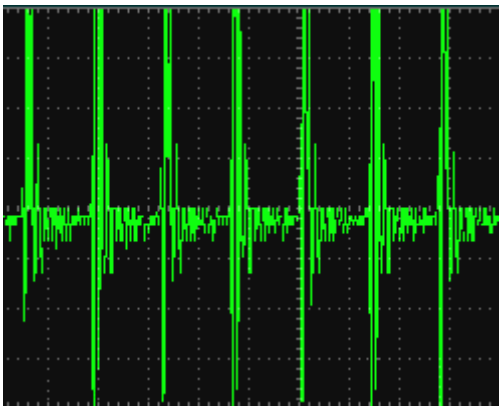
The arrangement is for the inner winding of the toroid to be oscillated by the Joule Thief circuit already described. This causes a pulsating magnetic field to envelope the outer winding of the toroid, producing an electrical output which is capable of doing useful work. The really important thing about this arrangement, is the fact that the amount of power coming out of the circuit is very much greater than the amount of power needed to make the circuit operate. The additional power is led out of the local environment and drawn into the circuit, becoming available to do useful work.

The overall circuit then looks like this:



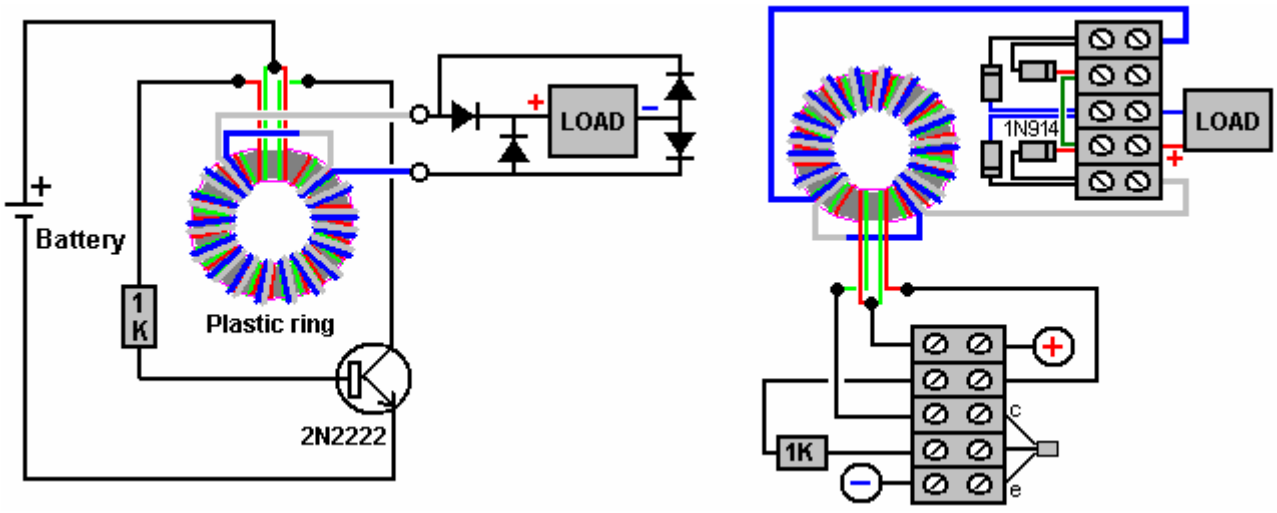
While the outer winding is shown here with thicker wire of a different colour, this is only to make the arrangement easier to understand. In reality, the outer winding is with exactly the same wire as the inner winding, and it will normally go all the way around the toroid. The total amount of wire needed to make the windings is about 70 metres and so it is normal to buy a full 100 metre reel of the twin-core wire, which allows both windings to be made and leaves spare wire for other things.

For those of you who are **very** technically minded, the output waveform looks like this:



and the voltage pulses in this output are occurring about 290,000 times per second.

What has worked better for me is using a bridge of four diodes rather than a single diode:



I have used this circuit, driven by a 1.5 volt battery, to charge 12-volt batteries, but the best results are in the five to six volt range. I have used this circuit to confirm COP>1 by charging one small 12V lead-acid battery with an identical battery, swapping the batteries over and repeating the process several times. The result was that both batteries gained genuine, usable power. I suspect that the effect would have been much greater if I had charged two or more batteries in parallel. The toroid was an 8-inch diameter, 10 mm by 12 mm offcut from a plastic pipe

which happened to be to hand and the wire used was plastic covered 6-amp equipment wire, again, because it was to hand at the time. Winding the toroid and setting up the circuit was done in a single evening.

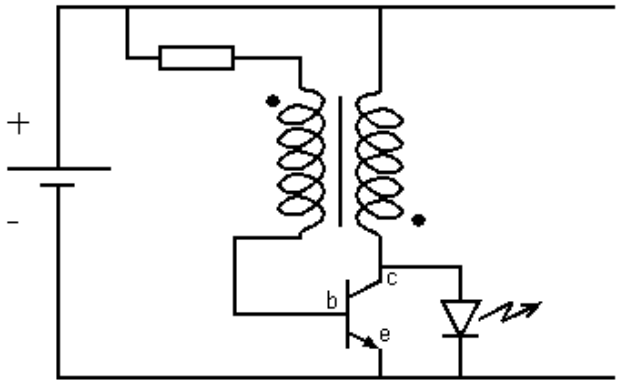
Overall, this is a very simple, cheap and easily constructed COP>10 device which has the potential of providing large amounts of free, useable, electrical power. With further development, it may well be possible to produce a version which could deliver the power needed by a whole household. It is also likely that these devices will become available for purchase a quite a low cost. All in all, this is a very important device and full credit must go to the development team who have carried the research to this point and who are continuing to refine the design to produce more and more power.

Advanced versions of the Joule Thief Circuit.

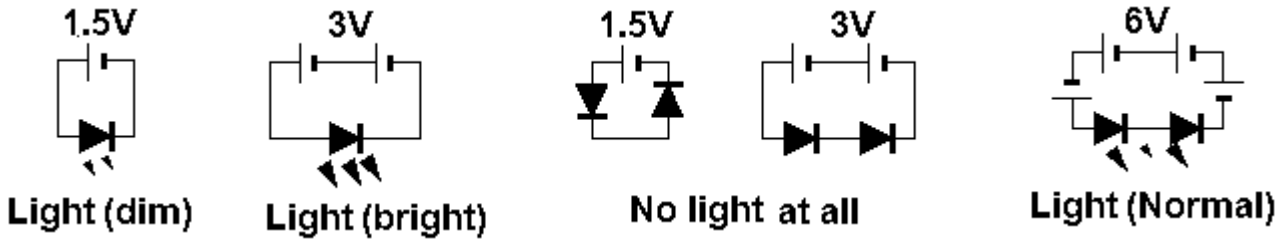
A contributor who prefers to go by his ID of “Ace_Propulsion” shows here a series of clever, innovative variations on the well-known Joule Thief circuit.

What is a Joule thief? A Joule Thief circuit is a minimalist self-oscillating voltage boosting circuit which is small, low-cost and easy-to-build. It is normally used for driving light loads. It can use nearly all of the energy in a single-cell battery, even those which are already far below the voltage level where other circuits consider the battery to be ‘fully discharged’ (or "dead").

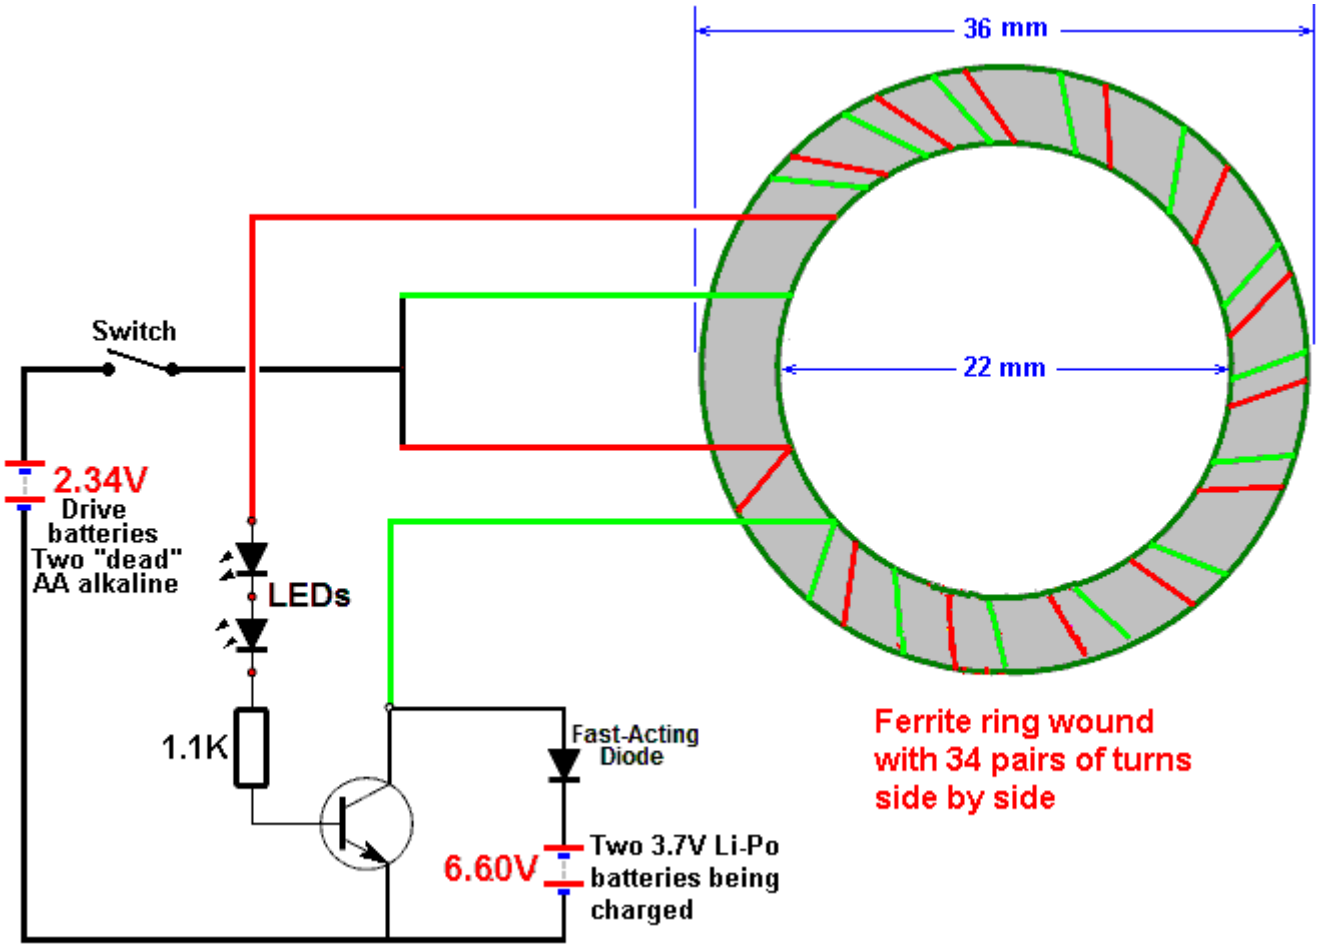
Notice the description "voltage booster". This means that the output voltage is increased at the expense of a higher input current draw. Conventional science says that a Joule Thief circuit can never ever achieve COP>1. A conventional Joule Thief circuit as shown below, will always have an energy loss between the Collector and Emitter of the transistor.



With proper modifications this circuit can acquire energy from the environment to power the output. This is quite simple to achieve. First, before we start discussing circuits, I'm going to tell you the weird stuff about LEDs:



Notice that you can illuminate an LED with just 1.5 Volts and get a brighter light by using 3 Volts. But if you connect two LEDs in series then that 3 Volts is too low to light them and so there is no light at all and zero current draw. Well, the weird stuff is that you can power ONE LED with 1.5V and can't power TWO LEDs in series with 3volts?!? And, while resistors control the brightness of the light they do not change the voltage required in any way. Now that's it! I used this on a Joule Thief and when I did, I got COP>1 using this circuit:



This circuit has an input current of 12.5 milliamps at 2.35 volts (which is 30 milliwatts) and an output current of 8 milliamps at 6.60 volts (which is 52.8 milliwatts) and that is COP=1.8 or 80% greater output power than the input power. The ferrite toroid is wound using 0.4 mm diameter enamelled copper wire (#26 AWG) and while the trrns are shown slanted in the diagram, the actual direction of the turns is radial, and anyway, the direction of the turns has no effect on circuit performance. It is expected that the diameter of the ferrite ring is not at all critical but only one diameter was available for testing. The fast-acting diode could be an FP607, UF5408 or similar, and it is also possible to use a transistor with the Base and Emitter connected together, instead of a high-speed diode. The LEDs used are 8 mm diameter types.

In this circuit it was found that the input voltage is important. The best input voltage is between 2.2 volts and 2.5 volts, so two Ni-Cad or two Ni-Mh batteries are about the optimum input as higher voltages just cause higher input currents without any improvement in the output power.

The key to free energy from this circuit is to use at least two LEDs connected in series. Place them in the current flow to the base of the transistor and the current fluctuations caused by their ‘weird stuff’ will boost the energy coming from the output.

one very important point is that there must be at least two LEDs and the circuit must **not** self-start, because if it does, then the input voltage is too high and the circuit will operate at COP<1. Because of this, you need to start the circuit operating by hand, and another very important point is that the output voltage should at least twice as much as the input voltage.

Features of this technique:

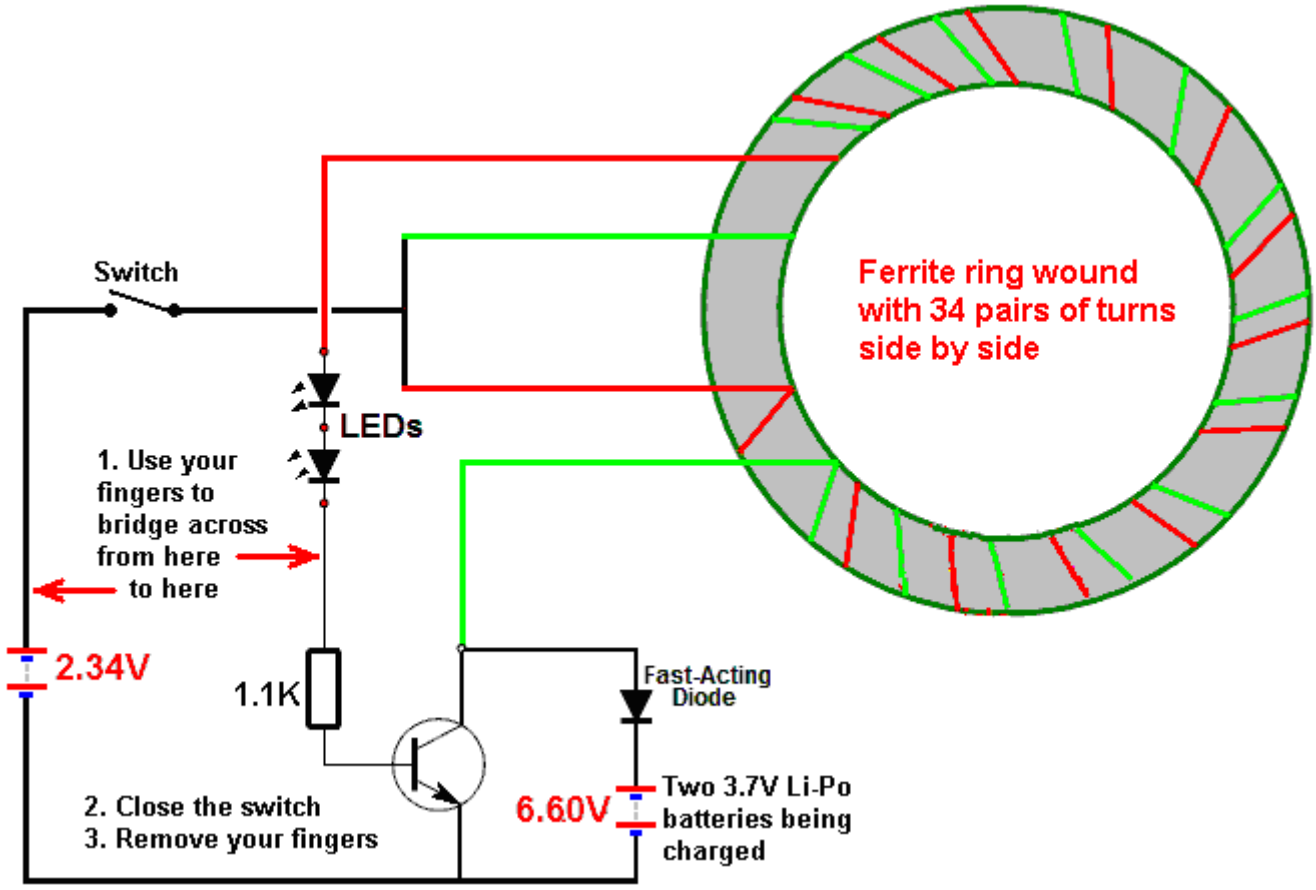
- COP>1 can be achieved and then with proper modification the circuit can become self-powered.
- You can extract energy from “dead” batteries and supplement it with additional energy drawn from the environment.
- Go to work and leave the circuit charging batteries at home while you are working.
- Interestingly, high-frequency sound is emitted by the circuit, and that sound tends to keep mosquitoes away!

Fine-tuning the circuit:
There are 5 parameters involved in the operation of this circuit:

1. Input voltage,
2. Output voltage, The coil winding,
3. The diameter of the toroid,
4. The number of LEDs, and
5. The resistor which feeds current to the base of the transistor.

The first step in assembling the circuit is to check the LEDs which you are going to use. These LEDs are going to be connected in series, so start with two and connect them across the battery. If the LEDs light up, then add an extra LED until the chain of LEDs do not light when connected across the battery. Doing this, will raise the COP of the circuit over 1 as the output power will then exceed the input power.

When setting up the toroid assembly, remember that winding more turns on the toroid will make a coil which has higher impedance which will increase the COP value, but too many turns may result in lower current which means a slower rate of charging from the output. The output voltage should **always** be more than twice the input voltage (for example: Input 2.35V Output 6.60V).



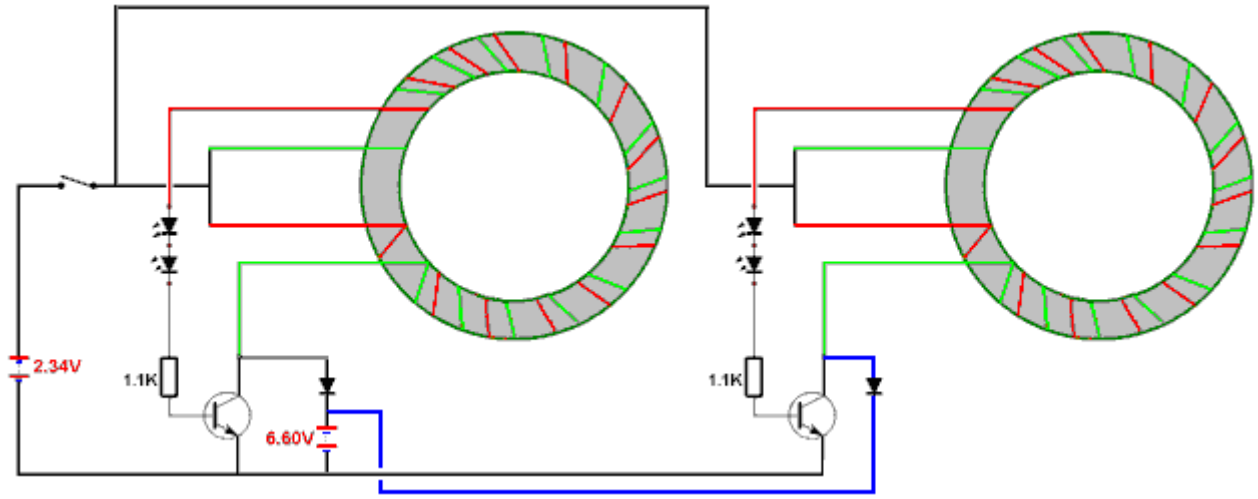
When the circuit has been built as shown above, if it starts running when the switch is closed, then the input voltage is too high, so keep adding an additional LED until the circuit will no longer self-start. Then, use your fingers to start it running by using your body resistance to bypass the LED chain very briefly to get the circuit oscillating. This is a low voltage section of the circuit and so there is no danger at all of getting a shock by doing this. An alternative would be to put a resistor in place instead of your fingers and use a press-to-make switch to trigger the circuit.

A further refinement is to add even more LEDs until the point is reached where the circuit will not start, even if you use your fingers to try to get it operating. When that point is reached, remove one of the LEDs and get the circuit running. Compare the input and output power levels, and then remove one more LED and repeat those power measurements. Keep doing that while you still have more than two LEDs until you determine what is the most effective number of LEDs in your circuit, that is, you find the best COP performance that your circuit can achieve.

In this circuit the LEDs are there to cause base current fluctuations as a mechanism to get COP>1 performance, and so, they are not there for lighting. You may increase the resistor value and so, lower the amount of input current used, but doing that results in lower output power. In my circuit, I used a 1100 ohm resistor.

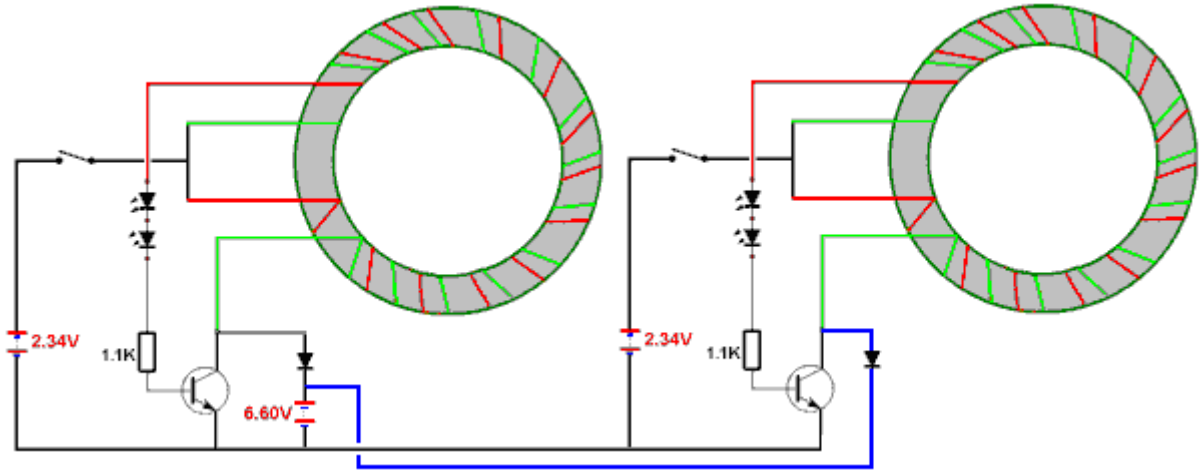
Further Experiments:
This section is about some experiments which I have done to see if I can improve the performance of the Joule Thief. Obviously, I have not tried every possible arrangement and so I invite you (the reader) to do further experiments as the Joule Thief is clearly a very good circuit with which to experiment.

Charging at just 8 milliamps is too low a rate for a 1000 Milliamp-Hour 7.4 Volt Li-Po battery pack, and so, it is necessary to increase the rate of charge. This can be done by using two or more of these circuits connected in parallel as shown here:

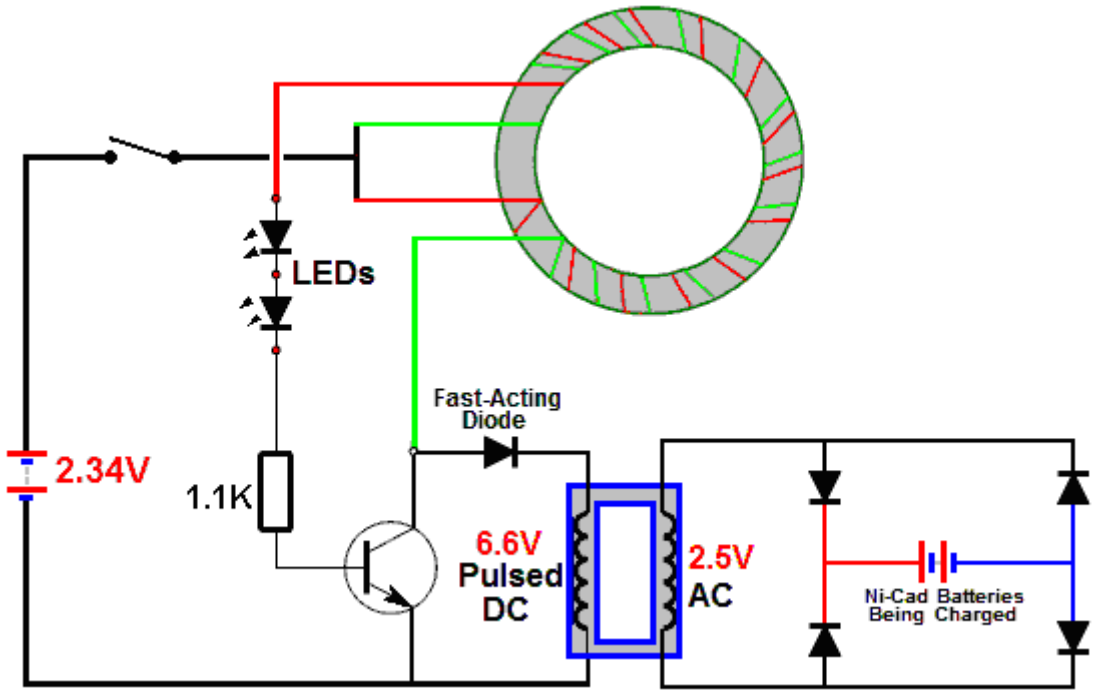


Batteries which are almost fully discharged, have a higher internal resistance than a new battery, and so the higher the current drawn by the circuit the lower the efficiency of the circuit will be. As a result of this, the effective input voltage used by this circuit is actually lower than the 2.34 volts shown in the circuit diagram.

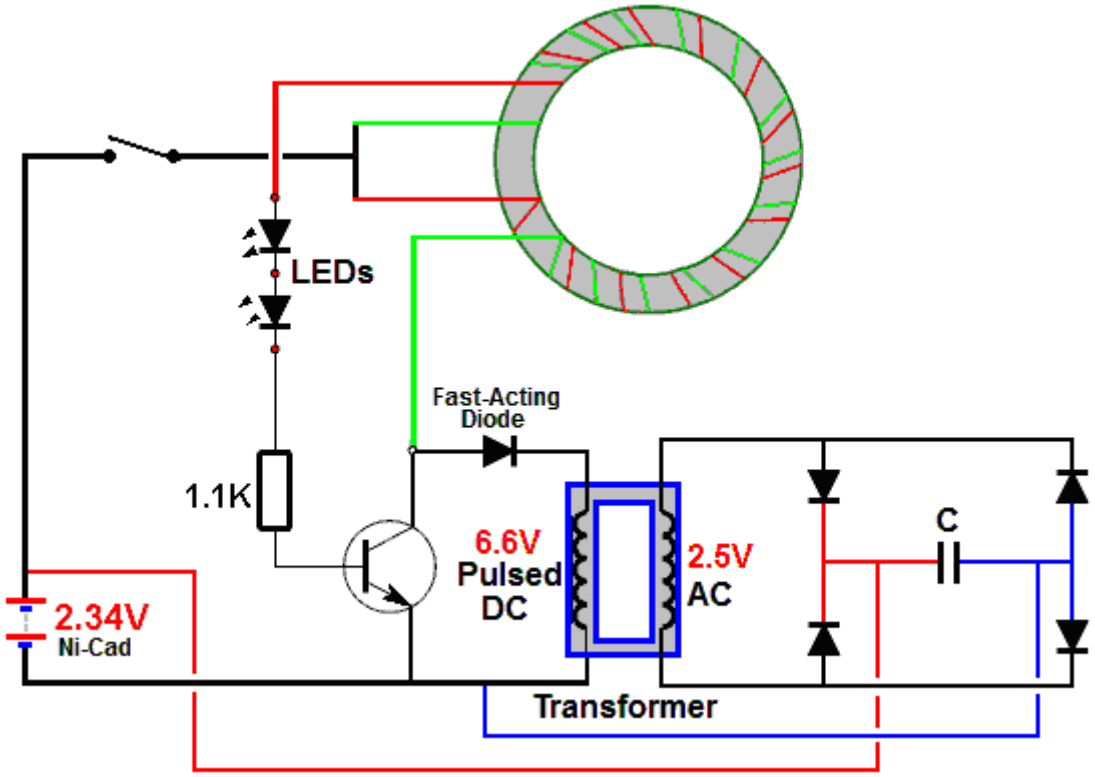
So perhaps it should be arranged like this:



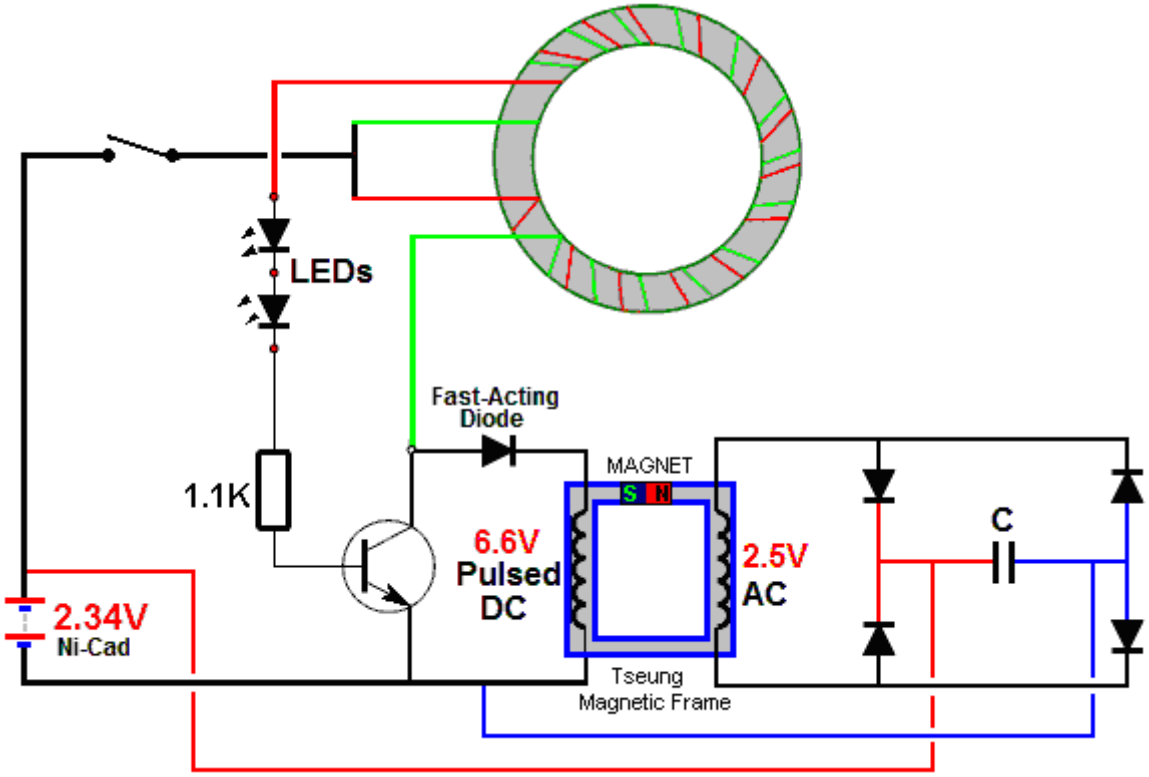
Remember that the output voltage should always be more than twice the input voltage. So if you want to charge Ni-Cad batteries which have a lower voltage, then you should use a step-down transformer as shown here:



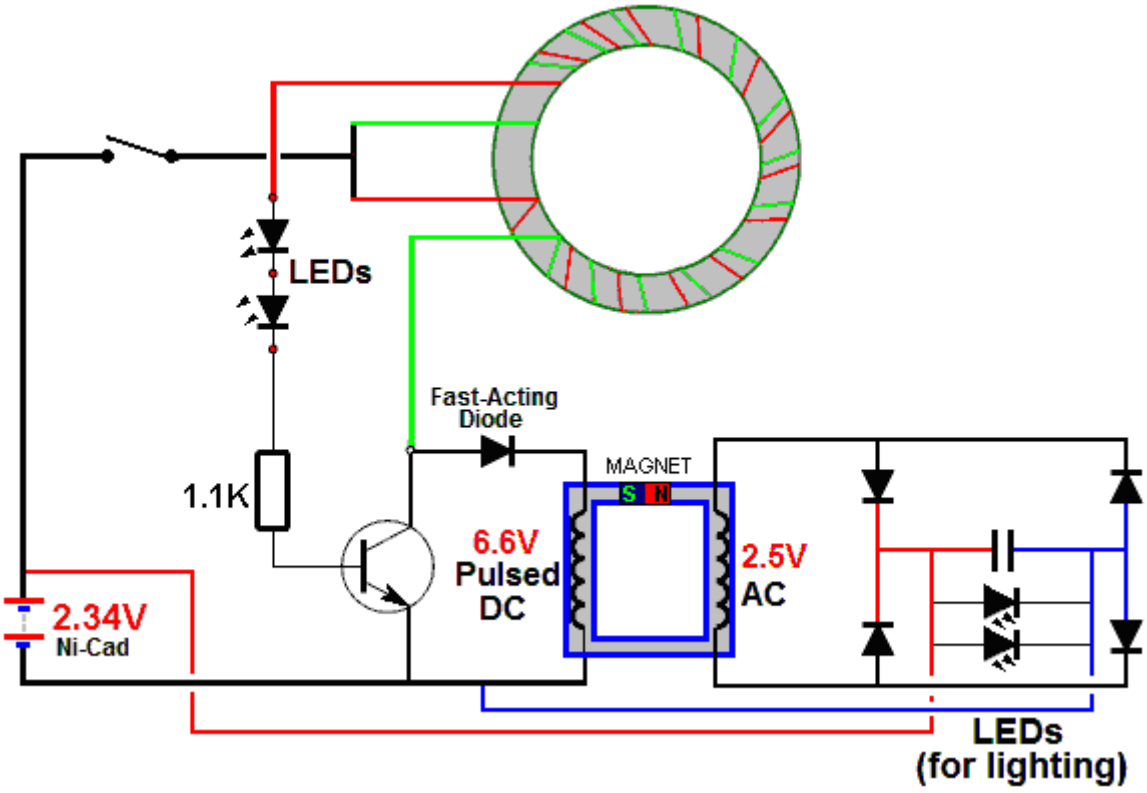
With the appropriate modifications it can become self-powered and self-charging as shown here:



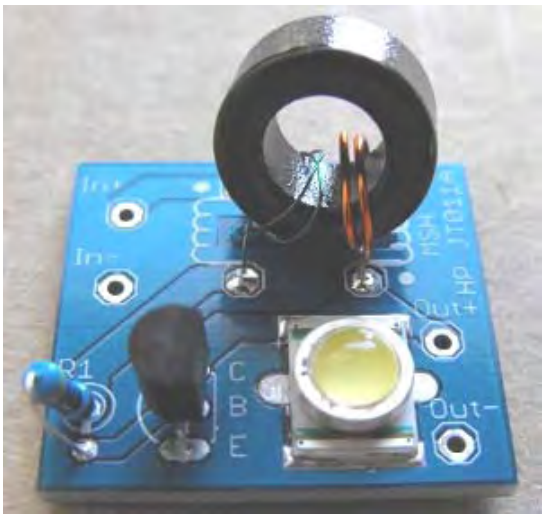
The performance of this circuit can be boosted further by using an asymmetrical transformer such as Lawrence Tseung's Magnetic Frame or Thane Heins' transformer as shown here:



Perpetual Lighting circuit:
Higher voltage results in lower LED resistance and so will decrease the efficiency of the circuit through negative feedback and so the circuit can become stabilised as shown here:



Also, check out the high-power Joule Thief circuits with 1-watt output and various other useful products at http://www.madscientisthut.com/Shopping/agora.cgi?product=Energy%20Harvesting&user4=Joule%20Thief%20Kits.

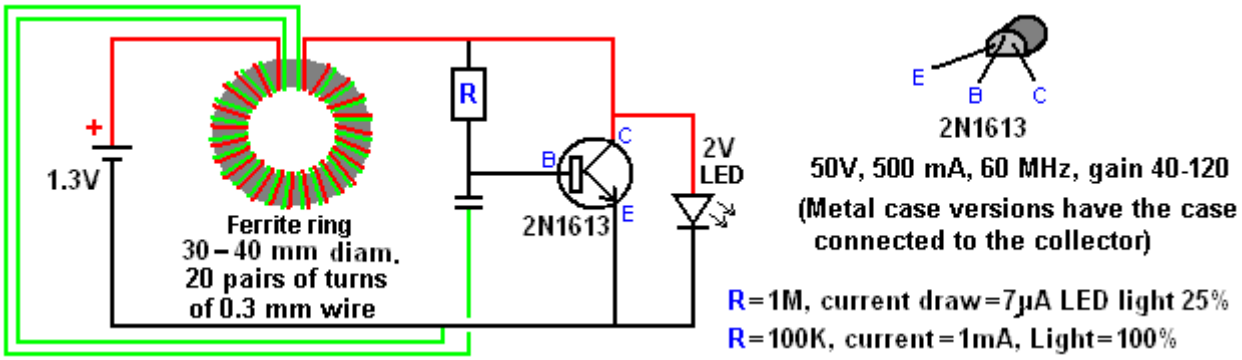


We come now to circuits designed by **Johnny Aum** of Romania who is an independent free-energy researcher since 1982 in spite of everyone around him saying that free-energy is not possible, shows some of his work on his johnnyaum3 YouTube channel. Johnny has shared three of his many high-efficiency designs, including his successful permanent magnet motor design, on the JL Naudin website since 1999.

The following two circuits are still under development. They can be considered to be Joule Thief circuits as they do roughly the same thing, but strictly speaking, these are not Joule Thief circuits but instead are completely new innovative designs, initially developed between 2009 and 2010.

The following circuit is aimed at minimum current draw and while it looks quite like a Joule Thief, you will notice that the end of one of the toroid windings does **not** connect to the start of the other winding, and while the wires

are bi-filar wound side by side as in a Joule Thief, the different connection of the windings makes it a quite different circuit. It runs from 44 to 49 kHz with increased COP at the higher frequency.



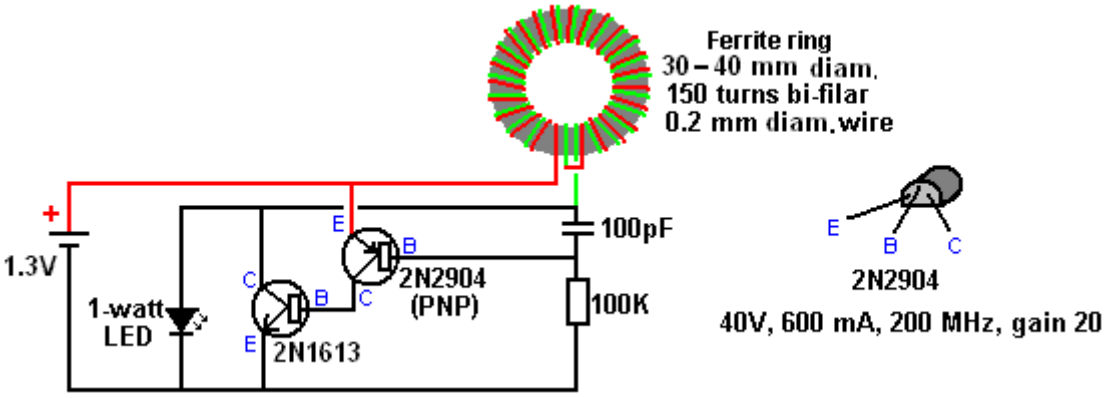
This circuit has a spectacular COP of around 650 at very low currents and you will notice that with a resistor value of 1Megohm, the current draw is only 7 microamps. Both of these circuits can recharge the battery to a certain degree and can recondition the driving battery. It is generally found that in any device, as the power level increases, the COP drops off. To get the full light output from the LED, the current increases to 1 milliamp, which, of course, is very impressive performance, and you can imagine how long a NiMh 3000 milliamp-hour AA battery could keep the LED lit at full power.

The second circuit from Johnny Aum is intended for more useful lighting levels for use where the mains is not available and can run for ten days on one battery due to the slight degree of battery recharging produced by the circuit. Here are some of Johnny's prototypes in operation:

Johnny stress that this circuit generates healing properties and the light is whiter than that produced by a classic circuit. This circuit runs at around 15 kHz. It should be pointed out that an obvious way to increase the lighting level is to have additional LEDs lit, whether by using more than one connected in parallel, and/or using two or more circuits, this is quite feasible as the circuits are very small, lightweight and cheap to make. One-watt LEDs in many different varieties are readily available from different suppliers.

The circuit for driving these powerful LEDs is somewhat different, with a PNP transistor being connected directly to a 2N1613 NPN transistor, boosting its gain by a factor of about 20 times. This connection method has no

appreciable voltage drop when switched on and is convenient for circuits which use very low voltages, such as this circuit. The ferrite toroid in this circuit is wound around its whole circumference with thin 0.2 mm diameter wire. On the prototypes, this resulted in 150 turns of the two wires side by side. This winding is a genuine bi-filar winding, but it is not connected like a Joule Thief. Instead, the end of one wire is connected to the start of the other wire, but not to anything else, leaving just two wires coming away from the toroid winding. It looks like this:



As you can see, this is a very simple-looking circuit with very few components, and yet it is very effective in driving a powerful LED.

A Suggestion

This is an arrangement of readily available, cheap parts for operating a useful light. Probably the most efficient circuit for this task is the 'Joule Thief' circuit and the light bulb usually chosen for this circuit is the compact fluorescent lightbulb ("CFL") which is widely available around the world and although there are many variations, looks something like this:

The arrow is pointing to a join in the construction where the bulb section joins the lower section which houses circuitry and the mains connector which can be one of many different types. However, that type of bulb has mains circuitry built into it which means that in order to get the higher efficiency which we would like, each bulb needs to be physically modified which is far from ideal. The circuitry inside a bulb of this type, converts the alternating current of the mains into Direct Current and then uses that direct current to supply an oscillator circuit which generates high-frequency pulses which power the bulb. Unfortunately, that circuitry gets in the way of low-power operation and so needs to be removed. People who have done this, say that the bottom can be popped off just by inserting a screwdriver into the crack and twisting the screwdriver to force the two pieces apart. If you try that, then let me wish you luck as it has never worked for me, even when applying enough force to permanently damage the material on both sides of the crack. Instead, I do it by cutting the plastic base 8 mm below the arrow line resulting in this:

The 8 mm clearance is because the glass tubes project down below the join and we need the remaining section of the plastic housing to support the bulb when we mount it on our circuit box. The cut should be made when holding the base section as the glass tubes are very fragile and easily damaged. If available, a Dremel or similar tool which has a small cutting disc very well suited to making this cut. The cut should be just deep enough to go through the plastic wall but not further than that. There is a tiny circuit board contained in the lower part, generally, with some very nice components which can be used for other circuits. The cut-down light bulb can be mounted on the circuit box using a strong adhesive, or a hole can be drilled very carefully in the centre, between the tubes (holding the base and not the tubes when doing this) and the base can then be bolted to the component box.

The glass tubes are U-shaped and there are two inter-tube horizontal connecting tubes in order to make all of the U-tubes function as one long zig-zag discharge path and get all of the tubes lit up at the same time. The two tubes which do not have this horizontal interconnecting tube, have two wires coming out of the bottom of them, and used to connect the circuit to the tubes. These four wires need to be cut, leaving them as long as possible, then each pair has the insulating enamel scraped off them and then soldered to a length of wire which will be used to connect to the new circuit, or alternatively, direct to the board if very small 'fiddly' work is no problem.

This adaption makes this low-cost method unsuitable for applications where an off-the-shelf bulb is needed so that replacements can be made without the need for any technically skilled person to be available. What we need therefore, is a bulb which does not have the mains circuitry (called "ballast") built into it, and the earlier 'PLD' bulbs are in that category. Unfortunately, they are more expensive and not so widely available. They look like this:

4-pin PLD bulb

2-pin PLD bulb

These have the enormous advantage of not requiring any work on the bulb in order to operate immediately with our circuit. We can build a suitable circuit from scratch, but it is very popular with home constructors making a one-off experiment to use the very cheap circuit found in Fuji's "Quick Snap" disposable camera which is very widely available. It looks like this:

There are various ways of adapting the circuit board found inside the camera, and thanks is due to 'Gadgetmall' of the http://www.overunity.com/10723/fuji-joule-thief-full-instructions-video-and-pics/new/#new forum for sharing his method of adaption and expertise with these circuits, which has allowed him to run a fluorescent light for 38 hours powered by just one AA size 1.5 volt battery

Disclaimer: This document must not be considered to be a recommendation for you to actually attempt to undertake any of the following modifications, and should you decide to do so, then any loss, damage or injury are wholly your responsibility and not that of anyone else.

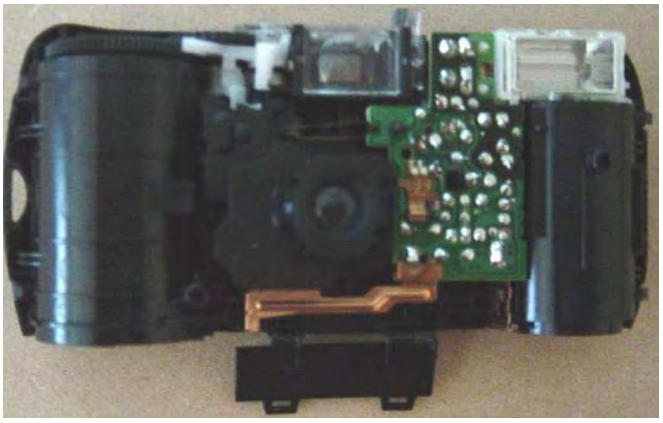
The camera needs to be taken apart in order to get at the circuitry inside it. A word of warning here, there is a high-voltage capacitor inside the camera and if it happens to be charged, then it is quite capable of giving you a really nasty shock, so as soon as the circuit board is exposed, I strongly recommend that you take great care to avoid a shock, even though it is not likely to be a fatal shock. As soon as the capacitor is exposed, then short across it's wires using a metal tool which has a plastic handle, such as a screwdriver or pair of pliers with a well-insulated grip. If the capacitor happens to be charged, then that may produce a bright spark which makes a loud crack.

The camera is taken apart like this:

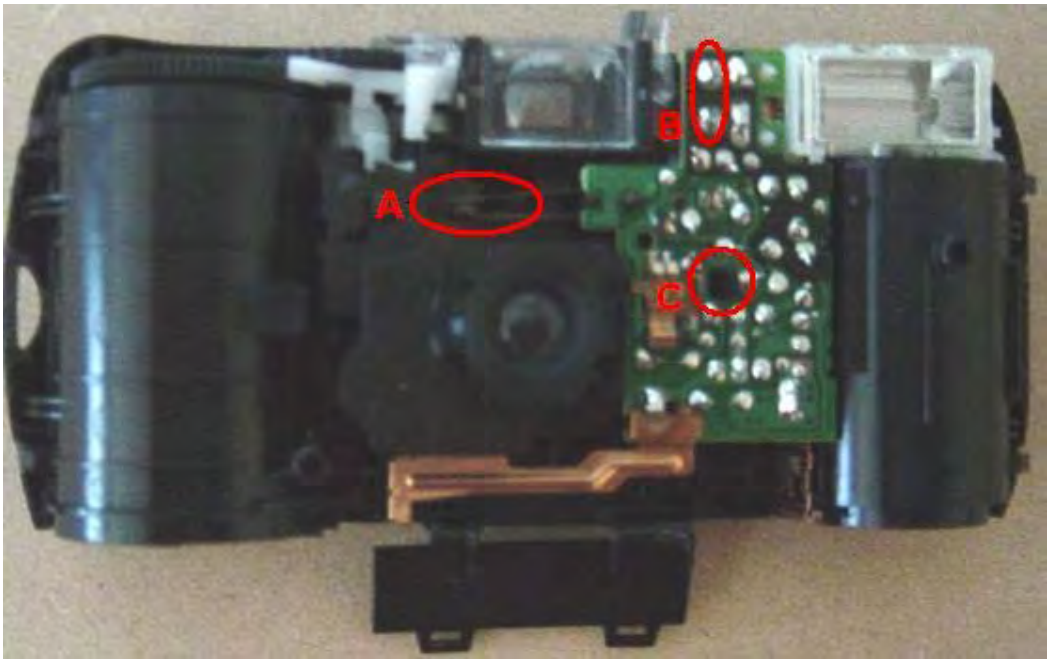
1. The green covering which is a piece of very sticky, strong plastic is peeled off. The join is underneath, where the black colouring ends.

2. In the middle of the bottom, there is a flap which you lever up, uncovering the battery. There are various varieties of Fuji "Quick Snap" camera with different circuitry, the one shown here was supplied by Asda (Wal-Mart in the UK) in 2012 and the circuit board is marked A07 or A60 while some earlier versions have a different layout for some components and even have the battery inserted the other way round. Before you remove the battery which in the UK is a 1.5V AAA alkaline battery, make a careful note of which way round the battery is inserted. In this case, the plus of the battery connects with the long copper arm. Remove the battery.

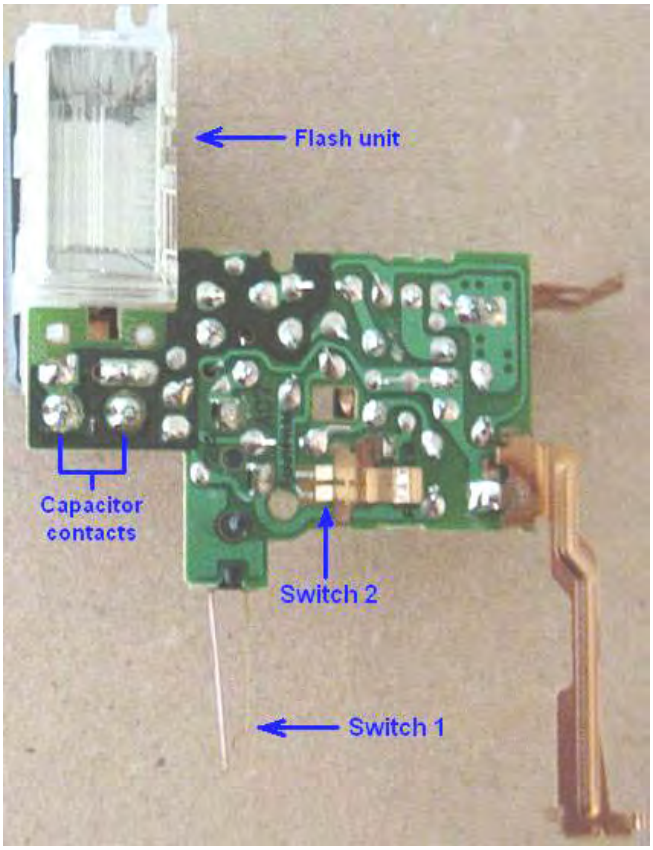
3. Pull off the black plastic covers on the underside of the camera, located at each end of the battery compartment, and then using a screwdriver, force the two halves of the black camera case apart, which leaves the front of the camera looking like this:



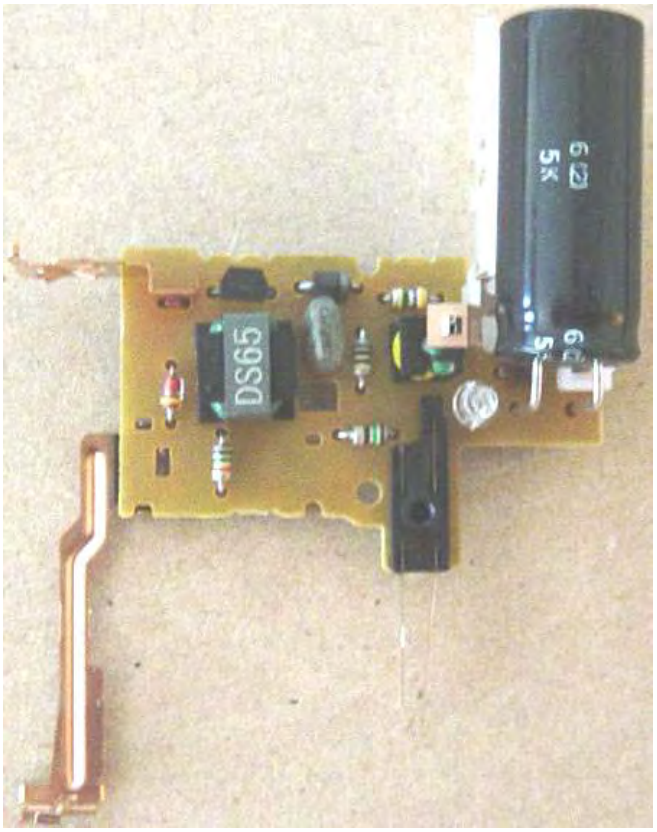
4. Make sure that the flash is not charged, first, by using a non-conducting item to press together the switch contacts marked "A" in the following picture, and then using some metal object with a plastic handle, bridge across the gap between the soldered points ringed around and marked "B" as they are the ends of the high-voltage capacitor. If the capacitor happens to be charged, then there will be a spark and a loud sound, but this is unlikely with a new camera unless you have been pressing the buttons since unwrapping it.



5. Press the black plastic latch marked “C” in the picture above, over towards the left and that releases the circuit board which can be lifted out and looks like this:



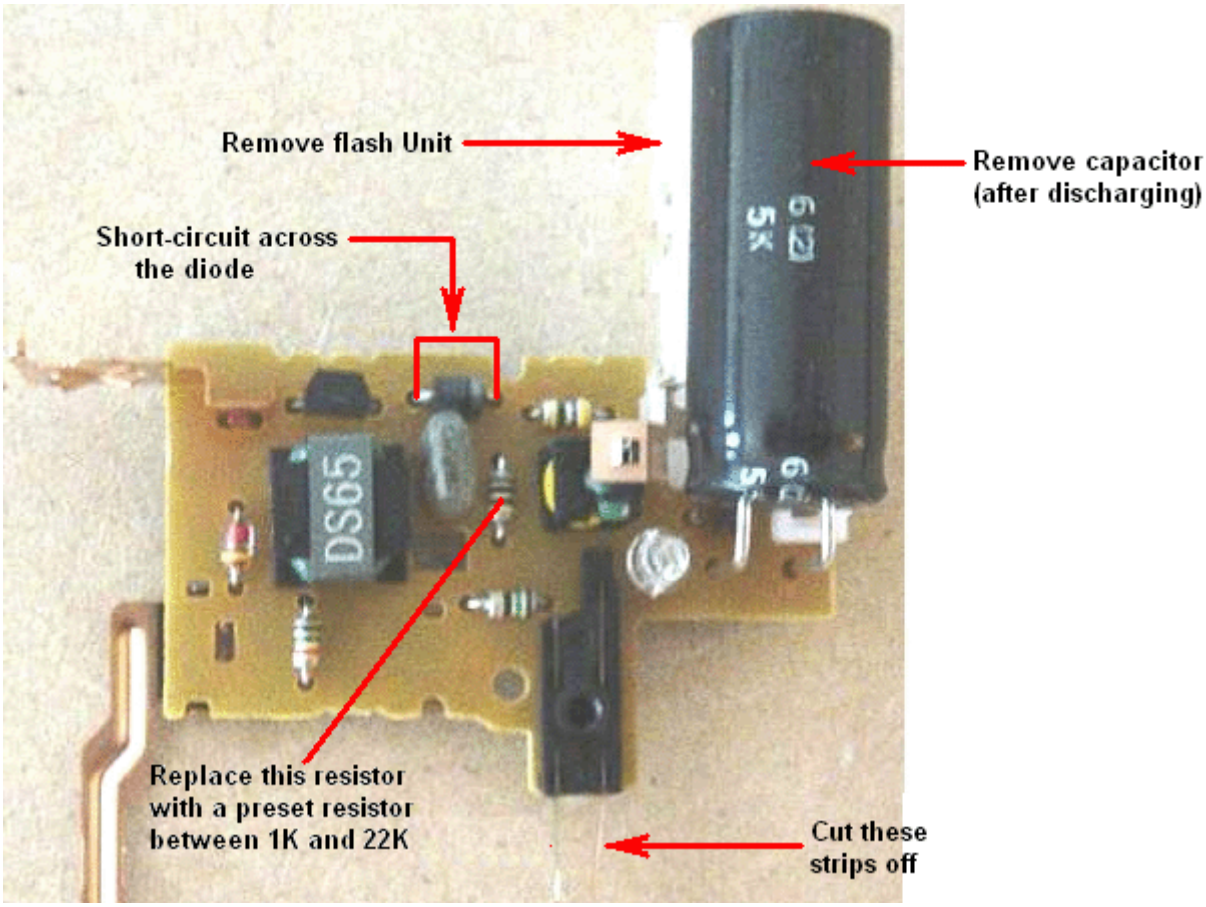
And seen from the top:



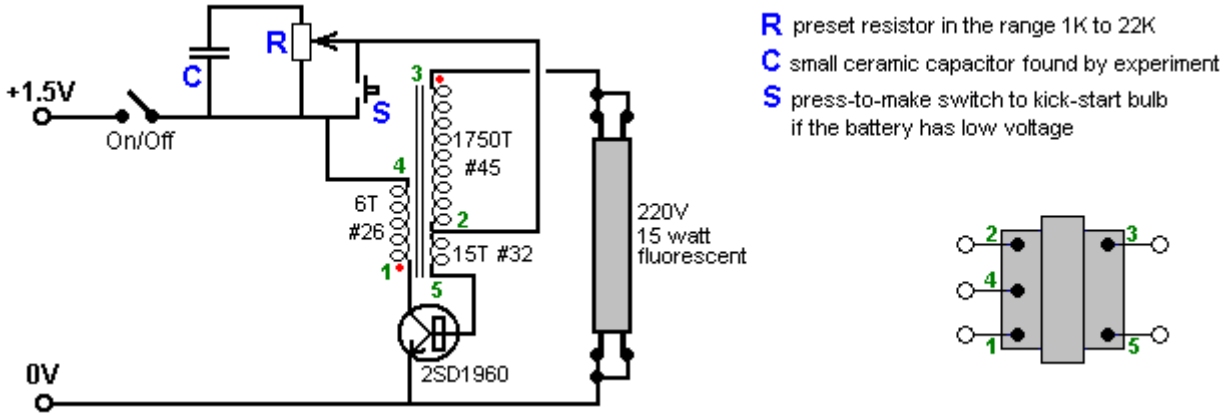
6. The board is quite small, being about 40 mm x 25 mm when the capacitor and flash unit are removed which is the next thing to do, probably by cutting the very tough capacitor leads and then cutting off the plastic pins holding the flash unit to the board, levering it upwards and cutting away it's metal contacts which link it to the board.

7. The two switches which form the camera's flash-charging switch and it's shutter release switch need to be wired permanently closed. These are marked "Switch 1" and "Switch 2" in step 5. above. I suggest that you cut the arms of Switch 1 to about half length, clamp them together with a pair of long-nosed pliers and bend them over to crimp them flat, and then solder them together. Switch 2 needs to be bridged across to make it permanently closed. A clip can be used to clamp the upper and lower contacts together so that they can be bridged with solder.

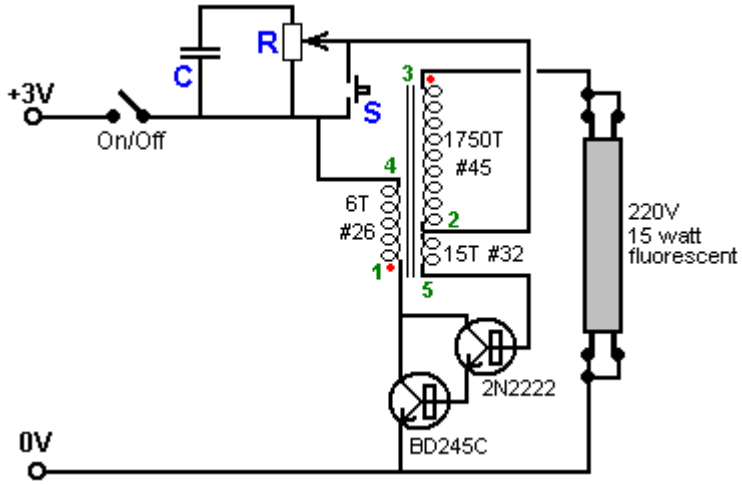
8. The rest of the modification is seen from the top of the board:



This is to achieve this 'Gadgetmall' circuit:

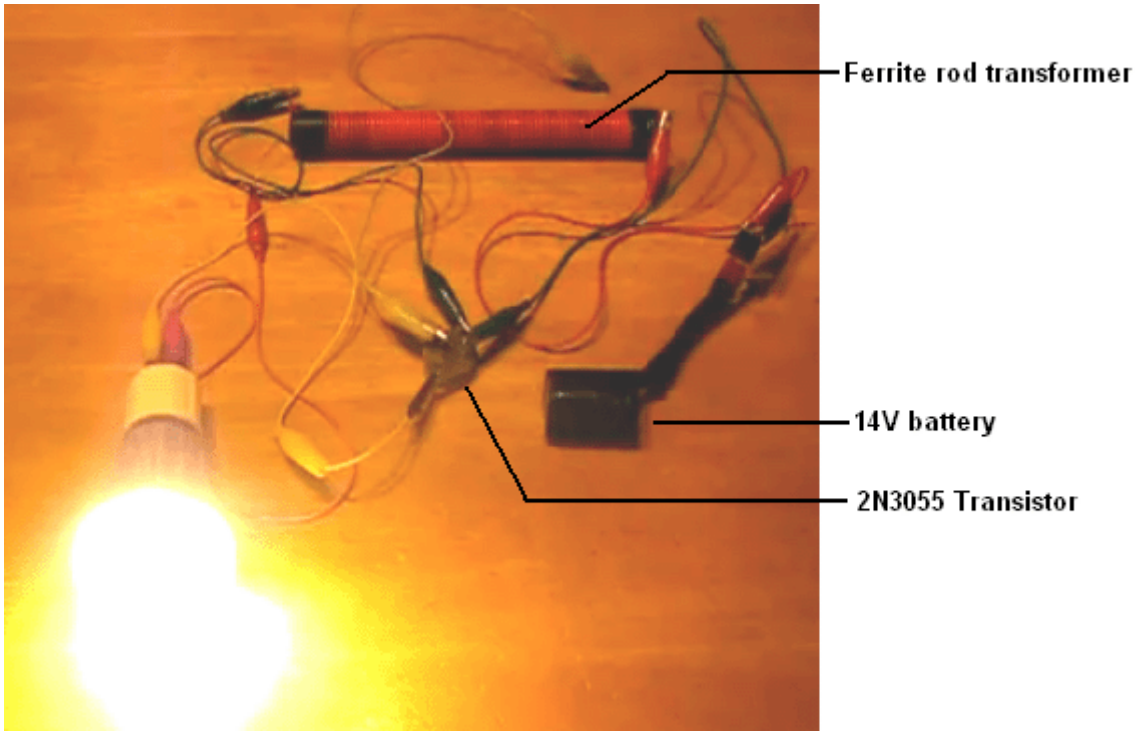


Gadgetmall comments that increasing the voltage supplied to this circuit, puts the 2SD1960 transistor at risk as it will overheat. That transistor is tiny, has no heat sink or space to fit one and was only intended to be on for a few seconds while the capacitor charges up in preparation for operating the flash bulb. This circuit modification runs the transistor continuously for very long periods and so we are already stepping outside the Fuji circuit designer's operating conditions. Also, we would like to run the circuit with somewhat higher voltage in order to get improved operation of the fluorescent tube or bulb. Consequently, we might consider using a more powerful transistor. The 2SD1960 transistor is rated at 30-volts, 5-amps, 170 MHz and 0.75 watts, so we might consider swapping it for, say, a BD245C transistor rated at 100-volts, 10-amps, 3 MHz and 80 watts as our circuit runs at under 0.1 MHz and the BD245C transistor can be mounted on a heat sink, although with it's much greater handling capacity, it should stay cool at these tiny powers. We can boost the gain of the BD245C by a factor of 200 or so, by using a BC109C or a 2N2222 transistor to form a Darlington pair, making the circuit:

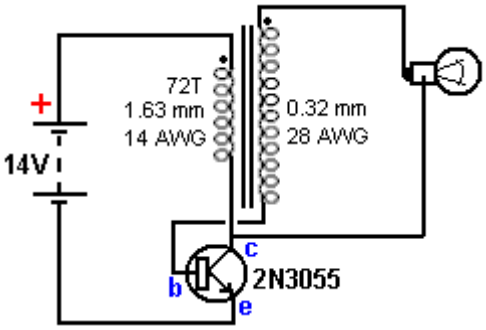


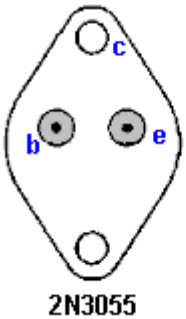
LaserSaber's Joule Thief Lighting Circuits.

Another very successful variation on the basic Joule Thief was put into the Public Domain on 4th October 2012. Details are on his web site www.laserhacker.com. His variation is extremely simple, both in concept and construction:



and in his video: http://solarpower.energygratis.com/2012/10/09/solar-electricity-super-joule-ringer-3-0-real-world-power-made-easy/ he demonstrates it lighting a mains-voltage LED bulb (seen above), a mains filament bulb, a halogen bulb and a compact fluorescent bulb with the ballast still in place, that is, as is sold in shops without any modification. The circuit is:



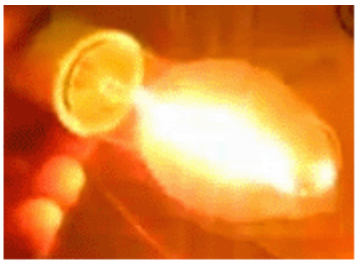


This “Super Joule Ringer 3.0” circuit is unusual in that the feedback to the base of the 2N3055 transistor is through the load (the bulb). The circuit is a high-frequency DC inverter which could hardly be any more simple, but please be aware that the high-frequency output voltage spikes are not sine wave, nor are they voltage controlled, and so this is not a circuit for driving things like TV sets. The transistor oscillates at high frequency governed by the characteristics of the 72-turn primary winding of the transformer. The output voltage level is a combination of the battery voltage and the turns ratio of the transformer.

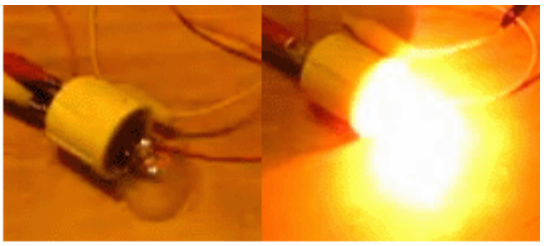
To raise the output voltage, the number of turns in the secondary can be increased. The number of turns is not specified, other than to say that the turns are laid close, side-by-side along the whole length of the 8-inch (200 mm) long ferrite rod, using enamelled copper wire of 0.32 mm diameter (28 AWG or 30 swg). Using arithmetic, that would suggest that there are some 600 turns wound directly on to the ferrite rod. The ferrite rod itself has a diameter of 0.625 inches (15.88 mm) which makes it an item which is likely to be difficult to find. However, I strongly suspect that the diameter of the ferrite rod is not at all critical.

Both of the coils are wound on the ferrite rod in the same direction, the secondary being wound first, placing it underneath the primary which is wound with 72 turns of insulated wire of 1.63 mm diameter (14 AWG or 16 swg). No current draw is indicated and it seems likely that it is quite high there being just two helical coils in the drive section. The (110-volt) bulbs demonstrated in his video are:

(BALLASTED) CFL



HALOGEN



SMALL INCANDESCENT

LED

MEDIUM AND LARGE INCANDESCENTS

A second, very practical lighting system from ‘LaserSaber’ is a Joule Thief driven LED lighting box, running from just one AA rechargeable battery. It looks like this:

Mounted on the end of the box is a single small solar panel:

which is able to charge the battery during the day. The unit is built into a small box which opens up to allow easy wiring, and different angles for positioning the LED lights. Not seen in these pictures is one other large LED cluster light which is also lit. It is a slight pity that the case does not allow the LED lights to shine on the solar panel when the lights are on, as that would provide some battery charging when the light is being used. The LED lights can provide a good deal of light:

A video of this unit being demonstrated is at http://www.youtube.com/watch?v=sFpzkyP6DCU.

Ed Gray's Power System.

The power tube presented to the public by Edwin Gray snr. operates by generating a series of very short, very sharp pulses using a spark gap. This device is reputed to have a power output which is one hundred times that of the power input. Ed Gray and his electric pulse motor are very famous, but as far as I am aware, nobody has successfully replicated this claimed performance. Further, an in-depth examination of the background details by Mr Mark McKay have turned up a number of facts which present a very different picture, and while it is perfectly correct to say that spark-gap pulses generate a good waveform for shocking the local zero-point energy field into the sort of imbalance which can provide a massive power inflow into a device or circuit, we need to be careful to get the full facts in this case.

First, let us put the whole thing in its proper perspective. In May 1973, Cal-Tech in the US performed an independent assessment of an engine provided to them by Edwin Gray. They measured the input and the output and certified that the output power was 275 times greater than the input power. This demonstrates clearly that excess power can be drawn into an engine and provide a performance which can power both the engine as well as doing additional useful work.

Having said that, it needs to be made clear that Edwin Gray did not build that small motor, did not understand how it worked, nor did he ever disclose the design in any of the patents which he obtained afterwards. We need to follow the sequence of events and notice when each thing happened. The history is as follows:

In 1957, a Russian immigrant to the USA, one Alexei Poppoff, showed Edwin Gray a circuit which he said that he had been shown by Nikola Tesla. Edwin Gray did not understand the circuit and had no idea how to create anything useful based on it. He then joined up with his next-door neighbour Marvin Cole, who held a Masters degree in Mechanical Engineering and who, unlike Gray, was able to understand the circuitry.

In 1958, Ed Gray left the Los Angles area in a hurry.

From 1958 to 1967 Marvin Cole, working alone, designed and built ever more powerful prototype engines, and it was a small one of these which was tested by Cal-Tech. In this period, Marvin also developed ever more powerful power supplies, which are the really important item in all of this.

In 1967, Ed Gray rejoins Marvin Cole and together from 1967 to 1972 they solicited venture capital and promoted the technology.

Early in 1972, Marvin Cole disappeared and never saw Gray again. It is not clear if he was intimidated, died, or just did not want to be involved in all the publicity and effort needed to turn the prototype engines into a commercial product. No matter what the reason, the result was that Edwin Gray was suddenly disconnected from the brains behind the project, and that left him in a very difficult position. He didn't want to let go of the dream of becoming rich through this spectacular development, and so he tried to continue the development on his own.

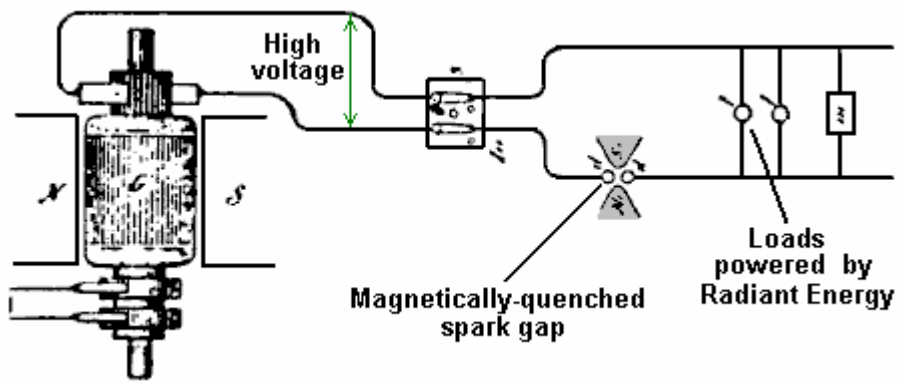
As already mentioned, in May of the following year (1973), Gray had a small Marvin Cole motor independently third-party tested at the famous Cal-Tech laboratory in Los Angles, where a measured input of just 27 watts produced a measured output of 10 horsepower (7460 watts). The objective was to provide solid evidence of a new technology which was capable of changing the world and so would attract investors. To further boost his image and convince potential investors, in that same year of 1973, Edwin staged demonstrations which jumped electromagnets up into the air, showing the strength of the power which drove the Marvin Cole engines.

It is very important to understand that all of Edwin Gray's patents were applied for after the departure of Marvin Cole. These do not disclose the technology tested by Cal-Tech and it must be understood that Edwin was very much afraid of revealing anything important in any of the patents in case some other person would understand the things which were a mystery to him and snatch away the prize of commercial success. Try watching Peter Lindemann's informative video at http://www.youtube.com/watch?v=dmf10hggUm4 for considerable additional information.

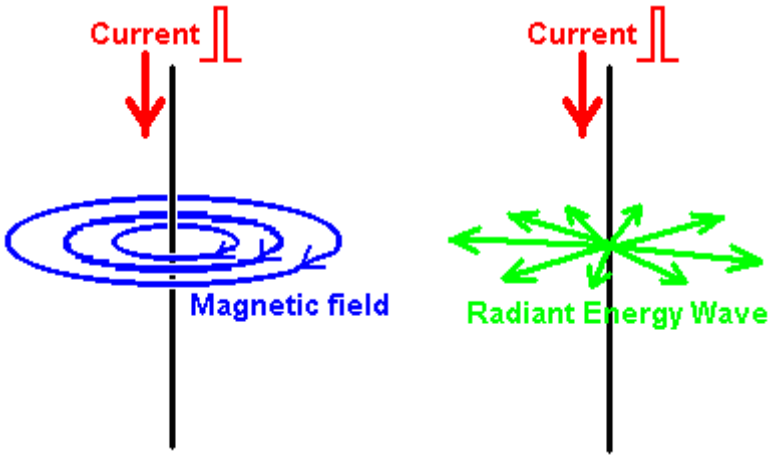
Marvin Cole's power system produced "cold electricity" which could power lights and other devices. It was frequently demonstrated that the output was not conventional electricity and powered light bulbs which were placed under water and at the same time, it was quite safe for a hand to be put into that same water along with the lit bulb. The glass of the conventional bulbs used in these demonstrations would have shattered when placed under water if they had been powered by conventional "hot electricity" as the sudden change in temperature

would have broken the glass. Powered as they were by "cold electricity", they ran cool and so there was no stress on the glass when submerged in water.

Peter Lindemann points out that Ed Gray's power conversion tube circuit is effectively a copy of Nikola Tesla's circuit for doing the same thing:



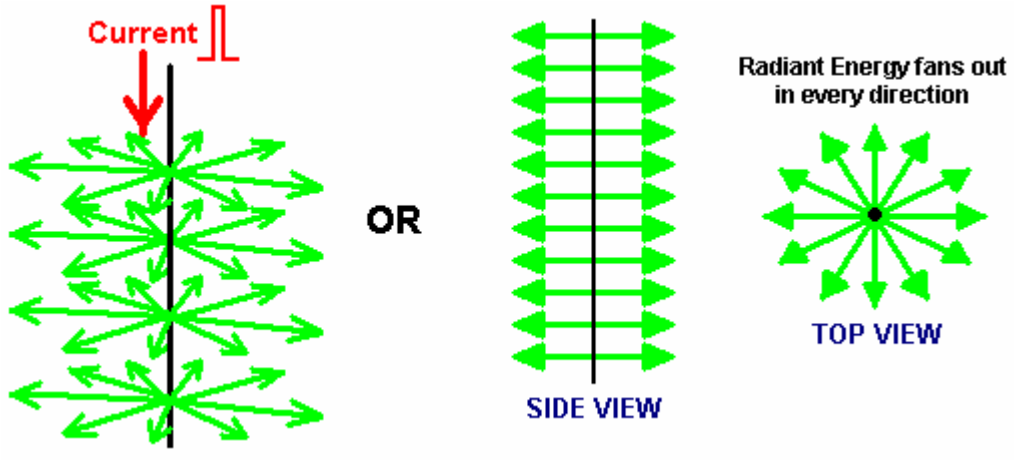
This was disclosed by Tesla in his 'Philadelphia and St Louis' lecture in 1893 and shows how loads can be powered when a high voltage source is pulsed by a magnetically-quenched sparks - this creates DC pulses of **very** short duration.



The diagram above, illustrates the difference between the Magnetic field generated around a conductor fed with a pulse of Direct Current and the Radiant Energy waves created by that pulse. If a sharp current pulse is driven down a vertical wire, it causes two different types of field. The first field is magnetic, where the lines of magnetic force rotate around the wire. These lines are horizontal, and rotate clockwise when viewed from above. The magnetic field remains as long as the current flows down the wire.

The second field is the Radiant Energy wave. This wave will only occur if the current pulse is in one direction, i.e. it will not occur if the wire is fed with alternating current. The wave radiates out horizontally from the vertical wire in every direction in the form of a shock wave. It is a one-off event and does not repeat if the current in the wire is maintained. The Radiant Energy briefly unbalances the zero-point energy field and that causes an energy flow as the field moves back into equilibrium again.

The Radiant energy wave is not restricted to a single plane as shown in the diagram above, which is intended to indicate the difference between the electromagnetic field circling around the wire, and the Radiant Energy field which radiates away from the wire. Both of these fields occur at all points along the full length of the wire as shown here:

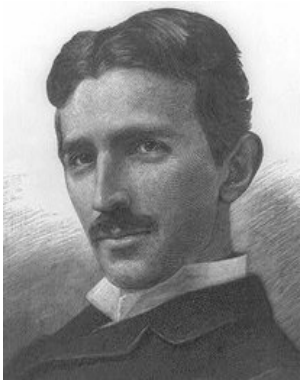


Radiant Energy, when converted to electrical power, produces a different kind of electrical power to that produced by batteries and by the mains supply. Power a motor with conventional electricity and it gets hot under load. Power the same motor by Radiant Energy electricity and under load the motor gets cold. Really overload it by stalling it and the motor housing is likely to be covered with frost. That is why this form of electricity is referred to as "cold" electricity.

In his book "Cold War Secrets - HAARP and Beyond", Gerry Vassilatos quotes research work done in this area by Tesla and others:

Tesla's Experiments.

In 1889 Tesla began experimenting with capacitors charged to high voltages and discharged in very short time intervals. These very short pulses produced very sharp shockwaves which he felt across the front of his whole body. He was aware that closing a switch on a high-voltage dynamo often produced a stinging shock. This was believed to be static electricity and it occurred only at switch-on and only for a few milliseconds. However, in those few milliseconds, bluish needles of energy stand out from the electrical cables and they leak to ground, often through the bodies of any people standing nearby, causing immediate death if the installation is large. While the generators of that time were rated at some thousands of volts, these discharges were millions of volts in intensity. The generator problem was eliminated by the used of highly insulated switches which were provided with a very large ground connection.



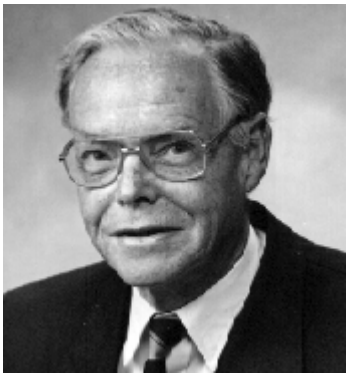
Tesla was intrigued by this phenomenon which appeared to match the effect of his capacitor discharges. He calculated that the voltages produced were hundreds of times greater than could be supplied by the capacitor or generator. It was clear that the power supplied was being amplified or augmented in some way, but the question was, from where was the extra energy coming?

Tesla continued to investigate through experiments, taking precautions against the high voltages being produced. He was soon able to produce these shockwaves whenever he wanted to. The shockwaves produced a stinging sensation no matter where he stood in his laboratory, and hands and face were particularly sensitive to the wave. These waves radiated out and penetrated metal, glass and every other kind of material. This was clearly not an electromagnetic wave, so he called the new wave 'Radiant Electricity'.

Tesla searched the literature to find references to this radiant energy but he could not find much. In 1842, Dr. Joseph Henry had observed that steel needles were magnetised by a Leyden Jar spark discharge located on a different floor of the building. The magnetising wave had passed through brick walls, oak doors, heavy stone and iron flooring and tin ceilings to reach the needles located in a vault in the cellar.

In 1872, Elihu Thomson took a large Ruhmkorrf Spark Coil, attached one pole of the coil to a cold-water pipe and the other pole to a metal table top. This resulted in a series of massive sparks which electrified the metal door knob of the room and produced the stinging shockwaves which Tesla was investigating. He found that any insulated metal object anywhere in the building would produce long continuous white sparks discharging to ground. This discovery was written up briefly in the Scientific American journal later that year.

Tesla concluded that all of the phenomena which he had observed, implied the presence of "a medium of gaseous structure, that is, one consisting of independent carriers capable of free motion - besides the air, another medium is present". This invisible medium is capable of carrying waves of energy through all substances, which suggests that, if physical, its basic structure is much smaller than the atoms which make up commonplace materials, allowing the stream of matter to pass freely through all solids. It appears that all of space is filled with this matter.



Thomas Henry Moray demonstrated this energy flow passing through glass and lighting standard electric light bulbs. Harold Aspden performed an experiment known as the "Aspden Effect" which also indicates the presence of this medium. Harold made this discovery when running tests not related to this subject. He started an electric motor which had a rotor mass of 800 grams and recorded the fact that it took an energy input of 300 joules to bring it up to its running speed of 3,250 revolutions per minute when it was driving no load.

The rotor having a mass of 800 grams and spinning at that speed, its kinetic energy together with that of the drive motor is no more than 15 joules, contrasting with the excessive energy of 300 joules needed to get it rotating at that speed. If the motor is left running for five minutes or more, and then switched off, it comes to rest after a few seconds. But, the motor can then be started again (in the same or opposite direction) and brought up to speed with only 30 joules **provided** that the time lapse between stopping and restarting is no more than a minute or so. If there is a delay of several minutes, then an energy input of 300 joules is needed to get the rotor spinning again.

This is not a transient heating phenomenon. At all times the bearing housings feel cool and any heating in the drive motor would imply an increase of resistance and a build-up of power to a higher steady state condition. The experimental evidence is that there is something unseen, which is put into motion by the machine rotor. That "something" has an effective mass density 20 times that of the rotor, but it is something that can move independently and take several minutes to decay, while the motor comes to rest in a few seconds.

Two machines of different rotor size and composition reveal the phenomenon and tests indicate variations with time of day and compass orientation of the spin axis. One machine, the one incorporating weaker magnets, showed evidence of gaining strength magnetically during the tests which were repeated over a period of several days.

This clearly shows that there is an unseen medium which interacts with everyday objects and actions, and confirms Tesla's discovery. Tesla continued to experiment and determined that a very short uni-directional pulse is necessary to generate the radiant energy wave. In other words, an alternating voltage does not create the effect, it has to be a DC pulse. The shorter the pulse time and the higher the voltage, the greater the energy wave. He found that using a capacitor and an arc discharge mechanism with a very powerful permanent magnet placed at right angles to the spark, improved the performance of his equipment by a major factor.

Additional experiments showed that the effects were altered by adjusting the duration of the electrical pulse. In each instance, the power of the radiated energy appeared to be constant irrespective of the distance from his apparatus. The energy was in the form of individual longitudinal waves. Objects placed near the equipment became powerfully electrified, retaining their charge for many minutes after the equipment was switched off.

Tesla was using a charging dynamo as a power source and he found that if he moved his magnetic discharger to one side of the dynamo, the radiant wave was positive. If he moved the magnetic discharger towards the other side of the dynamo, the radiant wave became negative in sign. This was clearly a new electrical force which travelled as light-like rays, showing them to be different in nature to the electromagnetic waves of Maxwell.

Investigating the effects of adjusting the duration of the pulses, Tesla found that a pulse train which had individual pulses with durations exceeding 100 microseconds, produced pain and mechanical pressures. At this duration, objects in the field visibly vibrated and were even pushed along by the field. Thin wires subjected to sudden bursts of the radiant field, exploded into vapour. When the pulse duration was reduced to 100 microseconds or below, the painful effect was no longer felt and the waves are harmless.

With a pulse duration of 1 microsecond, strong physiological heat was felt. With even shorter pulse durations, spontaneous illuminations capable of filling rooms with white light, were produced. Even shorter pulses produced cool room penetrating breezes with an accompanying uplift in mood and awareness. These effects have been verified by Eric Dollard who has written about them in some detail.

In 1890, Tesla discovered that if he placed a two-foot long single-turn deep copper helix coil near his magnetic disrupter, the thin-walled coil developed a sheath of white sparks with long silvery white streamers rising from the top of the coil. These discharges appeared to have much higher voltages than the generating circuit. This effect was greatly increased if the coil was placed inside the disrupter wire circle. The discharge seemed to hug the surface of the coil with a strange affinity, and rode up its surface to the open end. The shockwave flowed over the coil at right angles to the windings and produced very long discharges from the top of the coil. With the disrupter charge jumping one inch in its magnetic housing, the coil streamers were more than two feet in length. This effect was generated at the moment when the magnetic field quenched the spark and it was wholly unknown at that time.

This train of very short uni-directional pulses causes a very strange field to expand outwards. This field resembles a stuttering electrostatic field but has a far more powerful effect than would be expected from an electrostatic charge. Tesla was unable to account for the enormous voltage multiplication of his apparatus using any of the electrical formula of his day. He therefore presumed that the effect was entirely due to radiant transformation rules which would have to be determined through experimental measurements. This he proceeded to do.

Tesla had discovered a new induction law where radiant shockwaves actually auto-intensified when encountering segmented objects. The segmentation was the key to releasing the action. Radiant shockwaves encountered a helix and “flashed over” the outer skin, from end to end. This shockwave did not pass through the windings of the coil but treated the surface of the coil as a transmission path. Measurements showed that the voltage increase along the surface of the coil was exactly proportional to the length travelled along the coil, with the voltage increase reaching values of 10,000 volts per inch of coil. The 10,000 volts which he was feeding to his 24 inch coil were being magnified to 240,000 volts at the end of his coil. This was unheard of for simple equipment like that. Tesla also discovered that the voltage increase was mathematically linked to the resistance of the coil winding, with higher resistance windings producing higher voltages.

Tesla then began to refer to his disrupter loop as his special “primary” and to the long helical coil as his special “secondary” but he never intended anyone to equate these terms to those referring to electromagnetic transformers which operate in a completely different way.

There was an attribute which baffled Tesla for a time. His measurements showed that there was no current flowing in the long copper ‘secondary’ coil. Voltage was rising with every inch of the coil, but there was no current flow in the coil itself. Tesla started to refer to his measured results as his “electrostatic induction laws”. He found that each coil had its own optimum pulse duration and that the circuit driving it needed to be ‘tuned’ to the coil by adjusting the length of the pulses to give the best performance.

Tesla then noticed that the results given by his experiments paralleled the equations for dynamic gas movements, so he began wondering if the white flame discharges might not be a gaseous manifestation of electrostatic force. He found that when a metal point was connected to the upper terminal of the ‘secondary’ coil, the streamers were directed very much like water flowing through a pipe. When the stream was directed at distant metal plates, it produced electronic charges which could be measured as current at the receiving site but in transit, no current existed. The current only appeared when the stream was intercepted. Eric Dollard has stated that this intercepted current can reach several hundred or even thousands of amps.

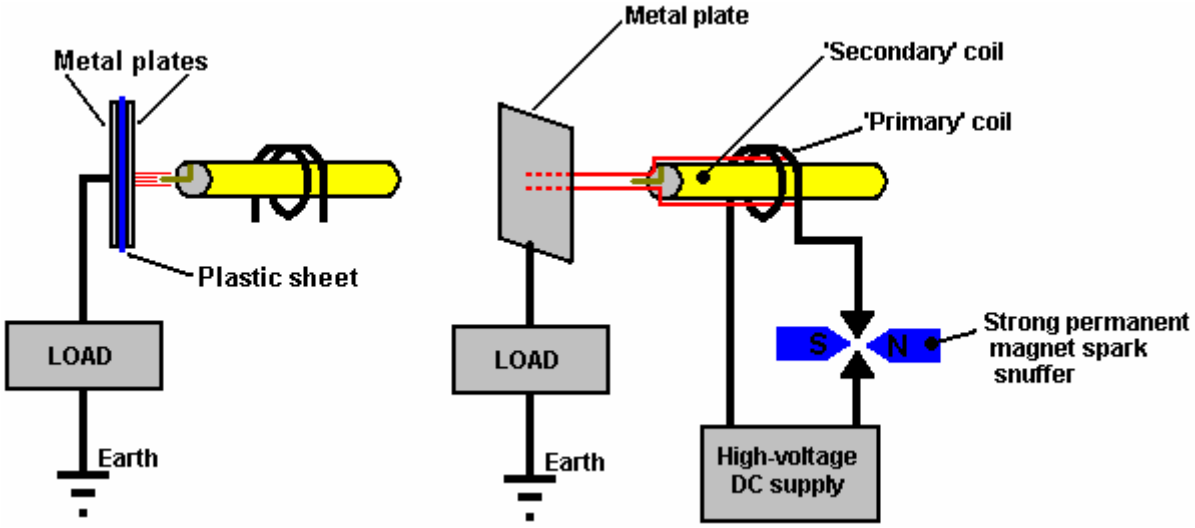
Tesla made another remarkable discovery. He connected a very heavy U-shaped copper bar directly across the primary of his disrupter, forming a dead short-circuit. He then connected several ordinary incandescent filament bulbs between the legs of the U-shaped bar. When the equipment was powered up, the lamps lit with a brilliant cold white light. This is quite impossible with conventional electricity, and it shows clearly that what Tesla was dealing with was something new. This new energy is sometimes called “cold electricity” and Edwin Gray snr. demonstrated how different it is by lighting incandescent-filament bulbs directly from his power tube, submerging them in water and putting his hand in the water. Cold electricity is generally considered to be harmless to humans. Ed Gray’s power tube operates by generating radiant electricity waves by using a spark gap, and collecting the energy using three encasing copper cylinders surrounding the spark gap. The cylinders are drilled with many holes as that enhances the pick-up and the load is driven directly from the current in the cylinders. When lighting bulbs, Ed used an air-cored transformer made of just a few turns of very heavy wire. I, personally, am aware of two people who have independently reproduced Ed’s power tube.

Tesla viewed the streamers coming off his coils as being wasted energy so he tried to suppress them. He tried a conical coil but found that this accentuated the problem. He then tried placing a copper sphere at the top of his

coil. This stopped the streamers but electrons were dislodged from the copper sphere, creating really dangerous conditions. This implied that metals generate electron flows when struck by the coil streamers (as had been seen when the streamers had been aimed at remote metal plates and current was generated as a result).

Tesla designed, built and used large globe lamps which required only a single external plate for receiving the radiant energy. No matter how far away these lamps were from the radiant source, they became brilliantly lit, almost to the level of an arc lamp and far, far brighter than any of the conventional Edison filament lamps. By adjusting the voltage and the pulse duration of his apparatus, Tesla could also heat or cool a room.

Tesla's experiments suggest that a method of extracting free-energy is to use a Tesla coil which has a metal spike instead of the more common metal sphere at the end of the 'secondary' coil. If the Tesla coil is fed with sufficiently short uni-directional pulses and the 'secondary' coil pointed at a metal plate, then it should be possible to draw off serious levels of power from the metal plate, just as Tesla discovered. This has been confirmed by Don Smith who uses two metal plates separated by a layer of plastic dielectric, forming a capacitor. He states that a well designed Tesla coil is capable of producing currents as high as the voltages and he demonstrates a hand-held 28 watt Tesla Coil played on the first plate producing a substantial continuous spark discharge between the second plate and ground. I estimate that the spark produced would have to be thousands of volts at a significant current, which puts it in the kilowatt range, like most of Don's other devices. Video: http://www.metacafe.com/watch/2820531/don_smith_free_energy/ Don's patent is in Chapter 3 and his .pdf document here: http://www.free-energy-info.tuks.nl/Smith.pdf in which he explains many of his high-power designs.



Don also points out that the positioning of the primary coil relative to the secondary coil of a Tesla Coil determines the amount of current which can be provided. Contrary to most opinion, it is possible to have Tesla Coil current as high as the voltage. Don always stresses that you have the option of picking the electrical component (as conventional science has done) which leads to "heat death" while the alternative option of selecting the magnetic component makes "the world your oyster". With a magnetic ripple imposed on the zero-point energy field, which Don prefers to call the 'ambient background energy', you can make as many electric conversions as you wish, without depleting the magnetic event in any way. In other words, you can draw off serious amounts of current from capacitor plates positioned at right angles to the magnetic flow, and every additional pair of plates gives you an additional source of major current without any need to increase the magnetic disturbance in any way. With his single metal plate, Tesla mentioned currents of a thousand amps being available. Please remember that a Tesla Coil produces seriously high voltages and is **not** a toy. Great care is needed around a Tesla Coil so, when it is running, keep well away from it.

Don also states that the collection and transfer of energy requires temporary storage which occurs as the capacitors and coils of a resonant circuit are cycled on and off. The frequency at which the capacitors and coils are pumped, determines the amount of electrical energy that moves onwards. The amount of Energy transferred relates directly to the density of lines of magnetic flux present. The Kinetic Energy formula is helpful in establishing the amount of energy present. This formula points to mass multiplied by the square of the velocity. In the case of electrical energy, intensity of voltage and amperes multiplied by cycles per second, replace velocity. Note that the "acceleration" of the Voltage and the Amperage, increases in a non-linear fashion as the Law of Squares applies, with each unit of increase causing a squaring of the flux lines present. In resonant air-core coil energy transfer, the increase in flux lines present disturbs more electrons than previously and this results in greater output energy than input energy being present and available.

Energy stored, multiplied by the cycles per second, is the energy being pumped by the system. Capacitors and inductors (coils) temporarily store electrons.

Capacitor formula: $W = 0.5 \times C \times V^2 \times Hz$ where:

W is the energy in Joules (Joules = Volts x Amps x seconds)
C is the capacitance in Farads
V is the voltage
Hz is the cycles per second

Inductor formula: $W = 0.5 \times L \times A^2 \times Hz$ where:

W is the energy in Joules
L is the inductance in Henrys
A is the current in amps
Hz is the frequency in cycles per second

Both one Henry and one Farad equal one volt. The higher the frequency, including the squaring of the flux lines, causes a large increase in the amount of energy being produced. This, combined with the use of a resonant energy induction system (all electrons moving in the same direction at the same time), make the move into COP>1 practical.

The damping process of conventional electrical power generation, has all of the available electrons bouncing randomly, mostly cancelling out each other, and so the useful energy available is only a very small percentage of the energy which is present. In a resonant induction system, a very high percentage of the energy present is useful. When resonating, (ohms-impedance-Z) becomes zero and all of the energy present becomes available, without being degraded in any way. Ohms is load or wasted energy and amperes is the rate of that wasting.
